NAME

intro − introduction to user commands

DESCRIPTION

Section 1 of the manual describes user commands and tools, for example, file manipulation tools, shells, compilers, web browsers, file and image viewers and editors, and so on.

NOTES

Linux is a flavor of UNIX, and as a first approximation all user commands under UNIX work precisely the same under Linux (and FreeBSD and lots of other UNIX-like systems).

Under Linux, there are GUIs (graphical user interfaces), where you can point and click and drag, and hopefully get work done without first reading lots of documentation. The traditional UNIX environment is a CLI (command line interface), where you type commands to tell the computer what to do. That is faster and more powerful, but requires finding out what the commands are. Below a bare minimum, to get started.

Login

In order to start working, you probably first have to open a session by giving your username and password. The program *login*(1) now starts a *shell* (command interpreter) for you. In case of a graphical login, you get a screen with menus or icons and a mouse click will start a shell in a window. See also *xterm*(1)

The shell

One types commands to the *shell*, the command interpreter. It is not built-in, but is just a program and you can change your shell. Everybody has their own favorite one. The standard one is called *sh*. See also *ash*(1), *bash*(1), *chsh*(1), *csh*(1), *dash*(1), *ksh*(1), *zsh*(1)

A session might go like:

```
knuth login: aeb
Password: ********
$ date
Tue Aug  6 23:50:44 CEST 2002
$ cal
     August 2002
Su Mo Tu We Th Fr Sa
             1  2  3
 4  5  6  7  8  9 10
11 12 13 14 15 16 17
18 19 20 21 22 23 24
25 26 27 28 29 30 31

$ ls
bin  tel
$ ls -l
total 2
drwxrwxr-x   2 aeb       1024 Aug  6 23:51 bin
-rw-rw-r--   1 aeb         37 Aug  6 23:52 tel
$ cat tel
maja    0501-1136285
peter   0136-7399214
$ cp tel tel2
$ ls -l
total 3
drwxr-xr-x   2 aeb       1024 Aug  6 23:51 bin
-rw-r--r--   1 aeb         37 Aug  6 23:52 tel
-rw-r--r--   1 aeb         37 Aug  6 23:53 tel2
$ mv tel tel1
$ ls -l
total 3
```

```
drwxr-xr-x   2 aeb       1024 Aug  6 23:51 bin
-rw-r--r--   1 aeb         37 Aug  6 23:52 tel1
-rw-r--r--   1 aeb         37 Aug  6 23:53 tel2
$ diff tel1 tel2
$ rm tel1
$ grep maja tel2
maja    0501-1136285
$
```

Here typing Control-D ended the session.

The **$** here was the command prompt—it is the shell's way of indicating that it is ready for the next command. The prompt can be customized in lots of ways, and one might include stuff like username, machine name, current directory, time, and so on. An assignment PS1="What next, master? " would change the prompt as indicated.

We see that there are commands *date* (that gives date and time), and *cal* (that gives a calendar).

The command *ls* lists the contents of the current directory—it tells you what files you have. With a *−l* option it gives a long listing, that includes the owner and size and date of the file, and the permissions people have for reading and/or changing the file. For example, the file "tel" here is 37 bytes long, owned by aeb and the owner can read and write it, others can only read it. Owner and permissions can be changed by the commands *chown* and *chmod*.

The command *cat* will show the contents of a file. (The name is from "concatenate and print": all files given as parameters are concatenated and sent to "standard output" (see *stdout*(3)), here the terminal screen.)

The command *cp* (from "copy") will copy a file.

The command *mv* (from "move"), on the other hand, only renames it.

The command *diff* lists the differences between two files. Here there was no output because there were no differences.

The command *rm* (from "remove") deletes the file, and be careful! it is gone. No wastepaper basket or anything. Deleted means lost.

The command *grep* (from "g/re/p") finds occurrences of a string in one or more files. Here it finds Maja's telephone number.

Pathnames and the current directory

Files live in a large tree, the file hierarchy. Each has a *pathname* describing the path from the root of the tree (which is called */*) to the file. For example, such a full pathname might be */home/aeb/tel*. Always using full pathnames would be inconvenient, and the name of a file in the current directory may be abbreviated by giving only the last component. That is why */home/aeb/tel* can be abbreviated to *tel* when the current directory is */home/aeb*.

The command *pwd* prints the current directory.

The command *cd* changes the current directory.

Try alternatively *cd* and *pwd* commands and explore *cd* usage: "cd", "cd .", "cd ..", "cd /", and "cd ~".

Directories

The command *mkdir* makes a new directory.

The command *rmdir* removes a directory if it is empty, and complains otherwise.

The command *find* (with a rather baroque syntax) will find files with given name or other properties. For example, "find . −name tel" would find the file *tel* starting in the present directory (which is called .). And "find / −name tel" would do the same, but starting at the root of the tree. Large searches on a multi-GB disk will be time-consuming, and it may be better to use *locate*(1)

Disks and filesystems

The command *mount* will attach the filesystem found on some disk (or floppy, or CDROM or so) to the big filesystem hierarchy. And *umount* detaches it again. The command *df* will tell you how much of your disk is still free.

Processes

On a UNIX system many user and system processes run simultaneously. The one you are talking to runs in the *foreground*, the others in the *background*. The command *ps* will show you which processes are active and what numbers these processes have. The command *kill* allows you to get rid of them. Without option this is a friendly request: please go away. And "kill −9" followed by the number of the process is an immediate kill. Foreground processes can often be killed by typing Control-C.

Getting information

There are thousands of commands, each with many options. Traditionally commands are documented on *man pages*, (like this one), so that the command "man kill" will document the use of the command "kill" (and "man man" document the command "man"). The program *man* sends the text through some *pager*, usually *less*. Hit the space bar to get the next page, hit q to quit.

In documentation it is customary to refer to man pages by giving the name and section number, as in *man*(1)Man pages are terse, and allow you to find quickly some forgotten detail. For newcomers an introductory text with more examples and explanations is useful.

A lot of GNU/FSF software is provided with info files. Type "info info" for an introduction on the use of the program *info*.

Special topics are often treated in HOWTOs. Look in */usr/share/doc/howto/en* and use a browser if you find HTML files there.

NAME

getent − get entries from Name Service Switch libraries

SYNOPSIS

getent [*option***]...** *database key***...**

DESCRIPTION

The **getent** command displays entries from databases supported by the Name Service Switch libraries, which are configured in */etc/nsswitch.conf*. If one or more *key* arguments are provided, then only the entries that match the supplied keys will be displayed. Otherwise, if no *key* is provided, all entries will be displayed (unless the database does not support enumeration).

The *database* may be any of those supported by the GNU C Library, listed below:

ahosts When no *key* is provided, use *sethostent*(3), *gethostent*(3), and *endhostent*(3) to enumerate the hosts database. This is identical to using *hosts*(5). When one or more *key* arguments are provided, pass each *key* in succession to *getaddrinfo*(3) with the address family **AF_UNSPEC**, enumerating each socket address structure returned.

ahostsv4
Same as **ahosts**, but use the address family **AF_INET**.

ahostsv6
Same as **ahosts**, but use the address family **AF_INET6**. The call to *getaddrinfo*(3) in this case includes the **AI_V4MAPPED** flag.

aliases When no *key* is provided, use *setaliasent*(3), *getaliasent*(3), and *endaliasent*(3) to enumerate the aliases database. When one or more *key* arguments are provided, pass each *key* in succession to *getaliasbyname*(3) and display the result.

ethers When one or more *key* arguments are provided, pass each *key* in succession to *ether_aton*(3) and *ether_hostton*(3) until a result is obtained, and display the result. Enumeration is not supported on **ethers**, so a *key* must be provided.

group When no *key* is provided, use *setgrent*(3), *getgrent*(3), and *endgrent*(3) to enumerate the group database. When one or more *key* arguments are provided, pass each numeric *key* to *getgrgid*(3) and each nonnumeric *key* to *getgrnam*(3) and display the result.

gshadow
When no *key* is provided, use *setsgent*(3), *getsgent*(3), and *endsgent*(3) to enumerate the gshadow database. When one or more *key* arguments are provided, pass each *key* in succession to *getsgnam*(3) and display the result.

hosts When no *key* is provided, use *sethostent*(3), *gethostent*(3), and *endhostent*(3) to enumerate the hosts database. When one or more *key* arguments are provided, pass each *key* to *gethostbyaddr*(3) or *gethostbyname2*(3), depending on whether a call to *inet_pton*(3) indicates that the *key* is an IPv6 or IPv4 address or not, and display the result.

initgroups
When one or more *key* arguments are provided, pass each *key* in succession to *getgrouplist*(3) and display the result. Enumeration is not supported on **initgroups**, so a *key* must be provided.

netgroup
When one *key* is provided, pass the *key* to *setnetgrent*(3) and, using *getnetgrent*(3) display the resulting string triple (*hostname*, *username*, *domainname*). Alternatively, three *keys* may be provided, which are interpreted as the *hostname*, *username*, and *domainname* to match to a netgroup name via *innetgr*(3). Enumeration is not supported on **netgroup**, so either one or three *keys* must be provided.

networks
When no *key* is provided, use *setnetent*(3), *getnetent*(3), and *endnetent*(3) to enumerate the networks database. When one or more *key* arguments are provided, pass each numeric *key* to *getnetbyaddr*(3) and each nonnumeric *key* to *getnetbyname*(3) and display the result.

passwd
When no *key* is provided, use *setpwent*(3), *getpwent*(3), and *endpwent*(3) to enumerate the passwd database. When one or more *key* arguments are provided, pass each numeric *key* to

getpwuid(3) and each nonnumeric *key* to *getpwnam*(3) and display the result.

protocols
When no *key* is provided, use *setprotoent*(3), *getprotoent*(3), and *endprotoent*(3) to enumerate the protocols database. When one or more *key* arguments are provided, pass each numeric *key* to *getprotobynumber*(3) and each nonnumeric *key* to *getprotobyname*(3) and display the result.

rpc When no *key* is provided, use *setrpcent*(3), *getrpcent*(3), and *endrpcent*(3) to enumerate the rpc database. When one or more *key* arguments are provided, pass each numeric *key* to *getrpcbynumber*(3) and each nonnumeric *key* to *getrpcbyname*(3) and display the result.

services
When no *key* is provided, use *setservent*(3), *getservent*(3), and *endservent*(3) to enumerate the services database. When one or more *key* arguments are provided, pass each numeric *key* to *getservbynumber*(3) and each nonnumeric *key* to *getservbyname*(3) and display the result.

shadow
When no *key* is provided, use *setspent*(3), *getspent*(3), and *endspent*(3) to enumerate the shadow database. When one or more *key* arguments are provided, pass each *key* in succession to *getspnam*(3) and display the result.

OPTIONS

−−service *service*
−s *service*
Override all databases with the specified service. (Since glibc 2.2.5.)

−−service *database*:*service*
−s *database*:*service*
Override only specified databases with the specified service. The option may be used multiple times, but only the last service for each database will be used. (Since glibc 2.4.)

−−no−idn
−i Disables IDN encoding in lookups for **ahosts**/**getaddrinfo**(3) (Since glibc-2.13.)

−−help
−? Print a usage summary and exit.

−−usage
Print a short usage summary and exit.

−−version
−V Print the version number, license, and disclaimer of warranty for **getent**.

EXIT STATUS

One of the following exit values can be returned by **getent**:

0 Command completed successfully.

1 Missing arguments, or *database* unknown.

2 One or more supplied *key* could not be found in the *database*.

3 Enumeration not supported on this *database*.

NAME

iconv − convert text from one character encoding to another

SYNOPSIS

iconv [*options*] [−f *from-encoding*] [−t *to-encoding*] [*inputfile*]...

DESCRIPTION

The **iconv** program reads in text in one encoding and outputs the text in another encoding. If no input files are given, or if it is given as a dash (−), **iconv** reads from standard input. If no output file is given, **iconv** writes to standard output.

If no *from-encoding* is given, the default is derived from the current locale's character encoding. If no *to-encoding* is given, the default is derived from the current locale's character encoding.

OPTIONS

−−from−code= *from-encoding*
−f *from-encoding*
Use *from-encoding* for input characters.

−−to−code=*to-encoding*
−t *to-encoding*
Use *to-encoding* for output characters.

If the string **//IGNORE** is appended to *to-encoding*, characters that cannot be converted are discarded and an error is printed after conversion.

If the string **//TRANSLIT** is appended to *to-encoding*, characters being converted are transliterated when needed and possible. This means that when a character cannot be represented in the target character set, it can be approximated through one or several similar looking characters. Characters that are outside of the target character set and cannot be transliterated are replaced with a question mark (?) in the output.

−−list
−l List all known character set encodings.

−c Silently discard characters that cannot be converted instead of terminating when encountering such characters.

−−output=*outputfile*
−o *outputfile*
Use *outputfile* for output.

−−silent
−s This option is ignored; it is provided only for compatibility.

−−verbose
Print progress information on standard error when processing multiple files.

−−help
−? Print a usage summary and exit.

−−usage
Print a short usage summary and exit.

−−version
−V Print the version number, license, and disclaimer of warranty for **iconv**.

EXIT STATUS

Zero on success, nonzero on errors.

ENVIRONMENT

Internally, the **iconv** program uses the *iconv*(3) function which in turn uses *gconv* modules (dynamically loaded shared libraries) to convert to and from a character set. Before calling *iconv*(3), the **iconv** program must first allocate a conversion descriptor using *iconv_open*(3). The operation of the latter function is influenced by the setting of the **GCONV_PATH** environment variable:

- If **GCONV_PATH** is not set, *iconv_open*(3) loads the system gconv module configuration cache file created by *iconvconfig*(8) and then, based on the configuration, loads the gconv modules needed to perform the conversion. If the system gconv module configuration cache file is not available then

the system gconv module configuration file is used.

- If **GCONV_PATH** is defined (as a colon-separated list of pathnames), the system gconv module configuration cache is not used. Instead, *iconv_open*(3) first tries to load the configuration files by searching the directories in **GCONV_PATH** in order, followed by the system default gconv module configuration file. If a directory does not contain a gconv module configuration file, any gconv modules that it may contain are ignored. If a directory contains a gconv module configuration file and it is determined that a module needed for this conversion is available in the directory, then the needed module is loaded from that directory, the order being such that the first suitable module found in **GCONV_PATH** is used. This allows users to use custom modules and even replace system-provided modules by providing such modules in **GCONV_PATH** directories.

FILES

/usr/lib/gconv
: Usual default gconv module path.

/usr/lib/gconv/gconv-modules
: Usual system default gconv module configuration file.

/usr/lib/gconv/gconv-modules.cache
: Usual system gconv module configuration cache.

Depending on the architecture, the above files may instead be located at directories with the path prefix */usr/lib64*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

EXAMPLES

Convert text from the ISO/IEC 8859-15 character encoding to UTF-8:

```
$ iconv -f ISO-8859-15 -t UTF-8 < input.txt > output.txt
```

The next example converts from UTF-8 to ASCII, transliterating when possible:

```
$ echo abc ß α € àḃç | iconv -f UTF-8 -t ASCII//TRANSLIT
abc ss ? EUR abc
```

locale(1), *uconv*(1), *iconv*(3), *nl_langinfo*(3), *charsets*(7), *iconvconfig*(8)

NAME

ldd − print shared object dependencies

SYNOPSIS

ldd [*option*]... *file*...

DESCRIPTION

ldd prints the shared objects (shared libraries) required by each program or shared object specified on the command line. An example of its use and output is the following:

```
$ ldd /bin/ls
    linux-vdso.so.1 (0x00007ffcc3563000)
    libselinux.so.1 => /lib64/libselinux.so.1 (0x00007f87e5459000)
    libcap.so.2 => /lib64/libcap.so.2 (0x00007f87e5254000)
    libc.so.6 => /lib64/libc.so.6 (0x00007f87e4e92000)
    libpcre.so.1 => /lib64/libpcre.so.1 (0x00007f87e4c22000)
    libdl.so.2 => /lib64/libdl.so.2 (0x00007f87e4a1e000)
    /lib64/ld-linux-x86-64.so.2 (0x00005574bf12e000)
    libattr.so.1 => /lib64/libattr.so.1 (0x00007f87e4817000)
    libpthread.so.0 => /lib64/libpthread.so.0 (0x00007f87e45fa000)
```

In the usual case, **ldd** invokes the standard dynamic linker (see *ld.so*(8)) with the **LD_TRACE_LOADED_OBJECTS** environment variable set to 1. This causes the dynamic linker to inspect the program's dynamic dependencies, and find (according to the rules described in *ld.so*(8)) and load the objects that satisfy those dependencies. For each dependency, **ldd** displays the location of the matching object and the (hexadecimal) address at which it is loaded. (The *linux-vdso* and *ld-linux* shared dependencies are special; see *vdso*(7) and *ld.so*(8).)

Security

Be aware that in some circumstances (e.g., where the program specifies an ELF interpreter other than *ld-linux.so*), some versions of **ldd** may attempt to obtain the dependency information by attempting to directly execute the program, which may lead to the execution of whatever code is defined in the program's ELF interpreter, and perhaps to execution of the program itself. (Before glibc 2.27, the upstream **ldd** implementation did this for example, although most distributions provided a modified version that did not.)

Thus, you should *never* employ **ldd** on an untrusted executable, since this may result in the execution of arbitrary code. A safer alternative when dealing with untrusted executables is:

```
$ objdump -p /path/to/program | grep NEEDED
```

Note, however, that this alternative shows only the direct dependencies of the executable, while **ldd** shows the entire dependency tree of the executable.

OPTIONS

--version
: Print the version number of **ldd**.

--verbose
-v Print all information, including, for example, symbol versioning information.

--unused
-u Print unused direct dependencies. (Since glibc 2.3.4.)

--data-relocs
-d Perform relocations and report any missing objects (ELF only).

--function-relocs
-r Perform relocations for both data objects and functions, and report any missing objects or functions (ELF only).

--help Usage information.

BUGS

ldd does not work on a.out shared libraries.

ldd does not work with some extremely old a.out programs which were built before **ldd** support was added to the compiler releases. If you use **ldd** on one of these programs, the program will attempt to

run with *argc* = 0 and the results will be unpredictable.

SEE ALSO

pldd(1), *sprof*(1), *ld.so*(8), *ldconfig*(8)

NAME

locale − get locale-specific information

SYNOPSIS

locale [*option*]
locale [*option*] **-a**
locale [*option*] **-m**
locale [*option*] *name*...

DESCRIPTION

The **locale** command displays information about the current locale, or all locales, on standard output.

When invoked without arguments, **locale** displays the current locale settings for each locale category (see *locale*(5)), based on the settings of the environment variables that control the locale (see *locale*(7)). Values for variables set in the environment are printed without double quotes, implied values are printed with double quotes.

If either the **−a** or the **−m** option (or one of their long-format equivalents) is specified, the behavior is as follows:

−−all−locales
−a Display a list of all available locales. The **−v** option causes the **LC_IDENTIFICATION** metadata about each locale to be included in the output.

−−charmaps
−m Display the available charmaps (character set description files). To display the current character set for the locale, use **locale −c charmap**.

The **locale** command can also be provided with one or more arguments, which are the names of locale keywords (for example, *date_fmt*, *ctype−class−names*, *yesexpr*, or *decimal_point*) or locale categories (for example, **LC_CTYPE** or **LC_TIME**). For each argument, the following is displayed:

- For a locale keyword, the value of that keyword to be displayed.
- For a locale category, the values of all keywords in that category are displayed.

When arguments are supplied, the following options are meaningful:

−−category−name
−c For a category name argument, write the name of the locale category on a separate line preceding the list of keyword values for that category.

For a keyword name argument, write the name of the locale category for this keyword on a separate line preceding the keyword value.

This option improves readability when multiple name arguments are specified. It can be combined with the **−k** option.

−−keyword−name
−k For each keyword whose value is being displayed, include also the name of that keyword, so that the output has the format:

```
keyword="value"
```

The **locale** command also knows about the following options:

−−verbose
−v Display additional information for some command-line option and argument combinations.

−−help
−? Display a summary of command-line options and arguments and exit.

−−usage
Display a short usage message and exit.

−−version
−V Display the program version and exit.

FILES

/usr/lib/locale/locale-archive
Usual default locale archive location.

/usr/share/i18n/locales
Usual default path for locale definition files.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

EXAMPLES

```
$ locale
LANG=en_US.UTF-8
LC_CTYPE="en_US.UTF-8"
LC_NUMERIC="en_US.UTF-8"
LC_TIME="en_US.UTF-8"
LC_COLLATE="en_US.UTF-8"
LC_MONETARY="en_US.UTF-8"
LC_MESSAGES="en_US.UTF-8"
LC_PAPER="en_US.UTF-8"
LC_NAME="en_US.UTF-8"
LC_ADDRESS="en_US.UTF-8"
LC_TELEPHONE="en_US.UTF-8"
LC_MEASUREMENT="en_US.UTF-8"
LC_IDENTIFICATION="en_US.UTF-8"
LC_ALL=

$ locale date_fmt
%a %b %e %H:%M:%S %Z %Y

$ locale -k date_fmt
date_fmt="%a %b %e %H:%M:%S %Z %Y"

$ locale -ck date_fmt
LC_TIME
date_fmt="%a %b %e %H:%M:%S %Z %Y"

$ locale LC_TELEPHONE
+%c (%a) %l
(%a) %l
11
1
UTF-8

$ locale -k LC_TELEPHONE
tel_int_fmt="+%c (%a) %l"
tel_dom_fmt="(%a) %l"
int_select="11"
int_prefix="1"
telephone-codeset="UTF-8"
```

The following example compiles a custom locale from the *./wrk* directory with the *localedef*(1) utility under the *$HOME/.locale* directory, then tests the result with the *date*(1) command, and then sets the environment variables **LOCPATH** and **LANG** in the shell profile file so that the custom locale will be used in the subsequent user sessions:

```
$ mkdir -p $HOME/.locale
$ I18NPATH=./wrk/ localedef -f UTF-8 -i fi_SE $HOME/.locale/fi_SE.UTF-8
$ LOCPATH=$HOME/.locale LC_ALL=fi_SE.UTF-8 date
$ echo "export LOCPATH=\$HOME/.locale" >> $HOME/.bashrc
```

```
$ echo "export LANG=fi_SE.UTF-8" >> $HOME/.bashrc
```

SEE ALSO

localedef(1), *charmap*(5), *locale*(5), *locale*(7)

NAME

localedef − compile locale definition files

SYNOPSIS

localedef [*options*] *outputpath*

localedef −−add−to−archive [*options*] *compiledpath*

localedef −−delete−from−archive [*options*] *localename ...*

localedef −−list−archive [*options*]

localedef −−help

localedef −−usage

localedef −−version

DESCRIPTION

The **localedef** program reads the indicated *charmap* and *input* files, compiles them to a binary form quickly usable by the locale functions in the C library (**setlocale**(3), *localeconv*(3), etc.), and places the output in *outputpath*.

The *outputpath* argument is interpreted as follows:

- If *outputpath* contains a slash character ('/'), it is interpreted as the name of the directory where the output definitions are to be stored. In this case, there is a separate output file for each locale category (*LC_TIME*, *LC_NUMERIC*, and so on).
- If the **−−no−archive** option is used, *outputpath* is the name of a subdirectory in */usr/lib/locale* where per-category compiled files are placed.
- Otherwise, *outputpath* is the name of a locale and the compiled locale data is added to the archive file */usr/lib/locale/locale−archive*. A locale archive is a memory-mapped file which contains all the system-provided locales; it is used by all localized programs when the environment variable **LOCPATH** is not set.

In any case, **localedef** aborts if the directory in which it tries to write locale files has not already been created.

If no *charmapfile* is given, the value *ANSI_X3.4−1968* (for ASCII) is used by default. If no *inputfile* is given, or if it is given as a dash (−), **localedef** reads from standard input.

OPTIONS

Operation-selection options

A few options direct **localedef** to do something other than compile locale definitions. Only one of these options should be used at a time.

−−add−to−archive
: Add the *compiledpath* directories to the locale archive file. The directories should have been created by previous runs of **localedef**, using **--no-archive**.

−−delete−from−archive
: Delete the named locales from the locale archive file.

−−list−archive
: List the locales contained in the locale archive file.

Other options

Some of the following options are sensible only for certain operations; generally, it should be self-evident which ones. Notice that **−f** and **−c** are reversed from what you might expect; that is, **−f** is not the same as **--force**.

−f *charmapfile*, **−−charmap=***charmapfile*
Specify the file that defines the character set that is used by the input file. If *charmapfile* contains a slash character ('/'), it is interpreted as the name of the character map. Otherwise, the file is sought in the current directory and the default directory for character maps. If the environment variable **I18NPATH** is set, *$I18NPATH/charmaps/* and *$I18NPATH/* are also searched after the current directory. The default directory for character maps is printed by **localedef --help**.

−i *inputfile*, **−−inputfile=***inputfile*
Specify the locale definition file to compile. The file is sought in the current directory and the default directory for locale definition files. If the environment variable **I18NPATH** is set, *$I18NPATH/locales/* and *$I18NPATH* are also searched after the current directory. The default directory for locale definition files is printed by **localedef --help**.

−u *repertoirefile*, **−−repertoire−map=***repertoirefile*
Read mappings from symbolic names to Unicode code points from *repertoirefile*. If *repertoirefile* contains a slash character ('/'), it is interpreted as the pathname of the repertoire map. Otherwise, the file is sought in the current directory and the default directory for repertoire maps. If the environment variable **I18NPATH** is set, *$I18NPATH/repertoiremaps/* and *$I18NPATH* are also searched after the current directory. The default directory for repertoire maps is printed by **localedef --help**.

−A *aliasfile*, **−−alias−file=***aliasfile*
Use *aliasfile* to look up aliases for locale names. There is no default aliases file.

−−force
−c Write the output files even if warnings were generated about the input file.

−−verbose
−v Generate extra warnings about errors that are normally ignored.

−−big−endian
Generate big-endian output.

−−little−endian
Generate little-endian output.

−−no−archive
Do not use the locale archive file, instead create *outputpath* as a subdirectory in the same directory as the locale archive file, and create separate output files for locale categories in it. This is helpful to prevent system locale archive updates from overwriting custom locales created with **localedef**.

−−no−hard−links
Do not create hard links between installed locales.

−−no−warnings=*warnings*
Comma-separated list of warnings to disable. Supported warnings are *ascii* and *intcurrsym*.

−−posix
Conform strictly to POSIX. Implies **--verbose**. This option currently has no other effect. POSIX conformance is assumed if the environment variable **POSIXLY_CORRECT** is set.

−−prefix= *pathname*
Set the prefix to be prepended to the full archive pathname. By default, the prefix is empty. Setting the prefix to *foo*, the archive would be placed in *foo/usr/lib/locale/locale−archive*.

−−quiet
Suppress all notifications and warnings, and report only fatal errors.

−−replace
Replace a locale in the locale archive file. Without this option, if the locale is in the archive file already, an error occurs.

−−warnings=*warnings*
Comma-separated list of warnings to enable. Supported warnings are *ascii* and *intcurrsym*.

−−help
−? Print a usage summary and exit. Also prints the default paths used by **localedef**.

−−usage
Print a short usage summary and exit.

−−version
−V Print the version number, license, and disclaimer of warranty for **localedef**.

EXIT STATUS

One of the following exit values can be returned by **localedef**:

0 Command completed successfully.

1 Warnings or errors occurred, output files were written.

4 Errors encountered, no output created.

ENVIRONMENT

POSIXLY_CORRECT
The **−−posix** flag is assumed if this environment variable is set.

I18NPATH
A colon-separated list of search directories for files.

FILES

/usr/share/i18n/charmaps
Usual default character map path.

/usr/share/i18n/locales
Usual default path for locale definition files.

/usr/share/i18n/repertoiremaps
Usual default repertoire map path.

/usr/lib/locale/locale−archive
Usual default locale archive location.

/usr/lib/locale
Usual default path for compiled individual locale data files.

outputpath/LC_ADDRESS
An output file that contains information about formatting of addresses and geography-related items.

outputpath/LC_COLLATE
An output file that contains information about the rules for comparing strings.

outputpath/LC_CTYPE
An output file that contains information about character classes.

outputpath/LC_IDENTIFICATION
An output file that contains metadata about the locale.

outputpath/LC_MEASUREMENT
An output file that contains information about locale measurements (metric versus US customary).

outputpath/LC_MESSAGES/SYS_LC_MESSAGES
An output file that contains information about the language messages should be printed in, and what an affirmative or negative answer looks like.

outputpath/LC_MONETARY
An output file that contains information about formatting of monetary values.

outputpath/LC_NAME
An output file that contains information about salutations for persons.

outputpath/LC_NUMERIC
An output file that contains information about formatting of nonmonetary numeric values.

outputpath/LC_PAPER
: An output file that contains information about settings related to standard paper size.

outputpath/LC_TELEPHONE
: An output file that contains information about formats to be used with telephone services.

outputpath/LC_TIME
: An output file that contains information about formatting of data and time values.

STANDARDS

POSIX.1-2008.

EXAMPLES

Compile the locale files for Finnish in the UTF−8 character set and add it to the default locale archive with the name **fi_FI.UTF-8**:

```
localedef −f UTF−8 −i fi_FI fi_FI.UTF−8
```

The next example does the same thing, but generates files into the *fi_FI.UTF−8* directory which can then be used by programs when the environment variable **LOCPATH** is set to the current directory (note that the last argument must contain a slash):

```
localedef −f UTF−8 −i fi_FI ./fi_FI.UTF−8
```

NAME

memusage − profile memory usage of a program

SYNOPSIS

memusage [*option*]... *program* [*programoption*]...

DESCRIPTION

memusage is a bash script which profiles memory usage of the program, *program*. It preloads the **libmemusage.so** library into the caller's environment (via the **LD_PRELOAD** environment variable; see *ld.so*(8)). The **libmemusage.so** library traces memory allocation by intercepting calls to *malloc*(3), *calloc*(3), *free*(3), and *realloc*(3); optionally, calls to *mmap*(2), *mremap*(2), and *munmap*(2) can also be intercepted.

memusage can output the collected data in textual form, or it can use *memusagestat*(1) (see the **−p** option, below) to create a PNG file containing graphical representation of the collected data.

Memory usage summary

The "Memory usage summary" line output by **memusage** contains three fields:

heap total
: Sum of *size* arguments of all *malloc*(3) calls, products of arguments (*nmemb***size*) of all *calloc*(3) calls, and sum of *length* arguments of all *mmap*(2) calls. In the case of *realloc*(3) and *mremap*(2), if the new size of an allocation is larger than the previous size, the sum of all such differences (new size minus old size) is added.

heap peak
: Maximum of all *size* arguments of *malloc*(3), all products of *nmemb***size* of *calloc*(3), all *size* arguments of *realloc*(3), *length* arguments of *mmap*(2), and *new_size* arguments of *mremap*(2).

stack peak
: Before the first call to any monitored function, the stack pointer address (base stack pointer) is saved. After each function call, the actual stack pointer address is read and the difference from the base stack pointer computed. The maximum of these differences is then the stack peak.

Immediately following this summary line, a table shows the number calls, total memory allocated or deallocated, and number of failed calls for each intercepted function. For *realloc*(3) and *mremap*(2), the additional field "nomove" shows reallocations that changed the address of a block, and the additional "dec" field shows reallocations that decreased the size of the block. For *realloc*(3), the additional field "free" shows reallocations that caused a block to be freed (i.e., the reallocated size was 0).

The "realloc/total memory" of the table output by **memusage** does not reflect cases where *realloc*(3) is used to reallocate a block of memory to have a smaller size than previously. This can cause sum of all "total memory" cells (excluding "free") to be larger than the "free/total memory" cell.

Histogram for block sizes

The "Histogram for block sizes" provides a breakdown of memory allocations into various bucket sizes.

OPTIONS

−n *name*, **−−progname=***name*
: Name of the program file to profile.

−p *file*, **−−png=** *file*
: Generate PNG graphic and store it in *file*.

−d *file*, **−−data=** *file*
: Generate binary data file and store it in *file*.

−u, **−−unbuffered**
: Do not buffer output.

−b *size*, **−−buffer=***size*
: Collect *size* entries before writing them out.

−−no−timer
: Disable timer-based (**SIGPROF**) sampling of stack pointer value.

−m, **−−mmap**
Also trace *mmap*(2), *mremap*(2), and *munmap*(2).

−?, **−−help**
Print help and exit.

−−usage
Print a short usage message and exit.

−V, **−−version**
Print version information and exit.

The following options apply only when generating graphical output:

−t, **−−time−based**
Use time (rather than number of function calls) as the scale for the X axis.

−T, **−−total**
Also draw a graph of total memory use.

−−title=*name*
Use *name* as the title of the graph.

−x *size*, **−−x−size**=*size*
Make the graph *size* pixels wide.

−y *size*, **−−y−size**=*size*
Make the graph *size* pixels high.

EXIT STATUS

The exit status of **memusage** is equal to the exit status of the profiled program.

BUGS

To report bugs, see

EXAMPLES

Below is a simple program that reallocates a block of memory in cycles that rise to a peak before then cyclically reallocating the memory in smaller blocks that return to zero. After compiling the program and running the following commands, a graph of the memory usage of the program can be found in the file *memusage.png*:

```
$ memusage --data=memusage.dat ./a.out
...
Memory usage summary: heap total: 45200, heap peak: 6440, stack peak: 224
        total calls  total memory  failed calls
 malloc|         1           400             0
realloc|        40         44800             0  (nomove:40, dec:19, free:0)
 calloc|         0             0             0
   free|         1           440
Histogram for block sizes:
  192-207             1   2% ================
...
 2192-2207            1   2% ================
 2240-2255            2   4% ================================
 2832-2847            2   4% ================================
 3440-3455            2   4% ================================
 4032-4047            2   4% ================================
 4640-4655            2   4% ================================
 5232-5247            2   4% ================================
 5840-5855            2   4% ================================
 6432-6447            1   2% ================
$ memusagestat memusage.dat memusage.png
```

Program source

```
#include <stdio.h>
#include <stdlib.h>
```

```
#define CYCLES 20

int
main(int argc, char *argv[])
{
    int i, j;
    size_t size;
    int *p;

    size = sizeof(*p) * 100;
    printf("malloc: %zu\n", size);
    p = malloc(size);

    for (i = 0; i < CYCLES; i++) {
        if (i < CYCLES / 2)
            j = i;
        else
            j--;

        size = sizeof(*p) * (j * 50 + 110);
        printf("realloc: %zu\n", size);
        p = realloc(p, size);

        size = sizeof(*p) * ((j + 1) * 150 + 110);
        printf("realloc: %zu\n", size);
        p = realloc(p, size);
    }

    free(p);
    exit(EXIT_SUCCESS);
}
```

SEE ALSO

NAME

memusagestat − generate graphic from memory profiling data

SYNOPSIS

memusagestat [*option*]... *datafile* [*outfile*]

DESCRIPTION

memusagestat creates a PNG file containing a graphical representation of the memory profiling data in the file *datafile*; that file is generated via the *−d* (or *−−data*) option of *memusage*(1).

The red line in the graph shows the heap usage (allocated memory) and the green line shows the stack usage. The x-scale is either the number of memory-handling function calls or (if the *−t* option is specified) time.

OPTIONS

−o *file*, **−−output=** *file*
: Name of the output file.

−s *string*, **−−string**=*string*
: Use *string* as the title inside the output graph.

−t, **−−time**
: Use time (rather than number of function calls) as the scale for the X axis.

−T, **−−total**
: Also draw a graph of total memory consumption.

−x *size*, **−−x−size**=*size*
: Make the output graph *size* pixels wide.

−y *size*, **−−y−size**=*size*
: Make the output graph *size* pixels high.

−?, **−−help**
: Print a help message and exit.

−−usage
: Print a short usage message and exit.

−V, **−−version**
: Print version information and exit.

BUGS

To report bugs, see

EXAMPLES

See *memusage*(1).

SEE ALSO

memusage(1), *mtrace*(1)

NAME

mtrace − interpret the malloc trace log

SYNOPSIS

mtrace [*option*]... [*binary*] *mtracedata*

DESCRIPTION

mtrace is a Perl script used to interpret and provide human readable output of the trace log contained in the file *mtracedata*, whose contents were produced by *mtrace*(3). If *binary* is provided, the output of **mtrace** also contains the source file name with line number information for problem locations (assuming that *binary* was compiled with debugging information).

For more information about the *mtrace*(3) function and **mtrace** script usage, see *mtrace*(3).

OPTIONS

−−help Print help and exit.

−−version
Print version information and exit.

BUGS

For bug reporting instructions, please see: .

SEE ALSO

memusage(1), *mtrace*(3)

NAME

pldd − display dynamic shared objects linked into a process

SYNOPSIS

pldd *pid*
pldd *option*

DESCRIPTION

The **pldd** command displays a list of the dynamic shared objects (DSOs) that are linked into the process with the specified process ID (PID). The list includes the libraries that have been dynamically loaded using *dlopen*(3).

OPTIONS

−−help
−? Display a help message and exit.

−−usage
Display a short usage message and exit.

−−version
−V Display program version information and exit.

EXIT STATUS

On success, **pldd** exits with the status 0. If the specified process does not exist, the user does not have permission to access its dynamic shared object list, or no command-line arguments are supplied, **pldd** exists with a status of 1. If given an invalid option, it exits with the status 64.

VERSIONS

Some other systems have a similar command.

STANDARDS

None.

HISTORY

glibc 2.15.

NOTES

The command

```
lsof −p PID
```

also shows output that includes the dynamic shared objects that are linked into a process.

The *gdb*(1) *info shared* command also shows the shared libraries being used by a process, so that one can obtain similar output to **pldd** using a command such as the following (to monitor the process with the specified *pid*):

```
$ gdb −ex "set confirm off" −ex "set height 0" −ex "info shared" \
       −ex "quit" −p $pid | grep '^0x.*0x'
```

BUGS

From glibc 2.19 to glibc 2.29, **pldd** was broken: it just hung when executed. This problem was fixed in glibc 2.30, and the fix has been backported to earlier glibc versions in some distributions.

EXAMPLES

```
$ echo $$               # Display PID of shell
1143
$ pldd $$               # Display DSOs linked into the shell
1143:   /usr/bin/bash
linux−vdso.so.1
/lib64/libtinfo.so.5
/lib64/libdl.so.2
/lib64/libc.so.6
/lib64/ld−linux−x86−64.so.2
/lib64/libnss_files.so.2
```

SEE ALSO

ldd(1), *lsof* (1), *dlopen*(3), *ld.so*(8)

NAME

sprof − read and display shared object profiling data

SYNOPSIS

sprof [*option*]... *shared-object-path* [*profile-data-path*]

DESCRIPTION

The **sprof** command displays a profiling summary for the shared object (shared library) specified as its first command-line argument. The profiling summary is created using previously generated profiling data in the (optional) second command-line argument. If the profiling data pathname is omitted, then **sprof** will attempt to deduce it using the soname of the shared object, looking for a file with the name *<soname>.profile* in the current directory.

OPTIONS

The following command-line options specify the profile output to be produced:

−−call−pairs

−c Print a list of pairs of call paths for the interfaces exported by the shared object, along with the number of times each path is used.

−−flat−profile

−p Generate a flat profile of all of the functions in the monitored object, with counts and ticks.

−−graph

−q Generate a call graph.

If none of the above options is specified, then the default behavior is to display a flat profile and a call graph.

The following additional command-line options are available:

−−help

−? Display a summary of command-line options and arguments and exit.

−−usage

Display a short usage message and exit.

−−version

−V Display the program version and exit.

STANDARDS

GNU.

EXAMPLES

The following example demonstrates the use of **sprof**. The example consists of a main program that calls two functions in a shared object. First, the code of the main program:

```
$ cat prog.c
#include <stdlib.h>

void x1(void);
void x2(void);

int
main(int argc, char *argv[])
{
    x1();
    x2();
    exit(EXIT_SUCCESS);
}
```

The functions *x1*() and *x2*() are defined in the following source file that is used to construct the shared object:

```
$ cat libdemo.c
#include <unistd.h>

void
```

```
consumeCpu1(int lim)
{
    for (unsigned int j = 0; j < lim; j++)
      getppid();
}

void
x1(void) {
    for (unsigned int j = 0; j < 100; j++)
      consumeCpu1(200000);
}

void
consumeCpu2(int lim)
{
    for (unsigned int j = 0; j < lim; j++)
      getppid();
}

void
x2(void)
{
    for (unsigned int j = 0; j < 1000; j++)
      consumeCpu2(10000);
}
```

Now we construct the shared object with the real name *libdemo.so.1.0.1*, and the soname *libdemo.so.1*:

```
$ cc -g -fPIC -shared -Wl,-soname,libdemo.so.1 \
      -o libdemo.so.1.0.1 libdemo.c
```

Then we construct symbolic links for the library soname and the library linker name:

```
$ ln -sf libdemo.so.1.0.1 libdemo.so.1
$ ln -sf libdemo.so.1 libdemo.so
```

Next, we compile the main program, linking it against the shared object, and then list the dynamic dependencies of the program:

```
$ cc -g -o prog prog.c -L. -ldemo
$ ldd prog
      linux-vdso.so.1 =>  (0x00007fff86d66000)
      libdemo.so.1 => not found
      libc.so.6 => /lib64/libc.so.6 (0x00007fd4dc138000)
      /lib64/ld-linux-x86-64.so.2 (0x00007fd4dc51f000)
```

In order to get profiling information for the shared object, we define the environment variable **LD_PROFILE** with the soname of the library:

```
$ export LD_PROFILE=libdemo.so.1
```

We then define the environment variable **LD_PROFILE_OUTPUT** with the pathname of the directory where profile output should be written, and create that directory if it does not exist already:

```
$ export LD_PROFILE_OUTPUT=$(pwd)/prof_data
$ mkdir -p $LD_PROFILE_OUTPUT
```

LD_PROFILE causes profiling output to be *appended* to the output file if it already exists, so we ensure that there is no preexisting profiling data:

```
$ rm -f $LD_PROFILE_OUTPUT/$LD_PROFILE.profile
```

We then run the program to produce the profiling output, which is written to a file in the directory specified in **LD_PROFILE_OUTPUT**:

```
$ LD_LIBRARY_PATH=. ./prog
$ ls prof_data
```

```
libdemo.so.1.profile
```

We then use the **sprof −p** option to generate a flat profile with counts and ticks:

```
$ sprof -p libdemo.so.1 $LD_PROFILE_OUTPUT/libdemo.so.1.profile
Flat profile:

Each sample counts as 0.01 seconds.
  %   cumulative   self              self     total
 time   seconds   seconds    calls  us/call  us/call  name
 60.00      0.06     0.06      100   600.00           consumeCpu1
 40.00      0.10     0.04     1000    40.00           consumeCpu2
  0.00      0.10     0.00        1     0.00           x1
  0.00      0.10     0.00        1     0.00           x2
```

The **sprof −q** option generates a call graph:

```
$ sprof -q libdemo.so.1 $LD_PROFILE_OUTPUT/libdemo.so.1.profile

index % time    self  children    called     name

                0.00    0.00      100/100         x1 [1]
[0]    100.0    0.00    0.00      100          consumeCpu1 [0]
-----------------------------------------------
                0.00    0.00        1/1           <UNKNOWN>
[1]      0.0    0.00    0.00        1          x1 [1]
                0.00    0.00      100/100         consumeCpu1 [0]
-----------------------------------------------
                0.00    0.00     1000/1000        x2 [3]
[2]      0.0    0.00    0.00     1000          consumeCpu2 [2]
-----------------------------------------------
                0.00    0.00        1/1           <UNKNOWN>
[3]      0.0    0.00    0.00        1          x2 [3]
                0.00    0.00     1000/1000        consumeCpu2 [2]
-----------------------------------------------
```

Above and below, the "<UNKNOWN>" strings represent identifiers that are outside of the profiled object (in this example, these are instances of *main()*).

The **sprof −c** option generates a list of call pairs and the number of their occurrences:

```
$ sprof -c libdemo.so.1 $LD_PROFILE_OUTPUT/libdemo.so.1.profile
<UNKNOWN>                   x1                                1
x1                          consumeCpu1                     100
<UNKNOWN>                   x2                                1
x2                          consumeCpu2                    1000
```

SEE ALSO

gprof (1), *ldd*(1), *ld.so*(8)

NAME

time − time a simple command or give resource usage

SYNOPSIS

time [*option* ...] *command* [*argument* ...]

DESCRIPTION

The **time** command runs the specified program *command* with the given arguments. When *command* finishes, **time** writes a message to standard error giving timing statistics about this program run. These statistics consist of (i) the elapsed real time between invocation and termination, (ii) the user CPU time (the sum of the *tms_utime* and *tms_cutime* values in a *struct tms* as returned by *times*(2)), and (iii) the system CPU time (the sum of the *tms_stime* and *tms_cstime* values in a *struct tms* as returned by *times*(2)).

Note: some shells (e.g., *bash*(1)) have a built-in **time** command that provides similar information on the usage of time and possibly other resources. To access the real command, you may need to specify its pathname (something like */usr/bin/time*).

OPTIONS

−p When in the POSIX locale, use the precise traditional format

```
"real %f\nuser %f\nsys %f\n"
```

(with numbers in seconds) where the number of decimals in the output for %f is unspecified but is sufficient to express the clock tick accuracy, and at least one.

EXIT STATUS

If *command* was invoked, the exit status is that of *command*. Otherwise, it is 127 if *command* could not be found, 126 if it could be found but could not be invoked, and some other nonzero value (1–125) if something else went wrong.

ENVIRONMENT

The variables **LANG**, **LC_ALL**, **LC_CTYPE**, **LC_MESSAGES**, **LC_NUMERIC**, and **NLSPATH** are used for the text and formatting of the output. **PATH** is used to search for *command*.

GNU VERSION

Below a description of the GNU 1.7 version of **time**. Disregarding the name of the utility, GNU makes it output lots of useful information, not only about time used, but also on other resources like memory, I/O and IPC calls (where available). The output is formatted using a format string that can be specified using the *−f* option or the **TIME** environment variable.

The default format string is:

```
%Uuser %Ssystem %Eelapsed %PCPU (%Xtext+%Ddata %Mmax)k
%Iinputs+%Ooutputs (%Fmajor+%Rminor)pagefaults %Wswaps
```

When the *−p* option is given, the (portable) output format is used:

```
real %e
user %U
sys %S
```

The format string

The format is interpreted in the usual printf-like way. Ordinary characters are directly copied, tab, newline, and backslash are escaped using \t, \n, and \\, a percent sign is represented by %%, and otherwise % indicates a conversion. The program **time** will always add a trailing newline itself. The conversions follow. All of those used by *tcsh*(1) are supported.

Time

%E Elapsed real time (in [hours:]minutes:seconds).

%e (Not in *tcsh*(1)Elapsed real time (in seconds).

%S Total number of CPU-seconds that the process spent in kernel mode.

%U Total number of CPU-seconds that the process spent in user mode.

%P Percentage of the CPU that this job got, computed as (%U + %S) / %E.

Memory

%M Maximum resident set size of the process during its lifetime, in Kbytes.

%t (Not in *tcsh*(1)Average resident set size of the process, in Kbytes.

%K Average total (data+stack+text) memory use of the process, in Kbytes.

%D Average size of the process's unshared data area, in Kbytes.

%p (Not in *tcsh*(1)Average size of the process's unshared stack space, in Kbytes.

%X Average size of the process's shared text space, in Kbytes.

%Z (Not in *tcsh*(1)System's page size, in bytes. This is a per-system constant, but varies between systems.

%F Number of major page faults that occurred while the process was running. These are faults where the page has to be read in from disk.

%R Number of minor, or recoverable, page faults. These are faults for pages that are not valid but which have not yet been claimed by other virtual pages. Thus the data in the page is still valid but the system tables must be updated.

%W Number of times the process was swapped out of main memory.

%c Number of times the process was context-switched involuntarily (because the time slice expired).

%w Number of waits: times that the program was context-switched voluntarily, for instance while waiting for an I/O operation to complete.

I/O

%I Number of filesystem inputs by the process.

%O Number of filesystem outputs by the process.

%r Number of socket messages received by the process.

%s Number of socket messages sent by the process.

%k Number of signals delivered to the process.

%C (Not in *tcsh*(1)Name and command-line arguments of the command being timed.

%x (Not in *tcsh*(1)Exit status of the command.

GNU options

−f *format*, **−−format=** *format*
Specify output format, possibly overriding the format specified in the environment variable TIME.

−p, −−portability
Use the portable output format.

−o *file*, **−−output=** *file*
Do not send the results to *stderr*, but overwrite the specified file.

−a, −−append
(Used together with −o.) Do not overwrite but append.

−v, −−verbose
Give very verbose output about all the program knows about.

−q, −−quiet
Don't report abnormal program termination (where *command* is terminated by a signal) or nonzero exit status.

GNU standard options

−−help Print a usage message on standard output and exit successfully.

−V, −−version
Print version information on standard output, then exit successfully.

−− Terminate option list.

BUGS

Not all resources are measured by all versions of UNIX, so some of the values might be reported as zero. The present selection was mostly inspired by the data provided by 4.2 or 4.3BSD.

GNU time version 1.7 is not yet localized. Thus, it does not implement the POSIX requirements.

The environment variable **TIME** was badly chosen. It is not unusual for systems like *autoconf*(1) or *make*(1) to use environment variables with the name of a utility to override the utility to be used. Uses like MORE or TIME for options to programs (instead of program pathnames) tend to lead to difficulties.

It seems unfortunate that −*o* overwrites instead of appends. (That is, the −*a* option should be the default.)

Mail suggestions and bug reports for GNU **time** to *bug−time@gnu.org*. Please include the version of **time**, which you can get by running

```
time −−version
```

and the operating system and C compiler you used.

NAME

intro − introduction to system calls

DESCRIPTION

Section 2 of the manual describes the Linux system calls. A system call is an entry point into the Linux kernel. Usually, system calls are not invoked directly: instead, most system calls have corresponding C library wrapper functions which perform the steps required (e.g., trapping to kernel mode) in order to invoke the system call. Thus, making a system call looks the same as invoking a normal library function.

In many cases, the C library wrapper function does nothing more than:

- copying arguments and the unique system call number to the registers where the kernel expects them;
- trapping to kernel mode, at which point the kernel does the real work of the system call;
- setting *errno* if the system call returns an error number when the kernel returns the CPU to user mode.

However, in a few cases, a wrapper function may do rather more than this, for example, performing some preprocessing of the arguments before trapping to kernel mode, or postprocessing of values returned by the system call. Where this is the case, the manual pages in Section 2 generally try to note the details of both the (usually GNU) C library API interface and the raw system call. Most commonly, the main DESCRIPTION will focus on the C library interface, and differences for the system call are covered in the NOTES section.

For a list of the Linux system calls, see *syscalls*(2).

RETURN VALUE

On error, most system calls return a negative error number (i.e., the negated value of one of the constants described in *errno*(3)). The C library wrapper hides this detail from the caller: when a system call returns a negative value, the wrapper copies the absolute value into the *errno* variable, and returns −1 as the return value of the wrapper.

The value returned by a successful system call depends on the call. Many system calls return 0 on success, but some can return nonzero values from a successful call. The details are described in the individual manual pages.

In some cases, the programmer must define a feature test macro in order to obtain the declaration of a system call from the header file specified in the man page SYNOPSIS section. (Where required, these feature test macros must be defined before including *any* header files.) In such cases, the required macro is described in the man page. For further information on feature test macros, see *feature_test_macros*(7).

STANDARDS

Certain terms and abbreviations are used to indicate UNIX variants and standards to which calls in this section conform. See *standards*(7).

NOTES

Calling directly

In most cases, it is unnecessary to invoke a system call directly, but there are times when the Standard C library does not implement a nice wrapper function for you. In this case, the programmer must manually invoke the system call using *syscall*(2). Historically, this was also possible using one of the _syscall macros described in *_syscall*(2).

Authors and copyright conditions

Look at the header of the manual page source for the author(s) and copyright conditions. Note that these can be different from page to page!

NAME

accept, accept4 − accept a connection on a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/socket.h>

int accept(int sockfd, struct sockaddr *_Nullable restrict addr,
           socklen_t *_Nullable restrict addrlen);

#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sys/socket.h>

int accept4(int sockfd, struct sockaddr *_Nullable restrict addr,
           socklen_t *_Nullable restrict addrlen, int flags);
```

DESCRIPTION

The **accept**() system call is used with connection-based socket types (**SOCK_STREAM**, **SOCK_SEQPACKET**). It extracts the first connection request on the queue of pending connections for the listening socket, *sockfd*, creates a new connected socket, and returns a new file descriptor referring to that socket. The newly created socket is not in the listening state. The original socket *sockfd* is unaffected by this call.

The argument *sockfd* is a socket that has been created with *socket*(2), bound to a local address with *bind*(2), and is listening for connections after a *listen*(2).

The argument *addr* is a pointer to a *sockaddr* structure. This structure is filled in with the address of the peer socket, as known to the communications layer. The exact format of the address returned *addr* is determined by the socket's address family (see *socket*(2) and the respective protocol man pages). When *addr* is NULL, nothing is filled in; in this case, *addrlen* is not used, and should also be NULL.

The *addrlen* argument is a value-result argument: the caller must initialize it to contain the size (in bytes) of the structure pointed to by *addr*; on return it will contain the actual size of the peer address.

The returned address is truncated if the buffer provided is too small; in this case, *addrlen* will return a value greater than was supplied to the call.

If no pending connections are present on the queue, and the socket is not marked as nonblocking, **accept**() blocks the caller until a connection is present. If the socket is marked nonblocking and no pending connections are present on the queue, **accept**() fails with the error **EAGAIN** or **EWOULDBLOCK**.

In order to be notified of incoming connections on a socket, you can use *select*(2), *poll*(2), or *epoll*(7). A readable event will be delivered when a new connection is attempted and you may then call **accept**() to get a socket for that connection. Alternatively, you can set the socket to deliver **SIGIO** when activity occurs on a socket; see *socket*(7) for details.

If *flags* is 0, then **accept4**() is the same as **accept**(). The following values can be bitwise ORed in *flags* to obtain different behavior:

SOCK_NONBLOCK
: Set the **O_NONBLOCK** file status flag on the open file description (see *open*(2)) referred to by the new file descriptor. Using this flag saves extra calls to *fcntl*(2) to achieve the same result.

SOCK_CLOEXEC
: Set the close-on-exec (**FD_CLOEXEC**) flag on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

RETURN VALUE

On success, these system calls return a file descriptor for the accepted socket (a nonnegative integer). On error, −1 is returned, *errno* is set to indicate the error, and *addrlen* is left unchanged.

Error handling

Linux **accept**() (and *accept4*()) passes already-pending network errors on the new socket as an error code from **accept**(). This behavior differs from other BSD socket implementations. For reliable operation the application should detect the network errors defined for the protocol after **accept**() and treat

them like **EAGAIN** by retrying. In the case of TCP/IP, these are **ENETDOWN**, **EPROTO**, **ENOPROTOOPT**, **EHOSTDOWN**, **ENONET**, **EHOSTUNREACH**, **EOPNOTSUPP**, and **ENETUNREACH**.

ERRORS

EAGAIN or **EWOULDBLOCK**
: The socket is marked nonblocking and no connections are present to be accepted. POSIX.1-2001 and POSIX.1-2008 allow either error to be returned for this case, and do not require these constants to have the same value, so a portable application should check for both possibilities.

EBADF
: *sockfd* is not an open file descriptor.

ECONNABORTED
: A connection has been aborted.

EFAULT
: The *addr* argument is not in a writable part of the user address space.

EINTR
: The system call was interrupted by a signal that was caught before a valid connection arrived; see *signal*(7).

EINVAL
: Socket is not listening for connections, or *addrlen* is invalid (e.g., is negative).

EINVAL
: (**accept4**()) invalid value in *flags*.

EMFILE
: The per-process limit on the number of open file descriptors has been reached.

ENFILE
: The system-wide limit on the total number of open files has been reached.

ENOBUFS
ENOMEM
: Not enough free memory. This often means that the memory allocation is limited by the socket buffer limits, not by the system memory.

ENOTSOCK
: The file descriptor *sockfd* does not refer to a socket.

EOPNOTSUPP
: The referenced socket is not of type **SOCK_STREAM**.

EPERM
: Firewall rules forbid connection.

EPROTO
: Protocol error.

In addition, network errors for the new socket and as defined for the protocol may be returned. Various Linux kernels can return other errors such as **ENOSR**, **ESOCKTNOSUPPORT**, **EPROTONOSUPPORT**, **ETIMEDOUT**. The value **ERESTARTSYS** may be seen during a trace.

VERSIONS

On Linux, the new socket returned by **accept**() does *not* inherit file status flags such as **O_NONBLOCK** and **O_ASYNC** from the listening socket. This behavior differs from the canonical BSD sockets implementation. Portable programs should not rely on inheritance or noninheritance of file status flags and always explicitly set all required flags on the socket returned from **accept**().

STANDARDS

accept()
: POSIX.1-2008.

accept4()
Linux.

HISTORY

accept()
POSIX.1-2001, SVr4, 4.4BSD (**accept**() first appeared in 4.2BSD).

accept4()
Linux 2.6.28, glibc 2.10.

NOTES

There may not always be a connection waiting after a **SIGIO** is delivered or *select*(2), *poll*(2), or *epoll*(7) return a readability event because the connection might have been removed by an asynchronous network error or another thread before **accept**() is called. If this happens, then the call will block waiting for the next connection to arrive. To ensure that **accept**() never blocks, the passed socket *sockfd* needs to have the **O_NONBLOCK** flag set (see *socket*(7)).

For certain protocols which require an explicit confirmation, such as DECnet, **accept**() can be thought of as merely dequeuing the next connection request and not implying confirmation. Confirmation can be implied by a normal read or write on the new file descriptor, and rejection can be implied by closing the new socket. Currently, only DECnet has these semantics on Linux.

The socklen_t type

In the original BSD sockets implementation (and on other older systems) the third argument of **accept**() was declared as an *int* *. A POSIX.1g draft standard wanted to change it into a *size_t* *C; later POSIX standards and glibc 2.x have *socklen_t* * .

EXAMPLES

See *bind*(2).

NAME

access, faccessat, faccessat2 − check user's permissions for a file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int access(const char *pathname, int mode);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <unistd.h>

int faccessat(int dirfd, const char *pathname, int mode, int  flags);
              /* But see C library/kernel differences, below */

#include <fcntl.h>           /* Definition of AT_* constants */
#include <sys/syscall.h>     /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_faccessat2,
            int dirfd, const char *pathname, int mode, int  flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

faccessat():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_ATFILE_SOURCE

DESCRIPTION

access() checks whether the calling process can access the file *pathname*. If *pathname* is a symbolic link, it is dereferenced.

The *mode* specifies the accessibility check(s) to be performed, and is either the value **F_OK**, or a mask consisting of the bitwise OR of one or more of **R_OK**, **W_OK**, and **X_OK**. **F_OK** tests for the existence of the file. **R_OK**, **W_OK**, and **X_OK** test whether the file exists and grants read, write, and execute permissions, respectively.

The check is done using the calling process's *real* UID and GID, rather than the effective IDs as is done when actually attempting an operation (e.g., *open*(2)) on the file. Similarly, for the root user, the check uses the set of permitted capabilities rather than the set of effective capabilities; and for non-root users, the check uses an empty set of capabilities.

This allows set-user-ID programs and capability-endowed programs to easily determine the invoking user's authority. In other words, **access**() does not answer the "can I read/write/execute this file?" question. It answers a slightly different question: "(assuming I'm a setuid binary) can *the user who invoked me* read/write/execute this file?", which gives set-user-ID programs the possibility to prevent malicious users from causing them to read files which users shouldn't be able to read.

If the calling process is privileged (i.e., its real UID is zero), then an **X_OK** check is successful for a regular file if execute permission is enabled for any of the file owner, group, or other.

faccessat()

faccessat() operates in exactly the same way as **access**(), except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **access**() for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *access*())

If *pathname* is absolute, then *dirfd* is ignored.

flags is constructed by ORing together zero or more of the following values:

AT_EACCESS
Perform access checks using the effective user and group IDs. By default, **faccessat**() uses the real IDs (like *access*())

AT_EMPTY_PATH (since Linux 5.8)
If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the *open*(2) **O_PATH** flag). In this case, *dirfd* can refer to any type of file, not just a directory. If *dirfd* is **AT_FDCWD**, the call operates on the current working directory. This flag is Linux-specific; define **_GNU_SOURCE** to obtain its definition.

AT_SYMLINK_NOFOLLOW
If *pathname* is a symbolic link, do not dereference it: instead return information about the link itself.

See *openat*(2) for an explanation of the need for **faccessat**().

faccessat2()
The description of **faccessat**() given above corresponds to POSIX.1 and to the implementation provided by glibc. However, the glibc implementation was an imperfect emulation (see BUGS) that papered over the fact that the raw Linux **faccessat**() system call does not have a *flags* argument. To allow for a proper implementation, Linux 5.8 added the **faccessat2**() system call, which supports the *flags* argument and allows a correct implementation of the **faccessat**() wrapper function.

RETURN VALUE
On success (all requested permissions granted, or *mode* is **F_OK** and the file exists), zero is returned. On error (at least one bit in *mode* asked for a permission that is denied, or *mode* is **F_OK** and the file does not exist, or some other error occurred), −1 is returned, and *errno* is set to indicate the error.

ERRORS
EACCES
The requested access would be denied to the file, or search permission is denied for one of the directories in the path prefix of *pathname*. (See also *path_resolution*(7).)

EBADF
(**faccessat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** (**faccessat**()) nor a valid file descriptor.

EFAULT
pathname points outside your accessible address space.

EINVAL
mode was incorrectly specified.

EINVAL
(**faccessat**()) Invalid flag specified in *flags*.

EIO An I/O error occurred.

ELOOP
Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG
pathname is too long.

ENOENT
A component of *pathname* does not exist or is a dangling symbolic link.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component used as a directory in *pathname* is not, in fact, a directory.

ENOTDIR
(**faccessat**()) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EPERM
Write permission was requested to a file that has the immutable flag set. See also *ioctl_iflags*(2).

EROFS
Write permission was requested for a file on a read-only filesystem.

ETXTBSY
Write access was requested to an executable which is being executed.

VERSIONS

If the calling process has appropriate privileges (i.e., is superuser), POSIX.1-2001 permits an implementation to indicate success for an **X_OK** check even if none of the execute file permission bits are set. Linux does not do this.

C library/kernel differences

The raw **faccessat**() system call takes only the first three arguments. The **AT_EACCESS** and **AT_SYMLINK_NOFOLLOW** flags are actually implemented within the glibc wrapper function for **faccessat**(). If either of these flags is specified, then the wrapper function employs *fstatat*(2) to determine access permissions, but see BUGS.

glibc notes

On older kernels where **faccessat**() is unavailable (and when the **AT_EACCESS** and **AT_SYMLINK_NOFOLLOW** flags are not specified), the glibc wrapper function falls back to the use of **access**(). When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

STANDARDS

access()
faccessat()
POSIX.1-2008.

faccessat2()
Linux.

HISTORY

access()
SVr4, 4.3BSD, POSIX.1-2001.

faccessat()
Linux 2.6.16, glibc 2.4.

faccessat2()
Linux 5.8.

NOTES

Warning: Using these calls to check if a user is authorized to, for example, open a file before actually doing so using *open*(2) creates a security hole, because the user might exploit the short time interval between checking and opening the file to manipulate it. **For this reason, the use of this system call should be avoided**. (In the example just described, a safer alternative would be to temporarily switch the process's effective user ID to the real ID and then call *open*(2).)

access() always dereferences symbolic links. If you need to check the permissions on a symbolic link, use **faccessat**() with the flag **AT_SYMLINK_NOFOLLOW**.

These calls return an error if any of the access types in *mode* is denied, even if some of the other access types in *mode* are permitted.

A file is accessible only if the permissions on each of the directories in the path prefix of *pathname* grant search (i.e., execute) access. If any directory is inaccessible, then the **access**() call fails, regardless of the permissions on the file itself.

Only access bits are checked, not the file type or contents. Therefore, if a directory is found to be writable, it probably means that files can be created in the directory, and not that the directory can be written as a file. Similarly, a DOS file may be reported as executable, but the *execve*(2) call will still fail.

These calls may not work correctly on NFSv2 filesystems with UID mapping enabled, because UID

mapping is done on the server and hidden from the client, which checks permissions. (NFS versions 3 and higher perform the check on the server.) Similar problems can occur to FUSE mounts.

BUGS

Because the Linux kernel's **faccessat**() system call does not support a *flags* argument, the glibc **faccessat**() wrapper function provided in glibc 2.32 and earlier emulates the required functionality using a combination of the **faccessat**() system call and *fstatat*(2). However, this emulation does not take ACLs into account. Starting with glibc 2.33, the wrapper function avoids this bug by making use of the **faccessat2**() system call where it is provided by the underlying kernel.

In Linux 2.4 (and earlier) there is some strangeness in the handling of **X_OK** tests for superuser. If all categories of execute permission are disabled for a nondirectory file, then the only **access**() test that returns −1 is when *mode* is specified as just **X_OK**; if **R_OK** or **W_OK** is also specified in *mode*, then **access**() returns 0 for such files. Early Linux 2.6 (up to and including Linux 2.6.3) also behaved in the same way as Linux 2.4.

Before Linux 2.6.20, these calls ignored the effect of the **MS_NOEXEC** flag if it was used to *mount*(2) the underlying filesystem. Since Linux 2.6.20, the **MS_NOEXEC** flag is honored.

NAME

acct − switch process accounting on or off

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int acct(const char *_Nullable *filename***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

acct():
Since glibc 2.21:
_DEFAULT_SOURCE
In glibc 2.19 and 2.20:
_DEFAULT_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)
Up to and including glibc 2.19:
_BSD_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)

DESCRIPTION

The **acct**() system call enables or disables process accounting. If called with the name of an existing file as its argument, accounting is turned on, and records for each terminating process are appended to *filename* as it terminates. An argument of NULL causes accounting to be turned off.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
Write permission is denied for the specified file, or search permission is denied for one of the directories in the path prefix of *filename* (see also *path_resolution*(7)), or *filename* is not a regular file.

EFAULT
filename points outside your accessible address space.

EIO Error writing to the file *filename*.

EISDIR
filename is a directory.

ELOOP
Too many symbolic links were encountered in resolving *filename*.

ENAMETOOLONG
filename was too long.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENOENT
The specified file does not exist.

ENOMEM
Out of memory.

ENOSYS
BSD process accounting has not been enabled when the operating system kernel was compiled. The kernel configuration parameter controlling this feature is **CONFIG_BSD_PROCESS_ACCT**.

ENOTDIR
A component used as a directory in *filename* is not in fact a directory.

EPERM
The calling process has insufficient privilege to enable process accounting. On Linux, the **CAP_SYS_PACCT** capability is required.

EROFS
filename refers to a file on a read-only filesystem.

EUSERS
There are no more free file structures or we ran out of memory.

STANDARDS
None.

HISTORY
SVr4, 4.3BSD.

NOTES
No accounting is produced for programs running when a system crash occurs. In particular, nonterminating processes are never accounted for.

The structure of the records written to the accounting file is described in *acct*(5).

SEE ALSO
acct(5)

NAME

add_key − add a key to the kernel's key management facility

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <keyutils.h>

key_serial_t add_key(const char ****type*, const char ****description***,**
const void *payload***[.**_plen_**], size_t** *plen***,**
key_serial_t *keyring***);**

Note: There is no glibc wrapper for this system call; see NOTES.

DESCRIPTION

add_key() creates or updates a key of the given *type* and *description*, instantiates it with the *payload* of length *plen*, attaches it to the nominated *keyring*, and returns the key's serial number.

The key may be rejected if the provided data is in the wrong format or it is invalid in some other way.

If the destination *keyring* already contains a key that matches the specified *type* and *description*, then, if the key type supports it, that key will be updated rather than a new key being created; if not, a new key (with a different ID) will be created and it will displace the link to the extant key from the keyring.

The destination *keyring* serial number may be that of a valid keyring for which the caller has *write* permission. Alternatively, it may be one of the following special keyring IDs:

KEY_SPEC_THREAD_KEYRING
This specifies the caller's thread-specific keyring (**thread−keyring**(7)).

KEY_SPEC_PROCESS_KEYRING
This specifies the caller's process-specific keyring (**process−keyring**(7)).

KEY_SPEC_SESSION_KEYRING
This specifies the caller's session-specific keyring (**session−keyring**(7)).

KEY_SPEC_USER_KEYRING
This specifies the caller's UID-specific keyring (**user−keyring**(7)).

KEY_SPEC_USER_SESSION_KEYRING
This specifies the caller's UID-session keyring (**user−session−keyring**(7)).

Key types

The key *type* is a string that specifies the key's type. Internally, the kernel defines a number of key types that are available in the core key management code. Among the types that are available for user-space use and can be specified as the *type* argument to **add_key**() are the following:

"keyring"
Keyrings are special key types that may contain links to sequences of other keys of any type. If this interface is used to create a keyring, then *payload* should be NULL and *plen* should be zero.

"user" This is a general purpose key type whose payload may be read and updated by user-space applications. The key is kept entirely within kernel memory. The payload for keys of this type is a blob of arbitrary data of up to 32,767 bytes.

"logon" (since Linux 3.3)
This key type is essentially the same as *"user"*, but it does not permit the key to read. This is suitable for storing payloads that you do not want to be readable from user space.

This key type vets the *description* to ensure that it is qualified by a "service" prefix, by checking to ensure that the *description* contains a ':' that is preceded by other characters.

"big_key" (since Linux 3.13)
This key type is similar to *"user"*, but may hold a payload of up to 1 MiB. If the key payload is large enough, then it may be stored encrypted in tmpfs (which can be swapped out) rather than kernel memory.

For further details on these key types, see *keyrings*(7).

RETURN VALUE

On success, **add_key**() returns the serial number of the key it created or updated. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
The keyring wasn't available for modification by the user.

EDQUOT
The key quota for this user would be exceeded by creating this key or linking it to the keyring.

EFAULT
One or more of *type*, *description*, and *payload* points outside process's accessible address space.

EINVAL
The size of the string (including the terminating null byte) specified in *type* or *description* exceeded the limit (32 bytes and 4096 bytes respectively).

EINVAL
The payload data was invalid.

EINVAL
type was *"logon"* and the *description* was not qualified with a prefix string of the form *"service:"*.

EKEYEXPIRED
The keyring has expired.

EKEYREVOKED
The keyring has been revoked.

ENOKEY
The keyring doesn't exist.

ENOMEM
Insufficient memory to create a key.

EPERM
The *type* started with a period ('.'). Key types that begin with a period are reserved to the implementation.

EPERM
type was *"keyring"* and the *description* started with a period ('.'). Keyrings with descriptions (names) that begin with a period are reserved to the implementation.

STANDARDS

Linux.

HISTORY

Linux 2.6.10.

NOTES

glibc does not provide a wrapper for this system call. A wrapper is provided in the *libkeyutils* library. (The accompanying package provides the <*keyutils.h*> header file.) When employing the wrapper in that library, link with −*lkeyutils*.

EXAMPLES

The program below creates a key with the type, description, and payload specified in its command-line arguments, and links that key into the session keyring. The following shell session demonstrates the use of the program:

```
$ ./a.out user mykey "Some payload"
Key ID is 64a4dca
$ grep '64a4dca' /proc/keys
064a4dca I--Q---     1 perm 3f010000  1000  1000 user    mykey: 12
```

Program source

```
#include <keyutils.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

int
main(int argc, char *argv[])
{
    key_serial_t key;

    if (argc != 4) {
        fprintf(stderr, "Usage: %s type description payload\n",
                argv[0]);
        exit(EXIT_FAILURE);
    }

    key = add_key(argv[1], argv[2], argv[3], strlen(argv[3]),
                  KEY_SPEC_SESSION_KEYRING);
    if (key == -1) {
        perror("add_key");
        exit(EXIT_FAILURE);
    }

    printf("Key ID is %jx\n", (uintmax_t) key);

    exit(EXIT_SUCCESS);
}
```

The kernel source files *Documentation/security/keys/core.rst* and *Documentation/keys/request−key.rst* (or, before Linux 4.13, in the files *Documentation/security/keys.txt* and *Documentation/security/keys−request−key.txt*).

NAME

adjtimex, clock_adjtime, ntp_adjtime − tune kernel clock

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/timex.h>

int adjtimex(struct timex ****buf*);**

int clock_adjtime(clockid_t *clk_id*, **struct timex ****buf***);**

int ntp_adjtime(struct timex ****buf*);**

DESCRIPTION

Linux uses David L. Mills' clock adjustment algorithm (see RFC 5905). The system call **adjtimex**() reads and optionally sets adjustment parameters for this algorithm. It takes a pointer to a *timex* structure, updates kernel parameters from (selected) field values, and returns the same structure updated with the current kernel values. This structure is declared as follows:

```
struct timex {
    int  modes;      /* Mode selector */
    long offset;     /* Time offset; nanoseconds, if STA_NANO
                        status flag is set, otherwise
                        microseconds */
    long freq;       /* Frequency offset; see NOTES for units */
    long maxerror;   /* Maximum error (microseconds) */
    long esterror;   /* Estimated error (microseconds) */
    int  status;     /* Clock command/status */
    long constant;   /* PLL (phase-locked loop) time constant */
    long precision;  /* Clock precision
                        (microseconds, read-only) */
    long tolerance;  /* Clock frequency tolerance (read-only);
                        see NOTES for units */
    struct timeval time;
                     /* Current time (read-only, except for
                        ADJ_SETOFFSET); upon return, time.tv_usec
                        contains nanoseconds, if STA_NANO status
                        flag is set, otherwise microseconds */
    long tick;       /* Microseconds between clock ticks */
    long ppsfreq;    /* PPS (pulse per second) frequency
                        (read-only); see NOTES for units */
    long jitter;     /* PPS jitter (read-only); nanoseconds, if
                        STA_NANO status flag is set, otherwise
                        microseconds */
    int  shift;      /* PPS interval duration
                        (seconds, read-only) */
    long stabil;     /* PPS stability (read-only);
                        see NOTES for units */
    long jitcnt;     /* PPS count of jitter limit exceeded
                        events (read-only) */
    long calcnt;     /* PPS count of calibration intervals
                        (read-only) */
    long errcnt;     /* PPS count of calibration errors
                        (read-only) */
    long stbcnt;     /* PPS count of stability limit exceeded
                        events (read-only) */
    int tai;         /* TAI offset, as set by previous ADJ_TAI
                        operation (seconds, read-only,
                        since Linux 2.6.26) */
    /* Further padding bytes to allow for future expansion */
};
```

The *modes* field determines which parameters, if any, to set. (As described later in this page, the constants used for **ntp_adjtime**() are equivalent but differently named.) It is a bit mask containing a bitwise OR combination of zero or more of the following bits:

ADJ_OFFSET
Set time offset from *buf.offset*. Since Linux 2.6.26, the supplied value is clamped to the range (−0.5s, +0.5s). In older kernels, an **EINVAL** error occurs if the supplied value is out of range.

ADJ_FREQUENCY
Set frequency offset from *buf.freq*. Since Linux 2.6.26, the supplied value is clamped to the range (−32768000, +32768000). In older kernels, an **EINVAL** error occurs if the supplied value is out of range.

ADJ_MAXERROR
Set maximum time error from *buf.maxerror*.

ADJ_ESTERROR
Set estimated time error from *buf.esterror*.

ADJ_STATUS
Set clock status bits from *buf.status*. A description of these bits is provided below.

ADJ_TIMECONST
Set PLL time constant from *buf.constant*. If the **STA_NANO** status flag (see below) is clear, the kernel adds 4 to this value.

ADJ_SETOFFSET (since Linux 2.6.39)
Add *buf.time* to the current time. If *buf.status* includes the **ADJ_NANO** flag, then *buf.time.tv_usec* is interpreted as a nanosecond value; otherwise it is interpreted as microseconds.

The value of *buf.time* is the sum of its two fields, but the field *buf.time.tv_usec* must always be nonnegative. The following example shows how to normalize a *timeval* with nanosecond resolution.

```
while (buf.time.tv_usec < 0) {
    buf.time.tv_sec  -= 1;
    buf.time.tv_usec += 1000000000;
}
```

ADJ_MICRO (since Linux 2.6.26)
Select microsecond resolution.

ADJ_NANO (since Linux 2.6.26)
Select nanosecond resolution. Only one of **ADJ_MICRO** and **ADJ_NANO** should be specified.

ADJ_TAI (since Linux 2.6.26)
Set TAI (Atomic International Time) offset from *buf.constant*.

ADJ_TAI should not be used in conjunction with **ADJ_TIMECONST**, since the latter mode also employs the *buf.constant* field.

For a complete explanation of TAI and the difference between TAI and UTC, see *BIPM*

ADJ_TICK
Set tick value from *buf.tick*.

Alternatively, *modes* can be specified as either of the following (multibit mask) values, in which case other bits should not be specified in *modes*:

ADJ_OFFSET_SINGLESHOT
Old-fashioned *adjtime*(3): (gradually) adjust time by value specified in *buf.offset*, which specifies an adjustment in microseconds.

ADJ_OFFSET_SS_READ (functional since Linux 2.6.28)
Return (in *buf.offset*) the remaining amount of time to be adjusted after an earlier **ADJ_OFFSET_SINGLESHOT** operation. This feature was added in Linux 2.6.24, but did not work correctly until Linux 2.6.28.

Ordinary users are restricted to a value of either 0 or **ADJ_OFFSET_SS_READ** for *modes*. Only the superuser may set any parameters.

The *buf.status* field is a bit mask that is used to set and/or retrieve status bits associated with the NTP implementation. Some bits in the mask are both readable and settable, while others are read-only.

STA_PLL (read-write)
Enable phase-locked loop (PLL) updates via **ADJ_OFFSET**.

STA_PPSFREQ (read-write)
Enable PPS (pulse-per-second) frequency discipline.

STA_PPSTIME (read-write)
Enable PPS time discipline.

STA_FLL (read-write)
Select frequency-locked loop (FLL) mode.

STA_INS (read-write)
Insert a leap second after the last second of the UTC day, thus extending the last minute of the day by one second. Leap-second insertion will occur each day, so long as this flag remains set.

STA_DEL (read-write)
Delete a leap second at the last second of the UTC day. Leap second deletion will occur each day, so long as this flag remains set.

STA_UNSYNC (read-write)
Clock unsynchronized.

STA_FREQHOLD (read-write)
Hold frequency. Normally adjustments made via **ADJ_OFFSET** result in dampened frequency adjustments also being made. So a single call corrects the current offset, but as offsets in the same direction are made repeatedly, the small frequency adjustments will accumulate to fix the long-term skew.

This flag prevents the small frequency adjustment from being made when correcting for an **ADJ_OFFSET** value.

STA_PPSSIGNAL (read-only)
A valid PPS (pulse-per-second) signal is present.

STA_PPSJITTER (read-only)
PPS signal jitter exceeded.

STA_PPSWANDER (read-only)
PPS signal wander exceeded.

STA_PPSERROR (read-only)
PPS signal calibration error.

STA_CLOCKERR (read-only)
Clock hardware fault.

STA_NANO (read-only; since Linux 2.6.26)
Resolution (0 = microsecond, 1 = nanoseconds). Set via **ADJ_NANO**, cleared via **ADJ_MICRO**.

STA_MODE (since Linux 2.6.26)
Mode (0 = Phase Locked Loop, 1 = Frequency Locked Loop).

STA_CLK (read-only; since Linux 2.6.26)
Clock source (0 = A, 1 = B); currently unused.

Attempts to set read-only *status* bits are silently ignored.

clock_adjtime ()
The **clock_adjtime**() system call (added in Linux 2.6.39) behaves like **adjtimex**() but takes an additional *clk_id* argument to specify the particular clock on which to act.

ntp_adjtime ()

The **ntp_adjtime**() library function (described in the NTP "Kernel Application Program API", KAPI) is a more portable interface for performing the same task as **adjtimex**(). Other than the following points, it is identical to **adjtimex**():

- The constants used in *modes* are prefixed with "MOD_" rather than "ADJ_", and have the same suffixes (thus, **MOD_OFFSET**, **MOD_FREQUENCY**, and so on), other than the exceptions noted in the following points.
- **MOD_CLKA** is the synonym for **ADJ_OFFSET_SINGLESHOT**.
- **MOD_CLKB** is the synonym for **ADJ_TICK**.
- The is no synonym for **ADJ_OFFSET_SS_READ**, which is not described in the KAPI.

RETURN VALUE

On success, **adjtimex**() and **ntp_adjtime**() return the clock state; that is, one of the following values:

TIME_OK Clock synchronized, no leap second adjustment pending.

TIME_INS Indicates that a leap second will be added at the end of the UTC day.

TIME_DEL Indicates that a leap second will be deleted at the end of the UTC day.

TIME_OOP Insertion of a leap second is in progress.

TIME_WAIT
A leap-second insertion or deletion has been completed. This value will be returned until the next **ADJ_STATUS** operation clears the **STA_INS** and **STA_DEL** flags.

TIME_ERROR
The system clock is not synchronized to a reliable server. This value is returned when any of the following holds true:

- Either **STA_UNSYNC** or **STA_CLOCKERR** is set.
- **STA_PPSSIGNAL** is clear and either **STA_PPSFREQ** or **STA_PPSTIME** is set.
- **STA_PPSTIME** and **STA_PPSJITTER** are both set.
- **STA_PPSFREQ** is set and either **STA_PPSWANDER** or **STA_PPSJITTER** is set.

The symbolic name **TIME_BAD** is a synonym for **TIME_ERROR**, provided for backward compatibility.

Note that starting with Linux 3.4, the call operates asynchronously and the return value usually will not reflect a state change caused by the call itself.

On failure, these calls return −1 and set *errno* to indicate the error.

ERRORS

EFAULT
buf does not point to writable memory.

EINVAL (before Linux 2.6.26)
An attempt was made to set *buf.freq* to a value outside the range (−33554432, +33554432).

EINVAL (before Linux 2.6.26)
An attempt was made to set *buf.offset* to a value outside the permitted range. Before Linux 2.0, the permitted range was (−131072, +131072). From Linux 2.0 onwards, the permitted range was (−512000, +512000).

EINVAL
An attempt was made to set *buf.status* to a value other than those listed above.

EINVAL
The *clk_id* given to **clock_adjtime**() is invalid for one of two reasons. Either the System-V style hard-coded positive clock ID value is out of range, or the dynamic *clk_id* does not refer to a valid instance of a clock object. See *clock_gettime*(2) for a discussion of dynamic clocks.

EINVAL
An attempt was made to set *buf.tick* to a value outside the range 900000/**HZ** to 1100000/**HZ**, where **HZ** is the system timer interrupt frequency.

ENODEV
The hot-pluggable device (like USB for example) represented by a dynamic *clk_id* has disappeared after its character device was opened. See *clock_gettime*(2) for a discussion of dynamic clocks.

EOPNOTSUPP
The given *clk_id* does not support adjustment.

EPERM
buf.modes is neither 0 nor **ADJ_OFFSET_SS_READ**, and the caller does not have sufficient privilege. Under Linux, the **CAP_SYS_TIME** capability is required.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
ntp_adjtime()	Thread safety	MT-Safe

STANDARDS

adjtimex()
clock_adjtime()
Linux.

The preferred API for the NTP daemon is **ntp_adjtime**().

NOTES

In struct *timex*, *freq*, *ppsfreq*, and *stabil* are ppm (parts per million) with a 16-bit fractional part, which means that a value of 1 in one of those fields actually means 2^-16 ppm, and 2^16=65536 is 1 ppm. This is the case for both input values (in the case of *freq*) and output values.

The leap-second processing triggered by **STA_INS** and **STA_DEL** is done by the kernel in timer context. Thus, it will take one tick into the second for the leap second to be inserted or deleted.

NTP "Kernel Application Program Interface"

NAME

alarm − set an alarm clock for delivery of a signal

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

unsigned int alarm(unsigned int *seconds***);**

DESCRIPTION

alarm() arranges for a **SIGALRM** signal to be delivered to the calling process in *seconds* seconds.

If *seconds* is zero, any pending alarm is canceled.

In any event any previously set **alarm**() is canceled.

RETURN VALUE

alarm() returns the number of seconds remaining until any previously scheduled alarm was due to be delivered, or zero if there was no previously scheduled alarm.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

NOTES

alarm() and *setitimer*(2) share the same timer; calls to one will interfere with use of the other.

Alarms created by **alarm**() are preserved across *execve*(2) and are not inherited by children created via *fork*(2).

sleep(3) may be implemented using **SIGALRM**; mixing calls to **alarm**() and *sleep*(3) is a bad idea.

Scheduling delays can, as ever, cause the execution of the process to be delayed by an arbitrary amount of time.

SEE ALSO

gettimeofday(2), *pause*(2), *select*(2), *setitimer*(2), *sigaction*(2), *signal*(2), *timer_create*(2), *timerfd_create*(2), *sleep*(3), *time*(7)

NAME

alloc_hugepages, free_hugepages − allocate or free huge pages

SYNOPSIS

void *syscall(SYS_alloc_hugepages, int *key***, void** *addr***[.***len***], size_t** *len***,**
int *prot***, int** *flag***);**
int syscall(SYS_free_hugepages, void *****addr*);**

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

The system calls **alloc_hugepages**() and **free_hugepages**() were introduced in Linux 2.5.36 and removed again in Linux 2.5.54. They existed only on i386 and ia64 (when built with **CONFIG_HUGETLB_PAGE**). In Linux 2.4.20, the syscall numbers exist, but the calls fail with the error **ENOSYS**.

On i386 the memory management hardware knows about ordinary pages (4 KiB) and huge pages (2 or 4 MiB). Similarly ia64 knows about huge pages of several sizes. These system calls serve to map huge pages into the process's memory or to free them again. Huge pages are locked into memory, and are not swapped.

The *key* argument is an identifier. When zero the pages are private, and not inherited by children. When positive the pages are shared with other applications using the same *key*, and inherited by child processes.

The *addr* argument of **free_hugepages**() tells which page is being freed: it was the return value of a call to **alloc_hugepages**(). (The memory is first actually freed when all users have released it.) The *addr* argument of **alloc_hugepages**() is a hint, that the kernel may or may not follow. Addresses must be properly aligned.

The *len* argument is the length of the required segment. It must be a multiple of the huge page size.

The *prot* argument specifies the memory protection of the segment. It is one of **PROT_READ**, **PROT_WRITE**, **PROT_EXEC**.

The *flag* argument is ignored, unless *key* is positive. In that case, if *flag* is **IPC_CREAT**, then a new huge page segment is created when none with the given key existed. If this flag is not set, then **ENOENT** is returned when no segment with the given key exists.

RETURN VALUE

On success, **alloc_hugepages**() returns the allocated virtual address, and **free_hugepages**() returns zero. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

ENOSYS
The system call is not supported on this kernel.

FILES

/proc/sys/vm/nr_hugepages
Number of configured hugetlb pages. This can be read and written.

/proc/meminfo
Gives info on the number of configured hugetlb pages and on their size in the three variables HugePages_Total, HugePages_Free, Hugepagesize.

STANDARDS

Linux on Intel processors.

HISTORY

These system calls are gone; they existed only in Linux 2.5.36 through to Linux 2.5.54.

NOTES

Now the hugetlbfs filesystem can be used instead. Memory backed by huge pages (if the CPU supports them) is obtained by using *mmap*(2) to map files in this virtual filesystem.

The maximal number of huge pages can be specified using the **hugepages=** boot parameter.

NAME

arch_prctl − set architecture-specific thread state

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <asm/prctl.h>      /* Definition of ARCH_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_arch_prctl, int op, unsigned long addr);
int syscall(SYS_arch_prctl, int op, unsigned long *addr);
```

Note: glibc provides no wrapper for **arch_prctl**(), necessitating the use of *syscall*(2).

DESCRIPTION

arch_prctl() sets architecture-specific process or thread state. *op* selects an operation and passes argument *addr* to it; *addr* is interpreted as either an *unsigned long* for the "set" operations, or as an *unsigned long* *, for the "get" operations.

Subfunctions for both x86 and x86-64 are:

ARCH_SET_CPUID (since Linux 4.12)
: Enable (*addr != 0*) or disable (*addr == 0*) the *cpuid* instruction for the calling thread. The instruction is enabled by default. If disabled, any execution of a *cpuid* instruction will instead generate a **SIGSEGV** signal. This feature can be used to emulate *cpuid* results that differ from what the underlying hardware would have produced (e.g., in a paravirtualization setting).

  The **ARCH_SET_CPUID** setting is preserved across *fork*(2) and *clone*(2) but reset to the default (i.e., *cpuid* enabled) on *execve*(2).

ARCH_GET_CPUID (since Linux 4.12)
: Return the setting of the flag manipulated by **ARCH_SET_CPUID** as the result of the system call (1 for enabled, 0 for disabled). *addr* is ignored.

Subfunctions for x86-64 only are:

ARCH_SET_FS
: Set the 64-bit base for the *FS* register to *addr*.

ARCH_GET_FS
: Return the 64-bit base value for the *FS* register of the calling thread in the *unsigned long* pointed to by *addr*.

ARCH_SET_GS
: Set the 64-bit base for the *GS* register to *addr*.

ARCH_GET_GS
: Return the 64-bit base value for the *GS* register of the calling thread in the *unsigned long* pointed to by *addr*.

RETURN VALUE

On success, **arch_prctl**() returns 0; on error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
: *addr* points to an unmapped address or is outside the process address space.

EINVAL
: *op* is not a valid operation.

ENODEV
: **ARCH_SET_CPUID** was requested, but the underlying hardware does not support CPUID faulting.

EPERM
: *addr* is outside the process address space.

STANDARDS

Linux/x86-64.

NOTES

arch_prctl() is supported only on Linux/x86-64 for 64-bit programs currently.

The 64-bit base changes when a new 32-bit segment selector is loaded.

ARCH_SET_GS is disabled in some kernels.

Context switches for 64-bit segment bases are rather expensive. As an optimization, if a 32-bit TLS base address is used, **arch_prctl**() may use a real TLS entry as if *set_thread_area*(2) had been called, instead of manipulating the segment base register directly. Memory in the first 2 GB of address space can be allocated by using *mmap*(2) with the **MAP_32BIT** flag.

Because of the aforementioned optimization, using **arch_prctl**() and *set_thread_area*(2) in the same thread is dangerous, as they may overwrite each other's TLS entries.

FS may be already used by the threading library. Programs that use **ARCH_SET_FS** directly are very likely to crash.

mmap(2), *modify_ldt*(2), *prctl*(2), *set_thread_area*(2)

AMD X86-64 Programmer's manual

NAME

bdflush − start, flush, or tune buffer-dirty-flush daemon

SYNOPSIS

#include <sys/kdaemon.h>

[[deprecated]] int bdflush(int *func***, long ****address***);**
[[deprecated]] int bdflush(int *func***, long** *data***);**

DESCRIPTION

Note: Since Linux 2.6, this system call is deprecated and does nothing. It is likely to disappear altogether in a future kernel release. Nowadays, the task performed by **bdflush**() is handled by the kernel *pdflush* thread.

bdflush() starts, flushes, or tunes the buffer-dirty-flush daemon. Only a privileged process (one with the **CAP_SYS_ADMIN** capability) may call **bdflush**().

If *func* is negative or 0, and no daemon has been started, then **bdflush**() enters the daemon code and never returns.

If *func* is 1, some dirty buffers are written to disk.

If *func* is 2 or more and is even (low bit is 0), then *address* is the address of a long word, and the tuning parameter numbered (*func*−2)/2 is returned to the caller in that address.

If *func* is 3 or more and is odd (low bit is 1), then *data* is a long word, and the kernel sets tuning parameter numbered (*func*−3)/2 to that value.

The set of parameters, their values, and their valid ranges are defined in the Linux kernel source file *fs/buffer.c*.

RETURN VALUE

If *func* is negative or 0 and the daemon successfully starts, **bdflush**() never returns. Otherwise, the return value is 0 on success and −1 on failure, with *errno* set to indicate the error.

ERRORS

EBUSY
An attempt was made to enter the daemon code after another process has already entered.

EFAULT
address points outside your accessible address space.

EINVAL
An attempt was made to read or write an invalid parameter number, or to write an invalid value to a parameter.

EPERM
Caller does not have the **CAP_SYS_ADMIN** capability.

STANDARDS

Linux.

HISTORY

Since glibc 2.23, glibc no longer supports this obsolete system call.

NAME

bind − bind a name to a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/socket.h>

int bind(int sockfd, const struct sockaddr *addr,
         socklen_t addrlen);
```

DESCRIPTION

When a socket is created with *socket*(2), it exists in a name space (address family) but has no address assigned to it. **bind**() assigns the address specified by *addr* to the socket referred to by the file descriptor *sockfd*. *addrlen* specifies the size, in bytes, of the address structure pointed to by *addr*. Traditionally, this operation is called “assigning a name to a socket”.

It is normally necessary to assign a local address using **bind**() before a **SOCK_STREAM** socket may receive connections (see *accept*(2)).

The rules used in name binding vary between address families. Consult the manual entries in Section 7 for detailed information. For **AF_INET**, see *ip*(7); for **AF_INET6**, see *ipv6*(7); for **AF_UNIX**, see *unix*(7); for **AF_APPLETALK**, see *ddp*(7); for **AF_PACKET**, see *packet*(7); for **AF_X25**, see *x25*(7); and for **AF_NETLINK**, see *netlink*(7).

The actual structure passed for the *addr* argument will depend on the address family. The *sockaddr* structure is defined as something like:

```
struct sockaddr {
    sa_family_t sa_family;
    char        sa_data[14];
}
```

The only purpose of this structure is to cast the structure pointer passed in *addr* in order to avoid compiler warnings. See EXAMPLES below.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
The address is protected, and the user is not the superuser.

EADDRINUSE
The given address is already in use.

EADDRINUSE
(Internet domain sockets) The port number was specified as zero in the socket address structure, but, upon attempting to bind to an ephemeral port, it was determined that all port numbers in the ephemeral port range are currently in use. See the discussion of */proc/sys/net/ipv4/ip_local_port_range* *ip*(7).

EBADF
sockfd is not a valid file descriptor.

EINVAL
The socket is already bound to an address.

EINVAL
addrlen is wrong, or *addr* is not a valid address for this socket’s domain.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

The following errors are specific to UNIX domain (**AF_UNIX**) sockets:

EACCES
Search permission is denied on a component of the path prefix. (See also *path_resolution*(7).)

EADDRNOTAVAIL
A nonexistent interface was requested or the requested address was not local.

EFAULT
addr points outside the user's accessible address space.

ELOOP
Too many symbolic links were encountered in resolving *addr*.

ENAMETOOLONG
addr is too long.

ENOENT
A component in the directory prefix of the socket pathname does not exist.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component of the path prefix is not a directory.

EROFS
The socket inode would reside on a read-only filesystem.

STANDARDS
POSIX.1-2008.

HISTORY
POSIX.1-2001, SVr4, 4.4BSD (**bind**() first appeared in 4.2BSD).

BUGS
The transparent proxy options are not described.

EXAMPLES
An example of the use of **bind**() with Internet domain sockets can be found in *getaddrinfo*(3).

The following example shows how to bind a stream socket in the UNIX (**AF_UNIX**) domain, and accept connections:

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/socket.h>
#include <sys/un.h>
#include <unistd.h>

#define MY_SOCK_PATH "/somepath"
#define LISTEN_BACKLOG 50

#define handle_error(msg) \
    do { perror(msg); exit(EXIT_FAILURE); } while (0)

int
main(void)
{
    int                 sfd, cfd;
    socklen_t           peer_addr_size;
    struct sockaddr_un  my_addr, peer_addr;

    sfd = socket(AF_UNIX, SOCK_STREAM, 0);
    if (sfd == -1)
        handle_error("socket");

    memset(&my_addr, 0, sizeof(my_addr));
    my_addr.sun_family = AF_UNIX;
    strncpy(my_addr.sun_path, MY_SOCK_PATH,
```

```
                sizeof(my_addr.sun_path) - 1);

        if (bind(sfd, (struct sockaddr *) &my_addr,
                 sizeof(my_addr)) == -1)
            handle_error("bind");

        if (listen(sfd, LISTEN_BACKLOG) == -1)
            handle_error("listen");

        /* Now we can accept incoming connections one
           at a time using accept(2). */

        peer_addr_size = sizeof(peer_addr);
        cfd = accept(sfd, (struct sockaddr *) &peer_addr,
                     &peer_addr_size);
        if (cfd == -1)
            handle_error("accept");

        /* Code to deal with incoming connection(s)... */

        if (close(sfd) == -1)
            handle_error("close");

        if (unlink(MY_SOCK_PATH) == -1)
            handle_error("unlink");
    }
```

accept(2), *connect*(2), *getsockname*(2), *listen*(2), *socket*(2), *getaddrinfo*(3), *getifaddrs*(3), *ip*(7), *ipv6*(7), *path_resolution*(7), *socket*(7), *unix*(7)

NAME

bpf − perform a command on an extended BPF map or program

SYNOPSIS

#include <linux/bpf.h>

int bpf(int *cmd***, union bpf_attr ****attr***, unsigned int** *size***);**

DESCRIPTION

The **bpf**() system call performs a range of operations related to extended Berkeley Packet Filters. Extended BPF (or eBPF) is similar to the original ("classic") BPF (cBPF) used to filter network packets. For both cBPF and eBPF programs, the kernel statically analyzes the programs before loading them, in order to ensure that they cannot harm the running system.

eBPF extends cBPF in multiple ways, including the ability to call a fixed set of in-kernel helper functions (via the **BPF_CALL** opcode extension provided by eBPF) and access shared data structures such as eBPF maps.

Extended BPF Design/Architecture

eBPF maps are a generic data structure for storage of different data types. Data types are generally treated as binary blobs, so a user just specifies the size of the key and the size of the value at map-creation time. In other words, a key/value for a given map can have an arbitrary structure.

A user process can create multiple maps (with key/value-pairs being opaque bytes of data) and access them via file descriptors. Different eBPF programs can access the same maps in parallel. It's up to the user process and eBPF program to decide what they store inside maps.

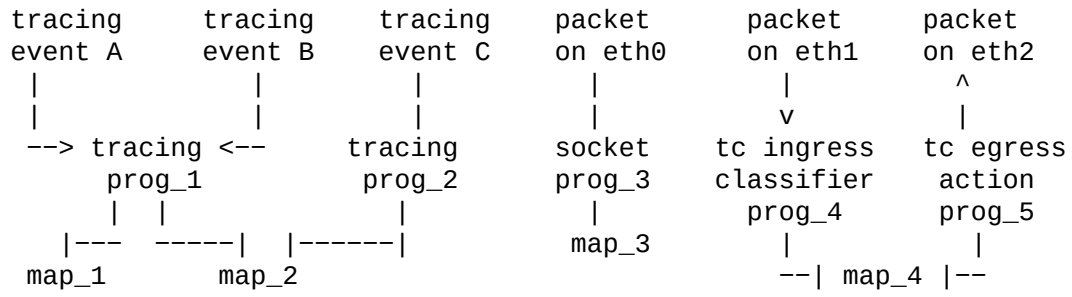
There's one special map type, called a program array. This type of map stores file descriptors referring to other eBPF programs. When a lookup in the map is performed, the program flow is redirected in-place to the beginning of another eBPF program and does not return back to the calling program. The level of nesting has a fixed limit of 32, so that infinite loops cannot be crafted. At run time, the program file descriptors stored in the map can be modified, so program functionality can be altered based on specific requirements. All programs referred to in a program-array map must have been previously loaded into the kernel via **bpf**(). If a map lookup fails, the current program continues its execution. See **BPF_MAP_TYPE_PROG_ARRAY** below for further details.

Generally, eBPF programs are loaded by the user process and automatically unloaded when the process exits. In some cases, for example, *tc-bpf*(8), the program will continue to stay alive inside the kernel even after the process that loaded the program exits. In that case, the tc subsystem holds a reference to the eBPF program after the file descriptor has been closed by the user-space program. Thus, whether a specific program continues to live inside the kernel depends on how it is further attached to a given kernel subsystem after it was loaded via **bpf**().

Each eBPF program is a set of instructions that is safe to run until its completion. An in-kernel verifier statically determines that the eBPF program terminates and is safe to execute. During verification, the kernel increments reference counts for each of the maps that the eBPF program uses, so that the attached maps can't be removed until the program is unloaded.

eBPF programs can be attached to different events. These events can be the arrival of network packets, tracing events, classification events by network queueing disciplines (for eBPF programs attached to a *tc*(8) classifier), and other types that may be added in the future. A new event triggers execution of the eBPF program, which may store information about the event in eBPF maps. Beyond storing data, eBPF programs may call a fixed set of in-kernel helper functions.

The same eBPF program can be attached to multiple events and different eBPF programs can access the same map:



Arguments

The operation to be performed by the **bpf**() system call is determined by the *cmd* argument. Each operation takes an accompanying argument, provided via *attr*, which is a pointer to a union of type *bpf_attr* (see below). The unused fields and padding must be zeroed out before the call. The *size* argument is the size of the union pointed to by *attr*.

The value provided in *cmd* is one of the following:

BPF_MAP_CREATE
Create a map and return a file descriptor that refers to the map. The close-on-exec file descriptor flag (see *fcntl*(2)) is automatically enabled for the new file descriptor.

BPF_MAP_LOOKUP_ELEM
Look up an element by key in a specified map and return its value.

BPF_MAP_UPDATE_ELEM
Create or update an element (key/value pair) in a specified map.

BPF_MAP_DELETE_ELEM
Look up and delete an element by key in a specified map.

BPF_MAP_GET_NEXT_KEY
Look up an element by key in a specified map and return the key of the next element.

BPF_PROG_LOAD
Verify and load an eBPF program, returning a new file descriptor associated with the program. The close-on-exec file descriptor flag (see *fcntl*(2)) is automatically enabled for the new file descriptor.

The *bpf_attr* union consists of various anonymous structures that are used by different **bpf**() commands:

```
union bpf_attr {
    struct {    /* Used by BPF_MAP_CREATE */
        __u32         map_type;
        __u32         key_size;    /* size of key in bytes */
        __u32         value_size;  /* size of value in bytes */
        __u32         max_entries; /* maximum number of entries
                                      in a map */
    };

    struct {    /* Used by BPF_MAP_*_ELEM and BPF_MAP_GET_NEXT_KEY
                   commands */
        __u32         map_fd;
        __aligned_u64 key;
        union {
            __aligned_u64 value;
            __aligned_u64 next_key;
        };
        __u64         flags;
    };

    struct {    /* Used by BPF_PROG_LOAD */
        __u32         prog_type;
        __u32         insn_cnt;
        __aligned_u64 insns;      /* 'const struct bpf_insn *' */
        __aligned_u64 license;    /* 'const char *' */
        __u32         log_level;  /* verbosity level of verifier */
        __u32         log_size;   /* size of user buffer */
        __aligned_u64 log_buf;    /* user supplied 'char *'
                                     buffer */
        __u32         kern_version;
                                  /* checked when prog_type=kprobe
                                     (since Linux 4.1) */
```

```
        };
    } __attribute__((aligned(8)));
```

eBPF maps

Maps are a generic data structure for storage of different types of data. They allow sharing of data between eBPF kernel programs, and also between kernel and user-space applications.

Each map type has the following attributes:

- type
- maximum number of elements
- key size in bytes
- value size in bytes

The following wrapper functions demonstrate how various **bpf**() commands can be used to access the maps. The functions use the *cmd* argument to invoke different operations.

BPF_MAP_CREATE

The **BPF_MAP_CREATE** command creates a new map, returning a new file descriptor that refers to the map.

```
int
bpf_create_map(enum bpf_map_type map_type,
               unsigned int key_size,
               unsigned int value_size,
               unsigned int max_entries)
{
    union bpf_attr attr = {
        .map_type    = map_type,
        .key_size    = key_size,
        .value_size  = value_size,
        .max_entries = max_entries
    };

    return bpf(BPF_MAP_CREATE, &attr, sizeof(attr));
}
```

The new map has the type specified by *map_type*, and attributes as specified in *key_size*, *value_size*, and *max_entries*. On success, this operation returns a file descriptor. On error, −1 is returned and *errno* is set to **EINVAL**, **EPERM**, or **ENOMEM**.

The *key_size* and *value_size* attributes will be used by the verifier during program loading to check that the program is calling **bpf_map_*_elem**() helper functions with a correctly initialized *key* and to check that the program doesn't access the map element *value* beyond the specified *value_size*. For example, when a map is created with a *key_size* of 8 and the eBPF program calls

```
bpf_map_lookup_elem(map_fd, fp - 4)
```

the program will be rejected, since the in-kernel helper function

```
bpf_map_lookup_elem(map_fd, void *key)
```

expects to read 8 bytes from the location pointed to by *key*, but the *fp − 4* (where *fp* is the top of the stack) starting address will cause out-of-bounds stack access.

Similarly, when a map is created with a *value_size* of 1 and the eBPF program contains

```
value = bpf_map_lookup_elem(...);
*(u32 *) value = 1;
```

the program will be rejected, since it accesses the *value* pointer beyond the specified 1 byte *value_size* limit.

Currently, the following values are supported for *map_type*:

```
enum bpf_map_type {
    BPF_MAP_TYPE_UNSPEC,  /* Reserve 0 as invalid map type */
```

```
        BPF_MAP_TYPE_HASH,
        BPF_MAP_TYPE_ARRAY,
        BPF_MAP_TYPE_PROG_ARRAY,
        BPF_MAP_TYPE_PERF_EVENT_ARRAY,
        BPF_MAP_TYPE_PERCPU_HASH,
        BPF_MAP_TYPE_PERCPU_ARRAY,
        BPF_MAP_TYPE_STACK_TRACE,
        BPF_MAP_TYPE_CGROUP_ARRAY,
        BPF_MAP_TYPE_LRU_HASH,
        BPF_MAP_TYPE_LRU_PERCPU_HASH,
        BPF_MAP_TYPE_LPM_TRIE,
        BPF_MAP_TYPE_ARRAY_OF_MAPS,
        BPF_MAP_TYPE_HASH_OF_MAPS,
        BPF_MAP_TYPE_DEVMAP,
        BPF_MAP_TYPE_SOCKMAP,
        BPF_MAP_TYPE_CPUMAP,
        BPF_MAP_TYPE_XSKMAP,
        BPF_MAP_TYPE_SOCKHASH,
        BPF_MAP_TYPE_CGROUP_STORAGE,
        BPF_MAP_TYPE_REUSEPORT_SOCKARRAY,
        BPF_MAP_TYPE_PERCPU_CGROUP_STORAGE,
        BPF_MAP_TYPE_QUEUE,
        BPF_MAP_TYPE_STACK,
        /* See /usr/include/linux/bpf.h for the full list. */
    };
```

map_type selects one of the available map implementations in the kernel. For all map types, eBPF programs access maps with the same **bpf_map_lookup_elem**() and **bpf_map_update_elem**() helper functions. Further details of the various map types are given below.

BPF_MAP_LOOKUP_ELEM

The **BPF_MAP_LOOKUP_ELEM** command looks up an element with a given *key* in the map referred to by the file descriptor *fd*.

```
    int
    bpf_lookup_elem(int fd, const void *key, void *value)
    {
        union bpf_attr attr = {
            .map_fd = fd,
            .key    = ptr_to_u64(key),
            .value  = ptr_to_u64(value),
        };

        return bpf(BPF_MAP_LOOKUP_ELEM, &attr, sizeof(attr));
    }
```

If an element is found, the operation returns zero and stores the element's value into *value*, which must point to a buffer of *value_size* bytes.

If no element is found, the operation returns −1 and sets *errno* to **ENOENT**.

BPF_MAP_UPDATE_ELEM

The **BPF_MAP_UPDATE_ELEM** command creates or updates an element with a given *key/value* in the map referred to by the file descriptor *fd*.

```
    int
    bpf_update_elem(int fd, const void *key, const void *value,
                    uint64_t flags)
    {
        union bpf_attr attr = {
            .map_fd = fd,
            .key    = ptr_to_u64(key),
            .value  = ptr_to_u64(value),
```

```
        .flags  = flags,
    };

    return bpf(BPF_MAP_UPDATE_ELEM, &attr, sizeof(attr));
}
```

The *flags* argument should be specified as one of the following:

BPF_ANY
Create a new element or update an existing element.

BPF_NOEXIST
Create a new element only if it did not exist.

BPF_EXIST
Update an existing element.

On success, the operation returns zero. On error, −1 is returned and *errno* is set to **EINVAL**, **EPERM**, **ENOMEM**, or **E2BIG**. **E2BIG** indicates that the number of elements in the map reached the *max_entries* limit specified at map creation time. **EEXIST** will be returned if *flags* specifies **BPF_NOEXIST** and the element with *key* already exists in the map. **ENOENT** will be returned if *flags* specifies **BPF_EXIST** and the element with *key* doesn't exist in the map.

BPF_MAP_DELETE_ELEM
The **BPF_MAP_DELETE_ELEM** command deletes the element whose key is *key* from the map referred to by the file descriptor *fd*.

```
int
bpf_delete_elem(int fd, const void *key)
{
    union bpf_attr attr = {
        .map_fd = fd,
        .key    = ptr_to_u64(key),
    };

    return bpf(BPF_MAP_DELETE_ELEM, &attr, sizeof(attr));
}
```

On success, zero is returned. If the element is not found, −1 is returned and *errno* is set to **ENOENT**.

BPF_MAP_GET_NEXT_KEY
The **BPF_MAP_GET_NEXT_KEY** command looks up an element by *key* in the map referred to by the file descriptor *fd* and sets the *next_key* pointer to the key of the next element.

```
int
bpf_get_next_key(int fd, const void *key, void *next_key)
{
    union bpf_attr attr = {
        .map_fd   = fd,
        .key      = ptr_to_u64(key),
        .next_key = ptr_to_u64(next_key),
    };

    return bpf(BPF_MAP_GET_NEXT_KEY, &attr, sizeof(attr));
}
```

If *key* is found, the operation returns zero and sets the *next_key* pointer to the key of the next element. If *key* is not found, the operation returns zero and sets the *next_key* pointer to the key of the first element. If *key* is the last element, −1 is returned and *errno* is set to **ENOENT**. Other possible *errno* values are **ENOMEM**, **EFAULT**, **EPERM**, and **EINVAL**. This method can be used to iterate over all elements in the map.

close(map_fd)
Delete the map referred to by the file descriptor *map_fd*. When the user-space program that created a map exits, all maps will be deleted automatically (but see NOTES).

eBPF map types
The following map types are supported:

BPF_MAP_TYPE_HASH
Hash-table maps have the following characteristics:

- Maps are created and destroyed by user-space programs. Both user-space and eBPF programs can perform lookup, update, and delete operations.
- The kernel takes care of allocating and freeing key/value pairs.
- The **map_update_elem**() helper will fail to insert new element when the *max_entries* limit is reached. (This ensures that eBPF programs cannot exhaust memory.)
- **map_update_elem**() replaces existing elements atomically.

Hash-table maps are optimized for speed of lookup.

BPF_MAP_TYPE_ARRAY
Array maps have the following characteristics:

- Optimized for fastest possible lookup. In the future the verifier/JIT compiler may recognize lookup() operations that employ a constant key and optimize it into constant pointer. It is possible to optimize a non-constant key into direct pointer arithmetic as well, since pointers and *value_size* are constant for the life of the eBPF program. In other words, **array_map_lookup_elem**() may be 'inlined' by the verifier/JIT compiler while preserving concurrent access to this map from user space.
- All array elements pre-allocated and zero initialized at init time
- The key is an array index, and must be exactly four bytes.
- **map_delete_elem**() fails with the error **EINVAL**, since elements cannot be deleted.
- **map_update_elem**() replaces elements in a **nonatomic** fashion; for atomic updates, a hash-table map should be used instead. There is however one special case that can also be used with arrays: the atomic built-in **__sync_fetch_and_add()** can be used on 32 and 64 bit atomic counters. For example, it can be applied on the whole value itself if it represents a single counter, or in case of a structure containing multiple counters, it could be used on individual counters. This is quite often useful for aggregation and accounting of events.

Among the uses for array maps are the following:

- As "global" eBPF variables: an array of 1 element whose key is (index) 0 and where the value is a collection of 'global' variables which eBPF programs can use to keep state between events.
- Aggregation of tracing events into a fixed set of buckets.
- Accounting of networking events, for example, number of packets and packet sizes.

BPF_MAP_TYPE_PROG_ARRAY (since Linux 4.2)
A program array map is a special kind of array map whose map values contain only file descriptors referring to other eBPF programs. Thus, both the *key_size* and *value_size* must be exactly four bytes. This map is used in conjunction with the **bpf_tail_call**() helper.

This means that an eBPF program with a program array map attached to it can call from kernel side into

```
void bpf_tail_call(void *context, void *prog_map,
                   unsigned int index);
```

and therefore replace its own program flow with the one from the program at the given program array slot, if present. This can be regarded as kind of a jump table to a different eBPF program. The invoked program will then reuse the same stack. When a jump into the new program has been performed, it won't return to the old program anymore.

If no eBPF program is found at the given index of the program array (because the map slot doesn't contain a valid program file descriptor, the specified lookup index/key is out of bounds, or the limit of 32 nested calls has been exceed), execution continues with the current eBPF program. This can be used as a fall-through for default cases.

A program array map is useful, for example, in tracing or networking, to handle individual system calls or protocols in their own subprograms and use their identifiers as an individual map index. This approach may result in performance benefits, and also makes it possible to overcome the maximum instruction limit of a single eBPF program. In dynamic environments, a user-space daemon might atomically replace individual subprograms at run-time with newer versions to alter overall program behavior, for instance, if global policies change.

eBPF programs

The **BPF_PROG_LOAD** command is used to load an eBPF program into the kernel. The return value for this command is a new file descriptor associated with this eBPF program.

```
char bpf_log_buf[LOG_BUF_SIZE];

int
bpf_prog_load(enum bpf_prog_type type,
              const struct bpf_insn *insns, int insn_cnt,
              const char *license)
{
    union bpf_attr attr = {
        .prog_type = type,
        .insns     = ptr_to_u64(insns),
        .insn_cnt  = insn_cnt,
        .license   = ptr_to_u64(license),
        .log_buf   = ptr_to_u64(bpf_log_buf),
        .log_size  = LOG_BUF_SIZE,
        .log_level = 1,
    };

    return bpf(BPF_PROG_LOAD, &attr, sizeof(attr));
}
```

prog_type is one of the available program types:

```
enum bpf_prog_type {
    BPF_PROG_TYPE_UNSPEC,        /* Reserve 0 as invalid
                                    program type */
    BPF_PROG_TYPE_SOCKET_FILTER,
    BPF_PROG_TYPE_KPROBE,
    BPF_PROG_TYPE_SCHED_CLS,
    BPF_PROG_TYPE_SCHED_ACT,
    BPF_PROG_TYPE_TRACEPOINT,
    BPF_PROG_TYPE_XDP,
    BPF_PROG_TYPE_PERF_EVENT,
    BPF_PROG_TYPE_CGROUP_SKB,
    BPF_PROG_TYPE_CGROUP_SOCK,
    BPF_PROG_TYPE_LWT_IN,
    BPF_PROG_TYPE_LWT_OUT,
    BPF_PROG_TYPE_LWT_XMIT,
    BPF_PROG_TYPE_SOCK_OPS,
    BPF_PROG_TYPE_SK_SKB,
    BPF_PROG_TYPE_CGROUP_DEVICE,
    BPF_PROG_TYPE_SK_MSG,
    BPF_PROG_TYPE_RAW_TRACEPOINT,
    BPF_PROG_TYPE_CGROUP_SOCK_ADDR,
    BPF_PROG_TYPE_LWT_SEG6LOCAL,
    BPF_PROG_TYPE_LIRC_MODE2,
    BPF_PROG_TYPE_SK_REUSEPORT,
```

```
        BPF_PROG_TYPE_FLOW_DISSECTOR,
        /* See /usr/include/linux/bpf.h for the full list. */
};
```

For further details of eBPF program types, see below.

The remaining fields of *bpf_attr* are set as follows:

- *insns* is an array of *struct bpf_insn* instructions.
- *insn_cnt* is the number of instructions in the program referred to by *insns*.
- *license* is a license string, which must be GPL compatible to call helper functions marked *gpl_only*. (The licensing rules are the same as for kernel modules, so that also dual licenses, such as "Dual BSD/GPL", may be used.)
- *log_buf* is a pointer to a caller-allocated buffer in which the in-kernel verifier can store the verification log. This log is a multi-line string that can be checked by the program author in order to understand how the verifier came to the conclusion that the eBPF program is unsafe. The format of the output can change at any time as the verifier evolves.
- *log_size* size of the buffer pointed to by *log_buf*. If the size of the buffer is not large enough to store all verifier messages, −1 is returned and *errno* is set to **ENOSPC**.
- *log_level* verbosity level of the verifier. A value of zero means that the verifier will not provide a log; in this case, *log_buf* must be a null pointer, and *log_size* must be zero.

Applying *close*(2) to the file descriptor returned by **BPF_PROG_LOAD** will unload the eBPF program (but see NOTES).

Maps are accessible from eBPF programs and are used to exchange data between eBPF programs and between eBPF programs and user-space programs. For example, eBPF programs can process various events (like kprobe, packets) and store their data into a map, and user-space programs can then fetch data from the map. Conversely, user-space programs can use a map as a configuration mechanism, populating the map with values checked by the eBPF program, which then modifies its behavior on the fly according to those values.

eBPF program types

The eBPF program type (*prog_type*) determines the subset of kernel helper functions that the program may call. The program type also determines the program input (context)—the format of *struct bpf_context* (which is the data blob passed into the eBPF program as the first argument).

For example, a tracing program does not have the exact same subset of helper functions as a socket filter program (though they may have some helpers in common). Similarly, the input (context) for a tracing program is a set of register values, while for a socket filter it is a network packet.

The set of functions available to eBPF programs of a given type may increase in the future.

The following program types are supported:

BPF_PROG_TYPE_SOCKET_FILTER (since Linux 3.19)

Currently, the set of functions for **BPF_PROG_TYPE_SOCKET_FILTER** is:

```
bpf_map_lookup_elem(map_fd, void *key)
                    /* look up key in a map_fd */
bpf_map_update_elem(map_fd, void *key, void *value)
                    /* update key/value */
bpf_map_delete_elem(map_fd, void *key)
                    /* delete key in a map_fd */
```

The *bpf_context* argument is a pointer to a *struct __sk_buff*.

BPF_PROG_TYPE_KPROBE (since Linux 4.1)

[To be documented]

BPF_PROG_TYPE_SCHED_CLS (since Linux 4.1)

[To be documented]

BPF_PROG_TYPE_SCHED_ACT (since Linux 4.1)

[To be documented]

Events

Once a program is loaded, it can be attached to an event. Various kernel subsystems have different ways to do so.

Since Linux 3.19, the following call will attach the program *prog_fd* to the socket *sockfd*, which was created by an earlier call to *socket*(2):

```
setsockopt(sockfd, SOL_SOCKET, SO_ATTACH_BPF,
           &prog_fd, sizeof(prog_fd));
```

Since Linux 4.1, the following call may be used to attach the eBPF program referred to by the file descriptor *prog_fd* to a perf event file descriptor, *event_fd*, that was created by a previous call to *perf_event_open*(2):

```
ioctl(event_fd, PERF_EVENT_IOC_SET_BPF, prog_fd);
```

RETURN VALUE

For a successful call, the return value depends on the operation:

BPF_MAP_CREATE
: The new file descriptor associated with the eBPF map.

BPF_PROG_LOAD
: The new file descriptor associated with the eBPF program.

All other commands
: Zero.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

E2BIG The eBPF program is too large or a map reached the *max_entries* limit (maximum number of elements).

EACCES
: For **BPF_PROG_LOAD**, even though all program instructions are valid, the program has been rejected because it was deemed unsafe. This may be because it may have accessed a disallowed memory region or an uninitialized stack/register or because the function constraints don't match the actual types or because there was a misaligned memory access. In this case, it is recommended to call **bpf**() again with *log_level = 1* and examine *log_buf* for the specific reason provided by the verifier.

EAGAIN
: For **BPF_PROG_LOAD**, indicates that needed resources are blocked. This happens when the verifier detects pending signals while it is checking the validity of the bpf program. In this case, just call **bpf**() again with the same parameters.

EBADF
: *fd* is not an open file descriptor.

EFAULT
: One of the pointers (*key* or *value* or *log_buf* or *insns*) is outside the accessible address space.

EINVAL
: The value specified in *cmd* is not recognized by this kernel.

EINVAL
: For **BPF_MAP_CREATE**, either *map_type* or attributes are invalid.

EINVAL
: For **BPF_MAP_*_ELEM** commands, some of the fields of *union bpf_attr* that are not used by this command are not set to zero.

EINVAL
: For **BPF_PROG_LOAD**, indicates an attempt to load an invalid program. eBPF programs can be deemed invalid due to unrecognized instructions, the use of reserved fields, jumps out of range, infinite loops or calls of unknown functions.

ENOENT
For **BPF_MAP_LOOKUP_ELEM** or **BPF_MAP_DELETE_ELEM**, indicates that the element with the given *key* was not found.

ENOMEM
Cannot allocate sufficient memory.

EPERM
The call was made without sufficient privilege (without the **CAP_SYS_ADMIN** capability).

STANDARDS
Linux.

HISTORY
Linux 3.18.

NOTES
Prior to Linux 4.4, all **bpf**() commands require the caller to have the **CAP_SYS_ADMIN** capability. From Linux 4.4 onwards, an unprivileged user may create limited programs of type **BPF_PROG_TYPE_SOCKET_FILTER** and associated maps. However they may not store kernel pointers within the maps and are presently limited to the following helper functions:

- get_random
- get_smp_processor_id
- tail_call
- ktime_get_ns

Unprivileged access may be blocked by writing the value 1 to the file */proc/sys/kernel/unprivileged_bpf_disabled*.

eBPF objects (maps and programs) can be shared between processes. For example, after *fork*(2), the child inherits file descriptors referring to the same eBPF objects. In addition, file descriptors referring to eBPF objects can be transferred over UNIX domain sockets. File descriptors referring to eBPF objects can be duplicated in the usual way, using *dup*(2) and similar calls. An eBPF object is deallocated only after all file descriptors referring to the object have been closed.

eBPF programs can be written in a restricted C that is compiled (using the **clang** compiler) into eBPF bytecode. Various features are omitted from this restricted C, such as loops, global variables, variadic functions, floating-point numbers, and passing structures as function arguments. Some examples can be found in the *samples/bpf/*_kern.c* files in the kernel source tree.

The kernel contains a just-in-time (JIT) compiler that translates eBPF bytecode into native machine code for better performance. Before Linux 4.15, the JIT compiler is disabled by default, but its operation can be controlled by writing one of the following integer strings to the file */proc/sys/net/core/bpf_jit_enable*:

0 Disable JIT compilation (default).

1 Normal compilation.

2 Debugging mode. The generated opcodes are dumped in hexadecimal into the kernel log. These opcodes can then be disassembled using the program *tools/net/bpf_jit_disasm.c* provided in the kernel source tree.

Since Linux 4.15, the kernel may be configured with the **CONFIG_BPF_JIT_ALWAYS_ON** option. In this case, the JIT compiler is always enabled, and the *bpf_jit_enable* is initialized to 1 and is immutable. (This kernel configuration option was provided as a mitigation for one of the Spectre attacks against the BPF interpreter.)

The JIT compiler for eBPF is currently available for the following architectures:

- x86-64 (since Linux 3.18; cBPF since Linux 3.0);
- ARM32 (since Linux 3.18; cBPF since Linux 3.4);
- SPARC 32 (since Linux 3.18; cBPF since Linux 3.5);
- ARM-64 (since Linux 3.18);
- s390 (since Linux 4.1; cBPF since Linux 3.7);

- PowerPC 64 (since Linux 4.8; cBPF since Linux 3.1);
- SPARC 64 (since Linux 4.12);
- x86-32 (since Linux 4.18);
- MIPS 64 (since Linux 4.18; cBPF since Linux 3.16);
- riscv (since Linux 5.1).

EXAMPLES

```
/* bpf+sockets example:
 * 1. create array map of 256 elements
 * 2. load program that counts number of packets received
 *    r0 = skb->data[ETH_HLEN + offsetof(struct iphdr, protocol)]
 *    map[r0]++
 * 3. attach prog_fd to raw socket via setsockopt()
 * 4. print number of received TCP/UDP packets every second
 */
int
main(int argc, char *argv[])
{
    int sock, map_fd, prog_fd, key;
    long long value = 0, tcp_cnt, udp_cnt;

    map_fd = bpf_create_map(BPF_MAP_TYPE_ARRAY, sizeof(key),
                            sizeof(value), 256);
    if (map_fd < 0) {
        printf("failed to create map '%s'\n", strerror(errno));
        /* likely not run as root */
        return 1;
    }

    struct bpf_insn prog[] = {
        BPF_MOV64_REG(BPF_REG_6, BPF_REG_1),        /* r6 = r1 */
        BPF_LD_ABS(BPF_B, ETH_HLEN + offsetof(struct iphdr, protocol)),
                                /* r0 = ip->proto */
        BPF_STX_MEM(BPF_W, BPF_REG_10, BPF_REG_0, -4),
                                /* *(u32 *)(fp - 4) = r0 */
        BPF_MOV64_REG(BPF_REG_2, BPF_REG_10),       /* r2 = fp */
        BPF_ALU64_IMM(BPF_ADD, BPF_REG_2, -4),      /* r2 = r2 - 4 */
        BPF_LD_MAP_FD(BPF_REG_1, map_fd),           /* r1 = map_fd */
        BPF_CALL_FUNC(BPF_FUNC_map_lookup_elem),
                                /* r0 = map_lookup(r1, r2) */
        BPF_JMP_IMM(BPF_JEQ, BPF_REG_0, 0, 2),
                                /* if (r0 == 0) goto pc+2 */
        BPF_MOV64_IMM(BPF_REG_1, 1),                /* r1 = 1 */
        BPF_XADD(BPF_DW, BPF_REG_0, BPF_REG_1, 0, 0),
                                /* lock *(u64 *) r0 += r1 */
        BPF_MOV64_IMM(BPF_REG_0, 0),                /* r0 = 0 */
        BPF_EXIT_INSN(),                            /* return r0 */
    };

    prog_fd = bpf_prog_load(BPF_PROG_TYPE_SOCKET_FILTER, prog,
                            sizeof(prog) / sizeof(prog[0]), "GPL");

    sock = open_raw_sock("lo");

    assert(setsockopt(sock, SOL_SOCKET, SO_ATTACH_BPF, &prog_fd,
                      sizeof(prog_fd)) == 0);

    for (;;) {
        key = IPPROTO_TCP;
```

```
            assert(bpf_lookup_elem(map_fd, &key, &tcp_cnt) == 0);
            key = IPPROTO_UDP;
            assert(bpf_lookup_elem(map_fd, &key, &udp_cnt) == 0);
            printf("TCP %lld UDP %lld packets\n", tcp_cnt, udp_cnt);
            sleep(1);
        }

        return 0;
    }
```

Some complete working code can be found in the *samples/bpf* directory in the kernel source tree.

Both classic and extended BPF are explained in the kernel source file *Documentation/networking/filter.txt*.

NAME

brk, sbrk − change data segment size

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int brk(void *addr);
void *sbrk(intptr_t increment);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

brk(), **sbrk**():
- Since glibc 2.19:
  - _DEFAULT_SOURCE
    - || ((_XOPEN_SOURCE >= 500) &&
      - ! (_POSIX_C_SOURCE >= 200112L))
- From glibc 2.12 to glibc 2.19:
  - _BSD_SOURCE || _SVID_SOURCE
    - || ((_XOPEN_SOURCE >= 500) &&
      - ! (_POSIX_C_SOURCE >= 200112L))
- Before glibc 2.12:
  - _BSD_SOURCE || _SVID_SOURCE || _XOPEN_SOURCE >= 500

DESCRIPTION

brk() and **sbrk**() change the location of the *program break*, which defines the end of the process's data segment (i.e., the program break is the first location after the end of the uninitialized data segment). Increasing the program break has the effect of allocating memory to the process; decreasing the break deallocates memory.

brk() sets the end of the data segment to the value specified by *addr*, when that value is reasonable, the system has enough memory, and the process does not exceed its maximum data size (see *setrlimit*(2)).

sbrk() increments the program's data space by *increment* bytes. Calling **sbrk**() with an *increment* of 0 can be used to find the current location of the program break.

RETURN VALUE

On success, **brk**() returns zero. On error, −1 is returned, and *errno* is set to **ENOMEM**.

On success, **sbrk**() returns the previous program break. (If the break was increased, then this value is a pointer to the start of the newly allocated memory). On error, *(void *) −1* is returned, and *errno* is set to **ENOMEM**.

STANDARDS

None.

HISTORY

4.3BSD; SUSv1, marked LEGACY in SUSv2, removed in POSIX.1-2001.

NOTES

Avoid using **brk**() and **sbrk**(): the *malloc*(3) memory allocation package is the portable and comfortable way of allocating memory.

Various systems use various types for the argument of **sbrk**(). Common are *int*, *ssize_t*, *ptrdiff_t*, *intptr_t*.

C library/kernel differences

The return value described above for **brk**() is the behavior provided by the glibc wrapper function for the Linux **brk**() system call. (On most other implementations, the return value from **brk**() is the same; this return value was also specified in SUSv2.) However, the actual Linux system call returns the new program break on success. On failure, the system call returns the current break. The glibc wrapper function does some work (i.e., checks whether the new break is less than *addr*) to provide the 0 and −1 return values described above.

On Linux, **sbrk**() is implemented as a library function that uses the **brk**() system call, and does some internal bookkeeping so that it can return the old break value.

SEE ALSO

execve(2), *getrlimit*(2), *end*(3), *malloc*(3)

NAME

cacheflush − flush contents of instruction and/or data cache

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/cachectl.h>

int cacheflush(void *addr***[.***nbytes***], int** *nbytes***, int** *cache***);**

Note: On some architectures, there is no glibc wrapper for this system call; see NOTES.

DESCRIPTION

cacheflush() flushes the contents of the indicated cache(s) for the user addresses in the range *addr* to *(addr+nbytes−1)*. *cache* may be one of:

ICACHE
: Flush the instruction cache.

DCACHE
: Write back to memory and invalidate the affected valid cache lines.

BCACHE
: Same as **(ICACHE|DCACHE)**.

RETURN VALUE

cacheflush() returns 0 on success. On error, it returns −1 and sets *errno* to indicate the error.

ERRORS

EFAULT
: Some or all of the address range *addr* to *(addr+nbytes−1)* is not accessible.

EINVAL
: *cache* is not one of **ICACHE**, **DCACHE**, or **BCACHE** (but see BUGS).

VERSIONS

cacheflush() should not be used in programs intended to be portable. On Linux, this call first appeared on the MIPS architecture, but nowadays, Linux provides a **cacheflush**() system call on some other architectures, but with different arguments.

Architecture-specific variants

glibc provides a wrapper for this system call, with the prototype shown in SYNOPSIS, for the following architectures: ARC, CSKY, MIPS, and NIOS2.

On some other architectures, Linux provides this system call, with different arguments:

M68K:

int cacheflush(unsigned long *addr***, int** *scope***, int** *cache***,**
unsigned long *len***);**

SH:

int cacheflush(unsigned long *addr***, unsigned long** *len***, int** *op***);**

NDS32:

int cacheflush(unsigned int *start***, unsigned int** *end***, int** *cache***);**

On the above architectures, glibc does not provide a wrapper for this system call; call it using *syscall*(2).

GCC alternative

Unless you need the finer grained control that this system call provides, you probably want to use the GCC built-in function **__builtin___clear_cache**(), which provides a portable interface across platforms supported by GCC and compatible compilers:

```
void __builtin___clear_cache(void *begin, void *end);
```

On platforms that don't require instruction cache flushes, **__builtin___clear_cache**() has no effect.

Note: On some GCC-compatible compilers, the prototype for this built-in function uses *char* * instead of *void* * for the parameters.

STANDARDS

Historically, this system call was available on all MIPS UNIX variants including RISC/os, IRIX, Ultrix, NetBSD, OpenBSD, and FreeBSD (and also on some non-UNIX MIPS operating systems), so that the existence of this call in MIPS operating systems is a de-facto standard.

BUGS

Linux kernels older than Linux 2.6.11 ignore the *addr* and *nbytes* arguments, making this function fairly expensive. Therefore, the whole cache is always flushed.

This function always behaves as if **BCACHE** has been passed for the *cache* argument and does not do any error checking on the *cache* argument.

NAME

capget, capset − set/get capabilities of thread(s)

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/capability.h> /* Definition of **CAP_*** and
_LINUX_CAPABILITY_* constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_capget, cap_user_header_t *hdrp***,**
cap_user_data_t *datap***);**
int syscall(SYS_capset, cap_user_header_t *hdrp***,**
const cap_user_data_t *datap***);**

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

These two system calls are the raw kernel interface for getting and setting thread capabilities. Not only are these system calls specific to Linux, but the kernel API is likely to change and use of these system calls (in particular the format of the *cap_user_*_t* types) is subject to extension with each kernel revision, but old programs will keep working.

The portable interfaces are *cap_set_proc*(3) and *cap_get_proc*(3); if possible, you should use those interfaces in applications; see NOTES.

Current details

Now that you have been warned, some current kernel details. The structures are defined as follows.

```
#define _LINUX_CAPABILITY_VERSION_1  0x19980330
#define _LINUX_CAPABILITY_U32S_1     1

        /* V2 added in Linux 2.6.25; deprecated */
#define _LINUX_CAPABILITY_VERSION_2  0x20071026
#define _LINUX_CAPABILITY_U32S_2     2

        /* V3 added in Linux 2.6.26 */
#define _LINUX_CAPABILITY_VERSION_3  0x20080522
#define _LINUX_CAPABILITY_U32S_3     2

typedef struct __user_cap_header_struct {
   __u32 version;
   int pid;
} *cap_user_header_t;

typedef struct __user_cap_data_struct {
   __u32 effective;
   __u32 permitted;
   __u32 inheritable;
} *cap_user_data_t;
```

The *effective*, *permitted*, and *inheritable* fields are bit masks of the capabilities defined in *capabilities*(7). Note that the **CAP_*** values are bit indexes and need to be bit-shifted before ORing into the bit fields. To define the structures for passing to the system call, you have to use the *struct __user_cap_header_struct* and *struct __user_cap_data_struct* names because the typedefs are only pointers.

Kernels prior to Linux 2.6.25 prefer 32-bit capabilities with version **_LINUX_CAPABILITY_VERSION_1**. Linux 2.6.25 added 64-bit capability sets, with version **_LINUX_CAPABILITY_VERSION_2**. There was, however, an API glitch, and Linux 2.6.26 added **_LINUX_CAPABILITY_VERSION_3** to fix the problem.

Note that 64-bit capabilities use *datap[0]* and *datap[1]*, whereas 32-bit capabilities use only *datap[0]*.

On kernels that support file capabilities (VFS capabilities support), these system calls behave slightly differently. This support was added as an option in Linux 2.6.24, and became fixed (nonoptional) in Linux 2.6.33.

For **capget**() calls, one can probe the capabilities of any process by specifying its process ID with the *hdrp->pid* field value.

For details on the data, see *capabilities*(7).

With VFS capabilities support

VFS capabilities employ a file extended attribute (see *xattr*(7)) to allow capabilities to be attached to executables. This privilege model obsoletes kernel support for one process asynchronously setting the capabilities of another. That is, on kernels that have VFS capabilities support, when calling **capset**(), the only permitted values for *hdrp->pid* are 0 or, equivalently, the value returned by *gettid*(2).

Without VFS capabilities support

On older kernels that do not provide VFS capabilities support **capset**() can, if the caller has the **CAP_SETPCAP** capability, be used to change not only the caller's own capabilities, but also the capabilities of other threads. The call operates on the capabilities of the thread specified by the *pid* field of *hdrp* when that is nonzero, or on the capabilities of the calling thread if *pid* is 0. If *pid* refers to a single-threaded process, then *pid* can be specified as a traditional process ID; operating on a thread of a multithreaded process requires a thread ID of the type returned by *gettid*(2). For **capset**(), *pid* can also be: −1, meaning perform the change on all threads except the caller and *init*(1); or a value less than −1, in which case the change is applied to all members of the process group whose ID is −*pid*.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

The calls fail with the error **EINVAL**, and set the *version* field of *hdrp* to the kernel preferred value of **_LINUX_CAPABILITY_VERSION_?** when an unsupported *version* value is specified. In this way, one can probe what the current preferred capability revision is.

ERRORS

EFAULT

Bad memory address. *hdrp* must not be NULL. *datap* may be NULL only when the user is trying to determine the preferred capability version format supported by the kernel.

EINVAL

One of the arguments was invalid.

EPERM

An attempt was made to add a capability to the permitted set, or to set a capability in the effective set that is not in the permitted set.

EPERM

An attempt was made to add a capability to the inheritable set, and either:

- that capability was not in the caller's bounding set; or
- the capability was not in the caller's permitted set and the caller lacked the **CAP_SETPCAP** capability in its effective set.

EPERM

The caller attempted to use **capset**() to modify the capabilities of a thread other than itself, but lacked sufficient privilege. For kernels supporting VFS capabilities, this is never permitted. For kernels lacking VFS support, the **CAP_SETPCAP** capability is required. (A bug in kernels before Linux 2.6.11 meant that this error could also occur if a thread without this capability tried to change its own capabilities by specifying the *pid* field as a nonzero value (i.e., the value returned by *getpid*(2)) instead of 0.)

ESRCH

No such thread.

STANDARDS

Linux.

NOTES

The portable interface to the capability querying and setting functions is provided by the *libcap* library and is available here:

NAME

chdir, fchdir − change working directory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int chdir(const char *path);
int fchdir(int fd);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

fchdir():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L
|| /* glibc up to and including 2.19: */ _BSD_SOURCE

DESCRIPTION

chdir() changes the current working directory of the calling process to the directory specified in *path*.

fchdir() is identical to **chdir**(); the only difference is that the directory is given as an open file descriptor.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, other errors can be returned. The more general errors for **chdir**() are listed below:

EACCES
Search permission is denied for one of the components of *path*. (See also *path_resolution*(7).)

EFAULT
path points outside your accessible address space.

EIO An I/O error occurred.

ELOOP
Too many symbolic links were encountered in resolving *path*.

ENAMETOOLONG
path is too long.

ENOENT
The directory specified in *path* does not exist.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component of *path* is not a directory.

The general errors for **fchdir**() are listed below:

EACCES
Search permission was denied on the directory open on *fd*.

EBADF
fd is not a valid file descriptor.

ENOTDIR
fd does not refer to a directory.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.4BSD.

NOTES

The current working directory is the starting point for interpreting relative pathnames (those not starting with '/').

A child process created via *fork*(2) inherits its parent's current working directory. The current working directory is left unchanged by *execve*(2).

SEE ALSO

chroot(2), *getcwd*(3), *path_resolution*(7)

NAME

chmod, fchmod, fchmodat − change permissions of a file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/stat.h>

int chmod(const char *pathname, mode_t mode);
int fchmod(int fd, mode_t mode);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <sys/stat.h>

int fchmodat(int dirfd, const char *pathname, mode_t mode, int flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

fchmod():
- Since glibc 2.24:
  - _POSIX_C_SOURCE >= 199309L
- glibc 2.19 to glibc 2.23
  - _POSIX_C_SOURCE
- glibc 2.16 to glibc 2.19:
  - _BSD_SOURCE || _POSIX_C_SOURCE
- glibc 2.12 to glibc 2.16:
  - _BSD_SOURCE || _XOPEN_SOURCE >= 500 || _POSIX_C_SOURCE >= 200809L
- glibc 2.11 and earlier:
  - _BSD_SOURCE || _XOPEN_SOURCE >= 500

fchmodat():
- Since glibc 2.10:
  - _POSIX_C_SOURCE >= 200809L
- Before glibc 2.10:
  - _ATFILE_SOURCE

DESCRIPTION

The **chmod**() and **fchmod**() system calls change a file's mode bits. (The file mode consists of the file permission bits plus the set-user-ID, set-group-ID, and sticky bits.) These system calls differ only in how the file is specified:

- **chmod**() changes the mode of the file specified whose pathname is given in *pathname*, which is dereferenced if it is a symbolic link.
- **fchmod**() changes the mode of the file referred to by the open file descriptor *fd*.

The new file mode is specified in *mode*, which is a bit mask created by ORing together zero or more of the following:

S_ISUID	(04000)	set-user-ID (set process effective user ID on *execve*(2))
S_ISGID	(02000)	set-group-ID (set process effective group ID on *execve*(2); mandatory locking, as described in *fcntl*(2); take a new file's group from parent directory, as described in *chown*(2) and *mkdir*(2))
S_ISVTX	(01000)	sticky bit (restricted deletion flag, as described in *unlink*(2))
S_IRUSR	(00400)	read by owner
S_IWUSR	(00200)	write by owner
S_IXUSR	(00100)	execute/search by owner ("search" applies for directories, and means that entries within the directory can be accessed)
S_IRGRP	(00040)	read by group
S_IWGRP	(00020)	write by group

S_IXGRP (00010) execute/search by group

S_IROTH (00004) read by others

S_IWOTH (00002) write by others

S_IXOTH (00001) execute/search by others

The effective UID of the calling process must match the owner of the file, or the process must be privileged (Linux: it must have the **CAP_FOWNER** capability).

If the calling process is not privileged (Linux: does not have the **CAP_FSETID** capability), and the group of the file does not match the effective group ID of the process or one of its supplementary group IDs, the **S_ISGID** bit will be turned off, but this will not cause an error to be returned.

As a security measure, depending on the filesystem, the set-user-ID and set-group-ID execution bits may be turned off if a file is written. (On Linux, this occurs if the writing process does not have the **CAP_FSETID** capability.) On some filesystems, only the superuser can set the sticky bit, which may have a special meaning. For the sticky bit, and for set-user-ID and set-group-ID bits on directories, see *inode*(7).

On NFS filesystems, restricting the permissions will immediately influence already open files, because the access control is done on the server, but open files are maintained by the client. Widening the permissions may be delayed for other clients if attribute caching is enabled on them.

fchmodat()

The **fchmodat**() system call operates in exactly the same way as **chmod**(), except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **chmod**() for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *chmod*())

If *pathname* is absolute, then *dirfd* is ignored.

flags can either be 0, or include the following flag:

AT_SYMLINK_NOFOLLOW

If *pathname* is a symbolic link, do not dereference it: instead operate on the link itself. This flag is not currently implemented.

See *openat*(2) for an explanation of the need for **fchmodat**().

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, errors other than those listed below can be returned.

The more general errors for **chmod**() are listed below:

EACCES

Search permission is denied on a component of the path prefix. (See also *path_resolution*(7).)

EBADF

(**fchmod**()) The file descriptor *fd* is not valid.

EBADF

(**fchmodat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT

pathname points outside your accessible address space.

EINVAL

(**fchmodat**()) Invalid flag specified in *flags*.

EIO An I/O error occurred.

ELOOP
Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG
pathname is too long.

ENOENT
The file does not exist.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component of the path prefix is not a directory.

ENOTDIR
(**fchmodat**()) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

ENOTSUP
(**fchmodat**()) *flags* specified **AT_SYMLINK_NOFOLLOW**, which is not supported.

EPERM
The effective UID does not match the owner of the file, and the process is not privileged (Linux: it does not have the **CAP_FOWNER** capability).

EPERM
The file is marked immutable or append-only. (See *ioctl_iflags*(2).)

EROFS
The named file resides on a read-only filesystem.

VERSIONS

C library/kernel differences

The GNU C library **fchmodat**() wrapper function implements the POSIX-specified interface described in this page. This interface differs from the underlying Linux system call, which does *not* have a *flags* argument.

glibc notes

On older kernels where **fchmodat**() is unavailable, the glibc wrapper function falls back to the use of **chmod**(). When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

STANDARDS

POSIX.1-2008.

HISTORY

NAME

chown, fchown, lchown, fchownat − change ownership of a file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int chown(const char *pathname, uid_t owner, gid_t group);
int fchown(int fd, uid_t owner, gid_t group);
int lchown(const char *pathname, uid_t owner, gid_t group);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <unistd.h>

int fchownat(int dirfd, const char *pathname,
             uid_t owner, gid_t group, int flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

fchown(), **lchown**():

```
/* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L
    || _XOPEN_SOURCE >= 500
    || /* glibc <= 2.19: */ _BSD_SOURCE
```

fchownat():

```
Since glibc 2.10:
    _POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
    _ATFILE_SOURCE
```

DESCRIPTION

These system calls change the owner and group of a file. The **chown**(), **fchown**(), and **lchown**() system calls differ only in how the file is specified:

- **chown**() changes the ownership of the file specified by *pathname*, which is dereferenced if it is a symbolic link.
- **fchown**() changes the ownership of the file referred to by the open file descriptor *fd*.
- **lchown**() is like **chown**(), but does not dereference symbolic links.

Only a privileged process (Linux: one with the **CAP_CHOWN** capability) may change the owner of a file. The owner of a file may change the group of the file to any group of which that owner is a member. A privileged process (Linux: with **CAP_CHOWN**) may change the group arbitrarily.

If the *owner* or *group* is specified as −1, then that ID is not changed.

When the owner or group of an executable file is changed by an unprivileged user, the **S_ISUID** and **S_ISGID** mode bits are cleared. POSIX does not specify whether this also should happen when root does the **chown**(); the Linux behavior depends on the kernel version, and since Linux 2.2.13, root is treated like other users. In case of a non-group-executable file (i.e., one for which the **S_IXGRP** bit is not set) the **S_ISGID** bit indicates mandatory locking, and is not cleared by a **chown**().

When the owner or group of an executable file is changed (by any user), all capability sets for the file are cleared.

fchownat()

The **fchownat**() system call operates in exactly the same way as **chown**(), except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **chown**() for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *chown*())

If *pathname* is absolute, then *dirfd* is ignored.

The *flags* argument is a bit mask created by ORing together 0 or more of the following values;

AT_EMPTY_PATH (since Linux 2.6.39)
If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the *open*(2) **O_PATH** flag). In this case, *dirfd* can refer to any type of file, not just a directory. If *dirfd* is **AT_FDCWD**, the call operates on the current working directory. This flag is Linux-specific; define **_GNU_SOURCE** to obtain its definition.

AT_SYMLINK_NOFOLLOW
If *pathname* is a symbolic link, do not dereference it: instead operate on the link itself, like **lchown**(). (By default, **fchownat**() dereferences symbolic links, like *chown*().)

See *openat*(2) for an explanation of the need for **fchownat**().

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, errors other than those listed below can be returned.

The more general errors for **chown**() are listed below.

EACCES
Search permission is denied on a component of the path prefix. (See also *path_resolution*(7).)

EBADF
(**fchown**()) *fd* is not a valid open file descriptor.

EBADF
(**fchownat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT
pathname points outside your accessible address space.

EINVAL
(**fchownat**()) Invalid flag specified in *flags*.

EIO (**fchown**()) A low-level I/O error occurred while modifying the inode.

ELOOP
Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG
pathname is too long.

ENOENT
The file does not exist.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component of the path prefix is not a directory.

ENOTDIR
(**fchownat**()) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EPERM
The calling process did not have the required permissions (see above) to change owner and/or group.

EPERM
The file is marked immutable or append-only. (See *ioctl_iflags*(2).)

EROFS
The named file resides on a read-only filesystem.

VERSIONS

The 4.4BSD version can be used only by the superuser (that is, ordinary users cannot give away files).

STANDARDS

POSIX.1-2008.

HISTORY

chown()
fchown()
lchown()
4.4BSD, SVr4, POSIX.1-2001.

fchownat()
POSIX.1-2008. Linux 2.6.16, glibc 2.4.

NOTES

Ownership of new files

When a new file is created (by, for example, *open*(2) or *mkdir*(2)), its owner is made the same as the filesystem user ID of the creating process. The group of the file depends on a range of factors, including the type of filesystem, the options used to mount the filesystem, and whether or not the set-group-ID mode bit is enabled on the parent directory. If the filesystem supports the **−o grpid** (or, synonymously **-o bsdgroups**) and **−o nogrpid** (or, synonymously **-o sysvgroups**) *mount*(8) options, then the rules are as follows:

- If the filesystem is mounted with **-o grpid**, then the group of a new file is made the same as that of the parent directory.
- If the filesystem is mounted with **−o nogrpid** and the set-group-ID bit is disabled on the parent directory, then the group of a new file is made the same as the process's filesystem GID.
- If the filesystem is mounted with **−o nogrpid** and the set-group-ID bit is enabled on the parent directory, then the group of a new file is made the same as that of the parent directory.

As at Linux 4.12, the **−o grpid** and **−o nogrpid** mount options are supported by ext2, ext3, ext4, and XFS. Filesystems that don't support these mount options follow the **−o nogrpid** rules.

glibc notes

On older kernels where **fchownat**() is unavailable, the glibc wrapper function falls back to the use of **chown**() and **lchown**(). When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

NFS

The **chown**() semantics are deliberately violated on NFS filesystems which have UID mapping enabled. Additionally, the semantics of all system calls which access the file contents are violated, because **chown**() may cause immediate access revocation on already open files. Client side caching may lead to a delay between the time where ownership have been changed to allow access for a user and the time where the file can actually be accessed by the user on other clients.

Historical details

The original Linux **chown**(), **fchown**(), and **lchown**() system calls supported only 16-bit user and group IDs. Subsequently, Linux 2.4 added **chown32**(), **fchown32**(), and **lchown32**(), supporting 32-bit IDs. The glibc **chown**(), **fchown**(), and **lchown**() wrapper functions transparently deal with the variations across kernel versions.

Before Linux 2.1.81 (except 2.1.46), **chown**() did not follow symbolic links. Since Linux 2.1.81, **chown**() does follow symbolic links, and there is a new system call **lchown**() that does not follow symbolic links. Since Linux 2.1.86, this new call (that has the same semantics as the old *chown*()) has got the same syscall number, and **chown**() got the newly introduced number.

EXAMPLES

The following program changes the ownership of the file named in its second command-line argument to the value specified in its first command-line argument. The new owner can be specified either as a numeric user ID, or as a username (which is converted to a user ID by using *getpwnam*(3) to perform a lookup in the system password file).

Program source

```
#include <pwd.h>
#include <stdio.h>
#include <stdlib.h>
```

```
#include <unistd.h>

int
main(int argc, char *argv[])
{
    char           *endptr;
    uid_t          uid;
    struct passwd  *pwd;

    if (argc != 3 || argv[1][0] == '\0') {
        fprintf(stderr, "%s <owner> <file>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    uid = strtol(argv[1], &endptr, 10);  /* Allow a numeric string */

    if (*endptr != '\0') {         /* Was not pure numeric string */
        pwd = getpwnam(argv[1]);   /* Try getting UID for username */
        if (pwd == NULL) {
            perror("getpwnam");
            exit(EXIT_FAILURE);
        }

        uid = pwd->pw_uid;
    }

    if (chown(argv[2], uid, -1) == -1) {
        perror("chown");
        exit(EXIT_FAILURE);
    }

    exit(EXIT_SUCCESS);
}
```

SEE ALSO

chgrp(1), *chown*(1), *chmod*(2), *flock*(2), *path_resolution*(7), *symlink*(7)

NAME

chroot − change root directory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int chroot(const char ****path*);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

chroot():
Since glibc 2.2.2:
_XOPEN_SOURCE && ! (_POSIX_C_SOURCE >= 200112L)
|| /* Since glibc 2.20: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _BSD_SOURCE
Before glibc 2.2.2:
none

DESCRIPTION

chroot() changes the root directory of the calling process to that specified in *path*. This directory will be used for pathnames beginning with /. The root directory is inherited by all children of the calling process.

Only a privileged process (Linux: one with the **CAP_SYS_CHROOT** capability in its user namespace) may call **chroot**().

This call changes an ingredient in the pathname resolution process and does nothing else. In particular, it is not intended to be used for any kind of security purpose, neither to fully sandbox a process nor to restrict filesystem system calls. In the past, **chroot**() has been used by daemons to restrict themselves prior to passing paths supplied by untrusted users to system calls such as *open*(2). However, if a folder is moved out of the chroot directory, an attacker can exploit that to get out of the chroot directory as well. The easiest way to do that is to *chdir*(2) to the to-be-moved directory, wait for it to be moved out, then open a path like ../../../etc/passwd.

A slightly trickier variation also works under some circumstances if *chdir*(2) is not permitted. If a daemon allows a "chroot directory" to be specified, that usually means that if you want to prevent remote users from accessing files outside the chroot directory, you must ensure that folders are never moved out of it.

This call does not change the current working directory, so that after the call '.' can be outside the tree rooted at '/'. In particular, the superuser can escape from a "chroot jail" by doing:

```
mkdir foo; chroot foo; cd ..
```

This call does not close open file descriptors, and such file descriptors may allow access to files outside the chroot tree.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Depending on the filesystem, other errors can be returned. The more general errors are listed below:

EACCES
Search permission is denied on a component of the path prefix. (See also *path_resolution*(7).)

EFAULT
path points outside your accessible address space.

EIO An I/O error occurred.

ELOOP
Too many symbolic links were encountered in resolving *path*.

ENAMETOOLONG
path is too long.

ENOENT
The file does not exist.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component of *path* is not a directory.

EPERM
The caller has insufficient privilege.

STANDARDS

None.

HISTORY

SVr4, 4.4BSD, SUSv2 (marked LEGACY). This function is not part of POSIX.1-2001.

NOTES

A child process created via *fork*(2) inherits its parent's root directory. The root directory is left unchanged by *execve*(2).

The magic symbolic link, */proc/*pid*/root*, can be used to discover a process's root directory; see *proc*(5) for details.

FreeBSD has a stronger **jail**() system call.

SEE ALSO

chroot(1), *chdir*(2), *pivot_root*(2), *path_resolution*(7), *switch_root*(8)

NAME

clock_getres, clock_gettime, clock_settime − clock and time functions

LIBRARY

Standard C library (*libc*, *−lc*), since glibc 2.17

Before glibc 2.17, Real-time library (*librt*, *−lrt*)

SYNOPSIS

```
#include <time.h>

int clock_getres(clockid_t clockid, struct timespec *_Nullable res);

int clock_gettime(clockid_t clockid, struct timespec *tp);
int clock_settime(clockid_t clockid, const struct timespec *tp);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

clock_getres(), **clock_gettime**(), **clock_settime**():
_POSIX_C_SOURCE >= 199309L

DESCRIPTION

The function **clock_getres**() finds the resolution (precision) of the specified clock *clockid*, and, if *res* is non-NULL, stores it in the *struct timespec* pointed to by *res*. The resolution of clocks depends on the implementation and cannot be configured by a particular process. If the time value pointed to by the argument *tp* of **clock_settime**() is not a multiple of *res*, then it is truncated to a multiple of *res*.

The functions **clock_gettime**() and **clock_settime**() retrieve and set the time of the specified clock *clockid*.

The *res* and *tp* arguments are *timespec*(3) structures.

The *clockid* argument is the identifier of the particular clock on which to act. A clock may be system-wide and hence visible for all processes, or per-process if it measures time only within a single process.

All implementations support the system-wide real-time clock, which is identified by **CLOCK_REALTIME**. Its time represents seconds and nanoseconds since the Epoch. When its time is changed, timers for a relative interval are unaffected, but timers for an absolute point in time are affected.

More clocks may be implemented. The interpretation of the corresponding time values and the effect on timers is unspecified.

Sufficiently recent versions of glibc and the Linux kernel support the following clocks:

CLOCK_REALTIME
A settable system-wide clock that measures real (i.e., wall-clock) time. Setting this clock requires appropriate privileges. This clock is affected by discontinuous jumps in the system time (e.g., if the system administrator manually changes the clock), and by frequency adjustments performed by NTP and similar applications via *adjtime*(3), *adjtimex*(2), *clock_adjtime*(2), and *ntp_adjtime*(3). This clock normally counts the number of seconds since 1970-01-01 00:00:00 Coordinated Universal Time (UTC) except that it ignores leap seconds; near a leap second it is typically adjusted by NTP to stay roughly in sync with UTC.

CLOCK_REALTIME_ALARM (since Linux 3.0; Linux-specific)
Like **CLOCK_REALTIME**, but not settable. See *timer_create*(2) for further details.

CLOCK_REALTIME_COARSE (since Linux 2.6.32; Linux-specific)
A faster but less precise version of **CLOCK_REALTIME**. This clock is not settable. Use when you need very fast, but not fine-grained timestamps. Requires per-architecture support, and probably also architecture support for this flag in the *vdso*(7).

CLOCK_TAI (since Linux 3.10; Linux-specific)
A nonsettable system-wide clock derived from wall-clock time but counting leap seconds. This clock does not experience discontinuities or frequency adjustments caused by inserting leap seconds as **CLOCK_REALTIME** does.

The acronym TAI refers to International Atomic Time.

CLOCK_MONOTONIC
A nonsettable system-wide clock that represents monotonic time since—as described by POSIX—"some unspecified point in the past". On Linux, that point corresponds to the

number of seconds that the system has been running since it was booted.

The **CLOCK_MONOTONIC** clock is not affected by discontinuous jumps in the system time (e.g., if the system administrator manually changes the clock), but is affected by frequency adjustments. This clock does not count time that the system is suspended. All **CLOCK_MONOTONIC** variants guarantee that the time returned by consecutive calls will not go backwards, but successive calls may—depending on the architecture—return identical (not-increased) time values.

CLOCK_MONOTONIC_COARSE (since Linux 2.6.32; Linux-specific)
A faster but less precise version of **CLOCK_MONOTONIC**. Use when you need very fast, but not fine-grained timestamps. Requires per-architecture support, and probably also architecture support for this flag in the *vdso*(7).

CLOCK_MONOTONIC_RAW (since Linux 2.6.28; Linux-specific)
Similar to **CLOCK_MONOTONIC**, but provides access to a raw hardware-based time that is not subject to frequency adjustments. This clock does not count time that the system is suspended.

CLOCK_BOOTTIME (since Linux 2.6.39; Linux-specific)
A nonsettable system-wide clock that is identical to **CLOCK_MONOTONIC**, except that it also includes any time that the system is suspended. This allows applications to get a suspend-aware monotonic clock without having to deal with the complications of **CLOCK_REALTIME**, which may have discontinuities if the time is changed using *settimeofday*(2) or similar.

CLOCK_BOOTTIME_ALARM (since Linux 3.0; Linux-specific)
Like **CLOCK_BOOTTIME**. See *timer_create*(2) for further details.

CLOCK_PROCESS_CPUTIME_ID (since Linux 2.6.12)
This is a clock that measures CPU time consumed by this process (i.e., CPU time consumed by all threads in the process). On Linux, this clock is not settable.

CLOCK_THREAD_CPUTIME_ID (since Linux 2.6.12)
This is a clock that measures CPU time consumed by this thread. On Linux, this clock is not settable.

Linux also implements dynamic clock instances as described below.

Dynamic clocks

In addition to the hard-coded System-V style clock IDs described above, Linux also supports POSIX clock operations on certain character devices. Such devices are called "dynamic" clocks, and are supported since Linux 2.6.39.

Using the appropriate macros, open file descriptors may be converted into clock IDs and passed to **clock_gettime**(), **clock_settime**(), and *clock_adjtime*(2). The following example shows how to convert a file descriptor into a dynamic clock ID.

```
#define CLOCKFD 3
#define FD_TO_CLOCKID(fd)   ((~(clockid_t) (fd) << 3) | CLOCKFD)
#define CLOCKID_TO_FD(clk)  ((unsigned int) ~((clk) >> 3))

struct timespec ts;
clockid_t clkid;
int fd;

fd = open("/dev/ptp0", O_RDWR);
clkid = FD_TO_CLOCKID(fd);
clock_gettime(clkid, &ts);
```

RETURN VALUE

clock_gettime(), **clock_settime**(), and **clock_getres**() return 0 for success. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
: **clock_settime**() does not have write permission for the dynamic POSIX clock device indicated.

EFAULT
: *tp* points outside the accessible address space.

EINVAL
: The *clockid* specified is invalid for one of two reasons. Either the System-V style hard coded positive value is out of range, or the dynamic clock ID does not refer to a valid instance of a clock object.

EINVAL
: (**clock_settime**()): *tp.tv_sec* is negative or *tp.tv_nsec* is outside the range [0, 999,999,999].

EINVAL
: The *clockid* specified in a call to **clock_settime**() is not a settable clock.

EINVAL (since Linux 4.3)
: A call to **clock_settime**() with a *clockid* of **CLOCK_REALTIME** attempted to set the time to a value less than the current value of the **CLOCK_MONOTONIC** clock.

ENODEV
: The hot-pluggable device (like USB for example) represented by a dynamic *clk_id* has disappeared after its character device was opened.

ENOTSUP
: The operation is not supported by the dynamic POSIX clock device specified.

EOVERFLOW
: The timestamp would not fit in *time_t* range. This can happen if an executable with 32-bit *time_t* is run on a 64-bit kernel when the time is 2038-01-19 03:14:08 UTC or later. However, when the system time is out of *time_t* range in other situations, the behavior is undefined.

EPERM
: **clock_settime**() does not have permission to set the clock indicated.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
clock_getres(), **clock_gettime**(), **clock_settime**()	Thread safety	MT-Safe

VERSIONS

POSIX.1 specifies the following:

> Setting the value of the **CLOCK_REALTIME** clock via **clock_settime**() shall have no effect on threads that are blocked waiting for a relative time service based upon this clock, including the **nanosleep**() function; nor on the expiration of relative timers based upon this clock. Consequently, these time services shall expire when the requested relative interval elapses, independently of the new or old value of the clock.

According to POSIX.1-2001, a process with "appropriate privileges" may set the **CLOCK_PROCESS_CPUTIME_ID** and **CLOCK_THREAD_CPUTIME_ID** clocks using **clock_settime**(). On Linux, these clocks are not settable (i.e., no process has "appropriate privileges").

C library/kernel differences

On some architectures, an implementation of **clock_gettime**() is provided in the *vdso*(7).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SUSv2. Linux 2.6.

On POSIX systems on which these functions are available, the symbol **_POSIX_TIMERS** is defined in <*unistd.h*> to a value greater than 0. POSIX.1-2008 makes these functions mandatory.

The symbols **_POSIX_MONOTONIC_CLOCK**, **_POSIX_CPUTIME**,

_POSIX_THREAD_CPUTIME indicate that **CLOCK_MONOTONIC**, **CLOCK_PROCESS_CPUTIME_ID**, **CLOCK_THREAD_CPUTIME_ID** are available. (See also *sysconf*(3).)

Historical note for SMP systems

Before Linux added kernel support for **CLOCK_PROCESS_CPUTIME_ID** and **CLOCK_THREAD_CPUTIME_ID**, glibc implemented these clocks on many platforms using timer registers from the CPUs (TSC on i386, AR.ITC on Itanium). These registers may differ between CPUs and as a consequence these clocks may return **bogus results** if a process is migrated to another CPU.

If the CPUs in an SMP system have different clock sources, then there is no way to maintain a correlation between the timer registers since each CPU will run at a slightly different frequency. If that is the case, then *clock_getcpuclockid(0)* will return **ENOENT** to signify this condition. The two clocks will then be useful only if it can be ensured that a process stays on a certain CPU.

The processors in an SMP system do not start all at exactly the same time and therefore the timer registers are typically running at an offset. Some architectures include code that attempts to limit these offsets on bootup. However, the code cannot guarantee to accurately tune the offsets. glibc contains no provisions to deal with these offsets (unlike the Linux Kernel). Typically these offsets are small and therefore the effects may be negligible in most cases.

Since glibc 2.4, the wrapper functions for the system calls described in this page avoid the abovementioned problems by employing the kernel implementation of **CLOCK_PROCESS_CPUTIME_ID** and **CLOCK_THREAD_CPUTIME_ID**, on systems that provide such an implementation (i.e., Linux 2.6.12 and later).

EXAMPLES

The program below demonstrates the use of **clock_gettime**() and **clock_getres**() with various clocks. This is an example of what we might see when running the program:

```
$ ./clock_times x
CLOCK_REALTIME : 1585985459.446 (18356 days +  7h 30m 59s)
     resolution:          0.000000001
CLOCK_TAI      : 1585985496.447 (18356 days +  7h 31m 36s)
     resolution:          0.000000001
CLOCK_MONOTONIC:      52395.722 (14h 33m 15s)
     resolution:          0.000000001
CLOCK_BOOTTIME :      72691.019 (20h 11m 31s)
     resolution:          0.000000001
```

NAME

clock_nanosleep − high-resolution sleep with specifiable clock

LIBRARY

Standard C library (*libc*, *−lc*), since glibc 2.17

Before glibc 2.17, Real-time library (*librt*, *−lrt*)

SYNOPSIS

```
#include <time.h>

int clock_nanosleep(clockid_t clockid, int flags,
                    const struct timespec *t,
                    struct timespec *_Nullable remain);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

clock_nanosleep():
_POSIX_C_SOURCE >= 200112L

DESCRIPTION

Like *nanosleep*(2), **clock_nanosleep**() allows the calling thread to sleep for an interval specified with nanosecond precision. It differs in allowing the caller to select the clock against which the sleep interval is to be measured, and in allowing the sleep interval to be specified as either an absolute or a relative value.

The time values passed to and returned by this call are specified using *timespec*(3) structures.

The *clockid* argument specifies the clock against which the sleep interval is to be measured. This argument can have one of the following values:

CLOCK_REALTIME
A settable system-wide real-time clock.

CLOCK_TAI (since Linux 3.10)
A system-wide clock derived from wall-clock time but counting leap seconds.

CLOCK_MONOTONIC
A nonsettable, monotonically increasing clock that measures time since some unspecified point in the past that does not change after system startup.

CLOCK_BOOTTIME (since Linux 2.6.39)
Identical to **CLOCK_MONOTONIC**, except that it also includes any time that the system is suspended.

CLOCK_PROCESS_CPUTIME_ID
A settable per-process clock that measures CPU time consumed by all threads in the process.

See *clock_getres*(2) for further details on these clocks. In addition, the CPU clock IDs returned by *clock_getcpuclockid*(3) and *pthread_getcpuclockid*(3) can also be passed in *clockid*.

If *flags* is 0, then the value specified in *t* is interpreted as an interval relative to the current value of the clock specified by *clockid*.

If *flags* is **TIMER_ABSTIME**, then *t* is interpreted as an absolute time as measured by the clock, *clockid*. If *t* is less than or equal to the current value of the clock, then **clock_nanosleep**() returns immediately without suspending the calling thread.

clock_nanosleep() suspends the execution of the calling thread until either at least the time specified by *t* has elapsed, or a signal is delivered that causes a signal handler to be called or that terminates the process.

If the call is interrupted by a signal handler, **clock_nanosleep**() fails with the error **EINTR**. In addition, if *remain* is not NULL, and *flags* was not **TIMER_ABSTIME**, it returns the remaining unslept time in *remain*. This value can then be used to call **clock_nanosleep**() again and complete a (relative) sleep.

RETURN VALUE

On successfully sleeping for the requested interval, **clock_nanosleep**() returns 0. If the call is interrupted by a signal handler or encounters an error, then it returns one of the positive error number listed in ERRORS.

ERRORS

EFAULT
: *t* or *remain* specified an invalid address.

EINTR
: The sleep was interrupted by a signal handler; see *signal*(7).

EINVAL
: The value in the *tv_nsec* field was not in the range [0, 999999999] or *tv_sec* was negative.

EINVAL
: *clockid* was invalid. (**CLOCK_THREAD_CPUTIME_ID** is not a permitted value for *clockid*.)

ENOTSUP
: The kernel does not support sleeping against this *clockid*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001. Linux 2.6, glibc 2.1.

NOTES

If the interval specified in *t* is not an exact multiple of the granularity underlying clock (see *time*(7)), then the interval will be rounded up to the next multiple. Furthermore, after the sleep completes, there may still be a delay before the CPU becomes free to once again execute the calling thread.

Using an absolute timer is useful for preventing timer drift problems of the type described in *nanosleep*(2). (Such problems are exacerbated in programs that try to restart a relative sleep that is repeatedly interrupted by signals.) To perform a relative sleep that avoids these problems, call *clock_gettime*(2) for the desired clock, add the desired interval to the returned time value, and then call **clock_nanosleep**() with the **TIMER_ABSTIME** flag.

clock_nanosleep() is never restarted after being interrupted by a signal handler, regardless of the use of the *sigaction*(2) **SA_RESTART** flag.

The *remain* argument is unused, and unnecessary, when *flags* is **TIMER_ABSTIME**. (An absolute sleep can be restarted using the same *t* argument.)

POSIX.1 specifies that **clock_nanosleep**() has no effect on signals dispositions or the signal mask.

POSIX.1 specifies that after changing the value of the **CLOCK_REALTIME** clock via *clock_settime*(2), the new clock value shall be used to determine the time at which a thread blocked on an absolute **clock_nanosleep**() will wake up; if the new clock value falls past the end of the sleep interval, then the **clock_nanosleep**() call will return immediately.

POSIX.1 specifies that changing the value of the **CLOCK_REALTIME** clock via *clock_settime*(2) shall have no effect on a thread that is blocked on a relative **clock_nanosleep**().

NAME

clone, __clone2, clone3 − create a child process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

/* Prototype for the glibc wrapper function */

```
#define _GNU_SOURCE
#include <sched.h>

int clone(int (*fn)(void *_Nullable), void *stack, int flags,
          void *_Nullable arg, ...  /* pid_t *_Nullable parent_tid,
                                       void *_Nullable tls,
                                       pid_t *_Nullable child_tid */ );
```

/* For the prototype of the raw clone() system call, see NOTES */

```
#include <linux/sched.h>    /* Definition of struct clone_args */
#include <sched.h>          /* Definition of CLONE_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

long syscall(SYS_clone3, struct clone_args *cl_args, size_t size);
```

Note: glibc provides no wrapper for **clone3**(), necessitating the use of *syscall*(2).

DESCRIPTION

These system calls create a new ("child") process, in a manner similar to *fork*(2).

By contrast with *fork*(2), these system calls provide more precise control over what pieces of execution context are shared between the calling process and the child process. For example, using these system calls, the caller can control whether or not the two processes share the virtual address space, the table of file descriptors, and the table of signal handlers. These system calls also allow the new child process to be placed in separate *namespaces*(7).

Note that in this manual page, "calling process" normally corresponds to "parent process". But see the descriptions of **CLONE_PARENT** and **CLONE_THREAD** below.

This page describes the following interfaces:

- The glibc **clone**() wrapper function and the underlying system call on which it is based. The main text describes the wrapper function; the differences for the raw system call are described toward the end of this page.
- The newer **clone3**() system call.

In the remainder of this page, the terminology "the clone call" is used when noting details that apply to all of these interfaces.

The clone() wrapper function

When the child process is created with the **clone**() wrapper function, it commences execution by calling the function pointed to by the argument *fn*. (This differs from *fork*(2), where execution continues in the child from the point of the *fork*(2) call.) The *arg* argument is passed as the argument of the function *fn*.

When the *fn*(*arg*) function returns, the child process terminates. The integer returned by *fn* is the exit status for the child process. The child process may also terminate explicitly by calling *exit*(2) or after receiving a fatal signal.

The *stack* argument specifies the location of the stack used by the child process. Since the child and calling process may share memory, it is not possible for the child process to execute in the same stack as the calling process. The calling process must therefore set up memory space for the child stack and pass a pointer to this space to **clone**(). Stacks grow downward on all processors that run Linux (except the HP PA processors), so *stack* usually points to the topmost address of the memory space set up for the child stack. Note that **clone**() does not provide a means whereby the caller can inform the kernel of the size of the stack area.

The remaining arguments to **clone**() are discussed below.

clone3()

The **clone3**() system call provides a superset of the functionality of the older **clone**() interface. It also provides a number of API improvements, including: space for additional flags bits; cleaner separation in the use of various arguments; and the ability to specify the size of the child's stack area.

As with *fork*(2), **clone3**() returns in both the parent and the child. It returns 0 in the child process and returns the PID of the child in the parent.

The *cl_args* argument of **clone3**() is a structure of the following form:

```
struct clone_args {
    u64 flags;        /* Flags bit mask */
    u64 pidfd;        /* Where to store PID file descriptor
                         (int *) */
    u64 child_tid;    /* Where to store child TID,
                         in child's memory (pid_t *) */
    u64 parent_tid;   /* Where to store child TID,
                         in parent's memory (pid_t *) */
    u64 exit_signal;  /* Signal to deliver to parent on
                         child termination */
    u64 stack;        /* Pointer to lowest byte of stack */
    u64 stack_size;   /* Size of stack */
    u64 tls;          /* Location of new TLS */
    u64 set_tid;      /* Pointer to a pid_t array
                         (since Linux 5.5) */
    u64 set_tid_size; /* Number of elements in set_tid
                         (since Linux 5.5) */
    u64 cgroup;       /* File descriptor for target cgroup
                         of child (since Linux 5.7) */
};
```

The *size* argument that is supplied to **clone3**() should be initialized to the size of this structure. (The existence of the *size* argument permits future extensions to the *clone_args* structure.)

The stack for the child process is specified via *cl_args.stack*, which points to the lowest byte of the stack area, and *cl_args.stack_size*, which specifies the size of the stack in bytes. In the case where the **CLONE_VM** flag (see below) is specified, a stack must be explicitly allocated and specified. Otherwise, these two fields can be specified as NULL and 0, which causes the child to use the same stack area as the parent (in the child's own virtual address space).

The remaining fields in the *cl_args* argument are discussed below.

Equivalence between clone() and clone3() arguments

Unlike the older **clone**() interface, where arguments are passed individually, in the newer **clone3**() interface the arguments are packaged into the *clone_args* structure shown above. This structure allows for a superset of the information passed via the **clone**() arguments.

The following table shows the equivalence between the arguments of **clone**() and the fields in the *clone_args* argument supplied to **clone3**():

clone()	**clone3()**	**Notes**
	cl_args field	
flags & ~0xff	*flags*	For most flags; details below
parent_tid	*pidfd*	See CLONE_PIDFD
child_tid	*child_tid*	See CLONE_CHILD_SETTID
parent_tid	*parent_tid*	See CLONE_PARENT_SETTID
flags & 0xff	*exit_signal*	
stack	*stack*	
---	*stack_size*	
tls	*tls*	See CLONE_SETTLS
---	*set_tid*	See below for details
---	*set_tid_size*	
---	*cgroup*	See CLONE_INTO_CGROUP

The child termination signal

When the child process terminates, a signal may be sent to the parent. The termination signal is specified in the low byte of *flags* (**clone**()) or in *cl_args.exit_signal* (**clone3**()). If this signal is specified as anything other than **SIGCHLD**, then the parent process must specify the **__WALL** or **__WCLONE** options when waiting for the child with *wait*(2). If no signal (i.e., zero) is specified, then the parent process is not signaled when the child terminates.

The set_tid array

By default, the kernel chooses the next sequential PID for the new process in each of the PID namespaces where it is present. When creating a process with **clone3**(), the *set_tid* array (available since Linux 5.5) can be used to select specific PIDs for the process in some or all of the PID namespaces where it is present. If the PID of the newly created process should be set only for the current PID namespace or in the newly created PID namespace (if *flags* contains **CLONE_NEWPID**) then the first element in the *set_tid* array has to be the desired PID and *set_tid_size* needs to be 1.

If the PID of the newly created process should have a certain value in multiple PID namespaces, then the *set_tid* array can have multiple entries. The first entry defines the PID in the most deeply nested PID namespace and each of the following entries contains the PID in the corresponding ancestor PID namespace. The number of PID namespaces in which a PID should be set is defined by *set_tid_size* which cannot be larger than the number of currently nested PID namespaces.

To create a process with the following PIDs in a PID namespace hierarchy:

PID NS level	Requested PID	Notes
0	31496	Outermost PID namespace
1	42	
2	7	Innermost PID namespace

Set the array to:

```
set_tid[0] = 7;
set_tid[1] = 42;
set_tid[2] = 31496;
set_tid_size = 3;
```

If only the PIDs in the two innermost PID namespaces need to be specified, set the array to:

```
set_tid[0] = 7;
set_tid[1] = 42;
set_tid_size = 2;
```

The PID in the PID namespaces outside the two innermost PID namespaces is selected the same way as any other PID is selected.

The *set_tid* feature requires **CAP_SYS_ADMIN** or (since Linux 5.9) **CAP_CHECKPOINT_RESTORE** in all owning user namespaces of the target PID namespaces.

Callers may only choose a PID greater than 1 in a given PID namespace if an **init** process (i.e., a process with PID 1) already exists in that namespace. Otherwise the PID entry for this PID namespace must be 1.

The flags mask

Both **clone**() and **clone3**() allow a flags bit mask that modifies their behavior and allows the caller to specify what is shared between the calling process and the child process. This bit mask—the *flags* argument of **clone**() or the *cl_args.flags* field passed to **clone3**()—is referred to as the *flags* mask in the remainder of this page.

The *flags* mask is specified as a bitwise OR of zero or more of the constants listed below. Except as noted below, these flags are available (and have the same effect) in both **clone**() and **clone3**().

CLONE_CHILD_CLEARTID (since Linux 2.5.49)

Clear (zero) the child thread ID at the location pointed to by *child_tid* (**clone**()) or *cl_args.child_tid* (**clone3**()) in child memory when the child exits, and do a wakeup on the futex at that address. The address involved may be changed by the *set_tid_address*(2) system call. This is used by threading libraries.

CLONE_CHILD_SETTID (since Linux 2.5.49)
Store the child thread ID at the location pointed to by *child_tid* (**clone**()) or *cl_args.child_tid* (**clone3**()) in the child's memory. The store operation completes before the clone call returns control to user space in the child process. (Note that the store operation may not have completed before the clone call returns in the parent process, which is relevant if the **CLONE_VM** flag is also employed.)

CLONE_CLEAR_SIGHAND (since Linux 5.5)
By default, signal dispositions in the child thread are the same as in the parent. If this flag is specified, then all signals that are handled in the parent (and not set to **SIG_IGN**) are reset to their default dispositions (**SIG_DFL**) in the child.

Specifying this flag together with **CLONE_SIGHAND** is nonsensical and disallowed.

CLONE_DETACHED (historical)
For a while (during the Linux 2.5 development series) there was a **CLONE_DETACHED** flag, which caused the parent not to receive a signal when the child terminated. Ultimately, the effect of this flag was subsumed under the **CLONE_THREAD** flag and by the time Linux 2.6.0 was released, this flag had no effect. Starting in Linux 2.6.2, the need to give this flag together with **CLONE_THREAD** disappeared.

This flag is still defined, but it is usually ignored when calling **clone**(). However, see the description of **CLONE_PIDFD** for some exceptions.

CLONE_FILES (since Linux 2.0)
If **CLONE_FILES** is set, the calling process and the child process share the same file descriptor table. Any file descriptor created by the calling process or by the child process is also valid in the other process. Similarly, if one of the processes closes a file descriptor, or changes its associated flags (using the *fcntl*(2) **F_SETFD** operation), the other process is also affected. If a process sharing a file descriptor table calls *execve*(2), its file descriptor table is duplicated (unshared).

If **CLONE_FILES** is not set, the child process inherits a copy of all file descriptors opened in the calling process at the time of the clone call. Subsequent operations that open or close file descriptors, or change file descriptor flags, performed by either the calling process or the child process do not affect the other process. Note, however, that the duplicated file descriptors in the child refer to the same open file descriptions as the corresponding file descriptors in the calling process, and thus share file offsets and file status flags (see *open*(2)).

CLONE_FS (since Linux 2.0)
If **CLONE_FS** is set, the caller and the child process share the same filesystem information. This includes the root of the filesystem, the current working directory, and the umask. Any call to *chroot*(2), *chdir*(2), or *umask*(2) performed by the calling process or the child process also affects the other process.

If **CLONE_FS** is not set, the child process works on a copy of the filesystem information of the calling process at the time of the clone call. Calls to *chroot*(2), *chdir*(2), or *umask*(2) performed later by one of the processes do not affect the other process.

CLONE_INTO_CGROUP (since Linux 5.7)
By default, a child process is placed in the same version 2 cgroup as its parent. The **CLONE_INTO_CGROUP** flag allows the child process to be created in a different version 2 cgroup. (Note that **CLONE_INTO_CGROUP** has effect only for version 2 cgroups.)

In order to place the child process in a different cgroup, the caller specifies **CLONE_INTO_CGROUP** in *cl_args.flags* and passes a file descriptor that refers to a version 2 cgroup in the *cl_args.cgroup* field. (This file descriptor can be obtained by opening a cgroup v2 directory using either the **O_RDONLY** or the **O_PATH** flag.) Note that all of the usual restrictions (described in *cgroups*(7)) on placing a process into a version 2 cgroup apply.

Among the possible use cases for **CLONE_INTO_CGROUP** are the following:

- Spawning a process into a cgroup different from the parent's cgroup makes it possible for a service manager to directly spawn new services into dedicated cgroups. This eliminates the accounting jitter that would be caused if the child process was first created in the same cgroup as the parent and then moved into the target cgroup. Furthermore, spawning the

child process directly into a target cgroup is significantly cheaper than moving the child process into the target cgroup after it has been created.

- The **CLONE_INTO_CGROUP** flag also allows the creation of frozen child processes by spawning them into a frozen cgroup. (See *cgroups*(7) for a description of the freezer controller.)
- For threaded applications (or even thread implementations which make use of cgroups to limit individual threads), it is possible to establish a fixed cgroup layout before spawning each thread directly into its target cgroup.

CLONE_IO (since Linux 2.6.25)
If **CLONE_IO** is set, then the new process shares an I/O context with the calling process. If this flag is not set, then (as with *fork*(2)) the new process has its own I/O context.

The I/O context is the I/O scope of the disk scheduler (i.e., what the I/O scheduler uses to model scheduling of a process's I/O). If processes share the same I/O context, they are treated as one by the I/O scheduler. As a consequence, they get to share disk time. For some I/O schedulers, if two processes share an I/O context, they will be allowed to interleave their disk access. If several threads are doing I/O on behalf of the same process (**aio_read**(3), for instance), they should employ **CLONE_IO** to get better I/O performance.

If the kernel is not configured with the **CONFIG_BLOCK** option, this flag is a no-op.

CLONE_NEWCGROUP (since Linux 4.6)
Create the process in a new cgroup namespace. If this flag is not set, then (as with *fork*(2)) the process is created in the same cgroup namespaces as the calling process.

For further information on cgroup namespaces, see *cgroup_namespaces*(7).

Only a privileged process (**CAP_SYS_ADMIN**) can employ **CLONE_NEWCGROUP**.

CLONE_NEWIPC (since Linux 2.6.19)
If **CLONE_NEWIPC** is set, then create the process in a new IPC namespace. If this flag is not set, then (as with *fork*(2)), the process is created in the same IPC namespace as the calling process.

For further information on IPC namespaces, see *ipc_namespaces*(7).

Only a privileged process (**CAP_SYS_ADMIN**) can employ **CLONE_NEWIPC**. This flag can't be specified in conjunction with **CLONE_SYSVSEM**.

CLONE_NEWNET (since Linux 2.6.24)
(The implementation of this flag was completed only by about Linux 2.6.29.)

If **CLONE_NEWNET** is set, then create the process in a new network namespace. If this flag is not set, then (as with *fork*(2)) the process is created in the same network namespace as the calling process.

For further information on network namespaces, see *network_namespaces*(7).

Only a privileged process (**CAP_SYS_ADMIN**) can employ **CLONE_NEWNET**.

CLONE_NEWNS (since Linux 2.4.19)
If **CLONE_NEWNS** is set, the cloned child is started in a new mount namespace, initialized with a copy of the namespace of the parent. If **CLONE_NEWNS** is not set, the child lives in the same mount namespace as the parent.

For further information on mount namespaces, see *namespaces*(7) and *mount_namespaces*(7).

Only a privileged process (**CAP_SYS_ADMIN**) can employ **CLONE_NEWNS**. It is not permitted to specify both **CLONE_NEWNS** and **CLONE_FS** in the same clone call.

CLONE_NEWPID (since Linux 2.6.24)
If **CLONE_NEWPID** is set, then create the process in a new PID namespace. If this flag is not set, then (as with *fork*(2)) the process is created in the same PID namespace as the calling process.

For further information on PID namespaces, see *namespaces*(7) and *pid_namespaces*(7).

Only a privileged process (**CAP_SYS_ADMIN**) can employ **CLONE_NEWPID**. This flag can't be specified in conjunction with **CLONE_THREAD**.

CLONE_NEWUSER
(This flag first became meaningful for **clone**() in Linux 2.6.23, the current **clone**() semantics were merged in Linux 3.5, and the final pieces to make the user namespaces completely usable were merged in Linux 3.8.)

If **CLONE_NEWUSER** is set, then create the process in a new user namespace. If this flag is not set, then (as with *fork*(2)) the process is created in the same user namespace as the calling process.

For further information on user namespaces, see *namespaces*(7) and *user_namespaces*(7).

Before Linux 3.8, use of **CLONE_NEWUSER** required that the caller have three capabilities: **CAP_SYS_ADMIN**, **CAP_SETUID**, and **CAP_SETGID**. Starting with Linux 3.8, no privileges are needed to create a user namespace.

This flag can't be specified in conjunction with **CLONE_THREAD** or **CLONE_PARENT**. For security reasons, **CLONE_NEWUSER** cannot be specified in conjunction with **CLONE_FS**.

CLONE_NEWUTS (since Linux 2.6.19)
If **CLONE_NEWUTS** is set, then create the process in a new UTS namespace, whose identifiers are initialized by duplicating the identifiers from the UTS namespace of the calling process. If this flag is not set, then (as with *fork*(2)) the process is created in the same UTS namespace as the calling process.

For further information on UTS namespaces, see *uts_namespaces*(7).

Only a privileged process (**CAP_SYS_ADMIN**) can employ **CLONE_NEWUTS**.

CLONE_PARENT (since Linux 2.3.12)
If **CLONE_PARENT** is set, then the parent of the new child (as returned by *getppid*(2)) will be the same as that of the calling process.

If **CLONE_PARENT** is not set, then (as with *fork*(2)) the child's parent is the calling process.

Note that it is the parent process, as returned by *getppid*(2), which is signaled when the child terminates, so that if **CLONE_PARENT** is set, then the parent of the calling process, rather than the calling process itself, is signaled.

The **CLONE_PARENT** flag can't be used in clone calls by the global init process (PID 1 in the initial PID namespace) and init processes in other PID namespaces. This restriction prevents the creation of multi-rooted process trees as well as the creation of unreapable zombies in the initial PID namespace.

CLONE_PARENT_SETTID (since Linux 2.5.49)
Store the child thread ID at the location pointed to by *parent_tid* (**clone**()) or *cl_args.parent_tid* (**clone3**()) in the parent's memory. (In Linux 2.5.32-2.5.48 there was a flag **CLONE_SETTID** that did this.) The store operation completes before the clone call returns control to user space.

CLONE_PID (Linux 2.0 to Linux 2.5.15)
If **CLONE_PID** is set, the child process is created with the same process ID as the calling process. This is good for hacking the system, but otherwise of not much use. From Linux 2.3.21 onward, this flag could be specified only by the system boot process (PID 0). The flag disappeared completely from the kernel sources in Linux 2.5.16. Subsequently, the kernel silently ignored this bit if it was specified in the *flags* mask. Much later, the same bit was recycled for use as the **CLONE_PIDFD** flag.

CLONE_PIDFD (since Linux 5.2)
If this flag is specified, a PID file descriptor referring to the child process is allocated and placed at a specified location in the parent's memory. The close-on-exec flag is set on this new file descriptor. PID file descriptors can be used for the purposes described in *pidfd_open*(2).

- When using **clone3**(), the PID file descriptor is placed at the location pointed to by *cl_args.pidfd*.
- When using **clone**(), the PID file descriptor is placed at the location pointed to by *parent_tid*. Since the *parent_tid* argument is used to return the PID file descriptor, **CLONE_PIDFD** cannot be used with **CLONE_PARENT_SETTID** when calling **clone**().

It is currently not possible to use this flag together with **CLONE_THREAD.** This means that the process identified by the PID file descriptor will always be a thread group leader.

If the obsolete **CLONE_DETACHED** flag is specified alongside **CLONE_PIDFD** when calling **clone**(), an error is returned. An error also results if **CLONE_DETACHED** is specified when calling **clone3**(). This error behavior ensures that the bit corresponding to **CLONE_DETACHED** can be reused for further PID file descriptor features in the future.

CLONE_PTRACE (since Linux 2.2)
If **CLONE_PTRACE** is specified, and the calling process is being traced, then trace the child also (see *ptrace*(2)).

CLONE_SETTLS (since Linux 2.5.32)
The TLS (Thread Local Storage) descriptor is set to *tls*.

The interpretation of *tls* and the resulting effect is architecture dependent. On x86, *tls* is interpreted as a *struct user_desc* * (see *set_thread_area*(2)). On x86-64 it is the new value to be set for the %fs base register (see the **ARCH_SET_FS** argument to *arch_prctl*(2)). On architectures with a dedicated TLS register, it is the new value of that register.

Use of this flag requires detailed knowledge and generally it should not be used except in libraries implementing threading.

CLONE_SIGHAND (since Linux 2.0)
If **CLONE_SIGHAND** is set, the calling process and the child process share the same table of signal handlers. If the calling process or child process calls *sigaction*(2) to change the behavior associated with a signal, the behavior is changed in the other process as well. However, the calling process and child processes still have distinct signal masks and sets of pending signals. So, one of them may block or unblock signals using *sigprocmask*(2) without affecting the other process.

If **CLONE_SIGHAND** is not set, the child process inherits a copy of the signal handlers of the calling process at the time of the clone call. Calls to *sigaction*(2) performed later by one of the processes have no effect on the other process.

Since Linux 2.6.0, the *flags* mask must also include **CLONE_VM** if **CLONE_SIGHAND** is specified.

CLONE_STOPPED (since Linux 2.6.0)
If **CLONE_STOPPED** is set, then the child is initially stopped (as though it was sent a **SIGSTOP** signal), and must be resumed by sending it a **SIGCONT** signal.

This flag was *deprecated* from Linux 2.6.25 onward, and was *removed* altogether in Linux 2.6.38. Since then, the kernel silently ignores it without error. Starting with Linux 4.6, the same bit was reused for the **CLONE_NEWCGROUP** flag.

CLONE_SYSVSEM (since Linux 2.5.10)
If **CLONE_SYSVSEM** is set, then the child and the calling process share a single list of System V semaphore adjustment (*semadj*) values (see *semop*(2)). In this case, the shared list accumulates *semadj* values across all processes sharing the list, and semaphore adjustments are performed only when the last process that is sharing the list terminates (or ceases sharing the list using *unshare*(2)). If this flag is not set, then the child has a separate *semadj* list that is initially empty.

CLONE_THREAD (since Linux 2.4.0)
If **CLONE_THREAD** is set, the child is placed in the same thread group as the calling process. To make the remainder of the discussion of **CLONE_THREAD** more readable, the term "thread" is used to refer to the processes within a thread group.

Thread groups were a feature added in Linux 2.4 to support the POSIX threads notion of a set of threads that share a single PID. Internally, this shared PID is the so-called thread group identifier (TGID) for the thread group. Since Linux 2.4, calls to *getpid*(2) return the TGID of the caller.

The threads within a group can be distinguished by their (system-wide) unique thread IDs (TID). A new thread's TID is available as the function result returned to the caller, and a thread can obtain its own TID using *gettid*(2).

When a clone call is made without specifying **CLONE_THREAD**, then the resulting thread is placed in a new thread group whose TGID is the same as the thread's TID. This thread is the *leader* of the new thread group.

A new thread created with **CLONE_THREAD** has the same parent process as the process that made the clone call (i.e., like **CLONE_PARENT**), so that calls to *getppid*(2) return the same value for all of the threads in a thread group. When a **CLONE_THREAD** thread terminates, the thread that created it is not sent a **SIGCHLD** (or other termination) signal; nor can the status of such a thread be obtained using *wait*(2). (The thread is said to be *detached*.)

After all of the threads in a thread group terminate the parent process of the thread group is sent a **SIGCHLD** (or other termination) signal.

If any of the threads in a thread group performs an *execve*(2), then all threads other than the thread group leader are terminated, and the new program is executed in the thread group leader.

If one of the threads in a thread group creates a child using *fork*(2), then any thread in the group can *wait*(2) for that child.

Since Linux 2.5.35, the *flags* mask must also include **CLONE_SIGHAND** if **CLONE_THREAD** is specified (and note that, since Linux 2.6.0, **CLONE_SIGHAND** also requires **CLONE_VM** to be included).

Signal dispositions and actions are process-wide: if an unhandled signal is delivered to a thread, then it will affect (terminate, stop, continue, be ignored in) all members of the thread group.

Each thread has its own signal mask, as set by *sigprocmask*(2).

A signal may be process-directed or thread-directed. A process-directed signal is targeted at a thread group (i.e., a TGID), and is delivered to an arbitrarily selected thread from among those that are not blocking the signal. A signal may be process-directed because it was generated by the kernel for reasons other than a hardware exception, or because it was sent using *kill*(2) or *sigqueue*(3). A thread-directed signal is targeted at (i.e., delivered to) a specific thread. A signal may be thread directed because it was sent using *tgkill*(2) or *pthread_sigqueue*(3), or because the thread executed a machine language instruction that triggered a hardware exception (e.g., invalid memory access triggering **SIGSEGV** or a floating-point exception triggering **SIGFPE**).

A call to *sigpending*(2) returns a signal set that is the union of the pending process-directed signals and the signals that are pending for the calling thread.

If a process-directed signal is delivered to a thread group, and the thread group has installed a handler for the signal, then the handler is invoked in exactly one, arbitrarily selected member of the thread group that has not blocked the signal. If multiple threads in a group are waiting to accept the same signal using *sigwaitinfo*(2), the kernel will arbitrarily select one of these threads to receive the signal.

CLONE_UNTRACED (since Linux 2.5.46)
If **CLONE_UNTRACED** is specified, then a tracing process cannot force **CLONE_PTRACE** on this child process.

CLONE_VFORK (since Linux 2.2)
If **CLONE_VFORK** is set, the execution of the calling process is suspended until the child releases its virtual memory resources via a call to *execve*(2) or *_exit*(2) (as with *vfork*(2)).

If **CLONE_VFORK** is not set, then both the calling process and the child are schedulable after the call, and an application should not rely on execution occurring in any particular order.

CLONE_VM (since Linux 2.0)
If **CLONE_VM** is set, the calling process and the child process run in the same memory space. In particular, memory writes performed by the calling process or by the child process are also visible in the other process. Moreover, any memory mapping or unmapping performed with *mmap*(2) or *munmap*(2) by the child or calling process also affects the other process.

If **CLONE_VM** is not set, the child process runs in a separate copy of the memory space of the calling process at the time of the clone call. Memory writes or file mappings/unmappings performed by one of the processes do not affect the other, as with *fork*(2).

If the **CLONE_VM** flag is specified and the **CLONE_VFORK** flag is not specified, then any alternate signal stack that was established by *sigaltstack*(2) is cleared in the child process.

RETURN VALUE

On success, the thread ID of the child process is returned in the caller's thread of execution. On failure, −1 is returned in the caller's context, no child process is created, and *errno* is set to indicate the error.

ERRORS

EACCES (**clone3**() only)
CLONE_INTO_CGROUP was specified in *cl_args.flags*, but the restrictions (described in *cgroups*(7)) on placing the child process into the version 2 cgroup referred to by *cl_args.cgroup* are not met.

EAGAIN
Too many processes are already running; see *fork*(2).

EBUSY (**clone3**() only)
CLONE_INTO_CGROUP was specified in *cl_args.flags*, but the file descriptor specified in *cl_args.cgroup* refers to a version 2 cgroup in which a domain controller is enabled.

EEXIST (**clone3**() only)
One (or more) of the PIDs specified in *set_tid* already exists in the corresponding PID namespace.

EINVAL
Both **CLONE_SIGHAND** and **CLONE_CLEAR_SIGHAND** were specified in the *flags* mask.

EINVAL
CLONE_SIGHAND was specified in the *flags* mask, but **CLONE_VM** was not. (Since Linux 2.6.0.)

EINVAL
CLONE_THREAD was specified in the *flags* mask, but **CLONE_SIGHAND** was not. (Since Linux 2.5.35.)

EINVAL
CLONE_THREAD was specified in the *flags* mask, but the current process previously called *unshare*(2) with the **CLONE_NEWPID** flag or used *setns*(2) to reassociate itself with a PID namespace.

EINVAL
Both **CLONE_FS** and **CLONE_NEWNS** were specified in the *flags* mask.

EINVAL (since Linux 3.9)
Both **CLONE_NEWUSER** and **CLONE_FS** were specified in the *flags* mask.

EINVAL
Both **CLONE_NEWIPC** and **CLONE_SYSVSEM** were specified in the *flags* mask.

EINVAL
CLONE_NEWPID and one (or both) of **CLONE_THREAD** or **CLONE_PARENT** were specified in the *flags* mask.

EINVAL
CLONE_NEWUSER and **CLONE_THREAD** were specified in the *flags* mask.

EINVAL (since Linux 2.6.32)
CLONE_PARENT was specified, and the caller is an init process.

EINVAL
Returned by the glibc **clone**() wrapper function when *fn* or *stack* is specified as NULL.

EINVAL
CLONE_NEWIPC was specified in the *flags* mask, but the kernel was not configured with the **CONFIG_SYSVIPC** and **CONFIG_IPC_NS** options.

EINVAL
CLONE_NEWNET was specified in the *flags* mask, but the kernel was not configured with the **CONFIG_NET_NS** option.

EINVAL
CLONE_NEWPID was specified in the *flags* mask, but the kernel was not configured with the **CONFIG_PID_NS** option.

EINVAL
CLONE_NEWUSER was specified in the *flags* mask, but the kernel was not configured with the **CONFIG_USER_NS** option.

EINVAL
CLONE_NEWUTS was specified in the *flags* mask, but the kernel was not configured with the **CONFIG_UTS_NS** option.

EINVAL
stack is not aligned to a suitable boundary for this architecture. For example, on aarch64, *stack* must be a multiple of 16.

EINVAL (**clone3**() only)
CLONE_DETACHED was specified in the *flags* mask.

EINVAL (**clone**() only)
CLONE_PIDFD was specified together with **CLONE_DETACHED** in the *flags* mask.

EINVAL
CLONE_PIDFD was specified together with **CLONE_THREAD** in the *flags* mask.

EINVAL (**clone**() only)
CLONE_PIDFD was specified together with **CLONE_PARENT_SETTID** in the *flags* mask.

EINVAL (**clone3**() only)
set_tid_size is greater than the number of nested PID namespaces.

EINVAL (**clone3**() only)
One of the PIDs specified in *set_tid* was an invalid.

EINVAL (**clone3**() only)
CLONE_THREAD or **CLONE_PARENT** was specified in the *flags* mask, but a signal was specified in *exit_signal*.

EINVAL (AArch64 only, Linux 4.6 and earlier)
stack was not aligned to a 128-bit boundary.

ENOMEM
Cannot allocate sufficient memory to allocate a task structure for the child, or to copy those parts of the caller's context that need to be copied.

ENOSPC (since Linux 3.7)
CLONE_NEWPID was specified in the *flags* mask, but the limit on the nesting depth of PID namespaces would have been exceeded; see *pid_namespaces*(7).

ENOSPC (since Linux 4.9; beforehand **EUSERS**)
CLONE_NEWUSER was specified in the *flags* mask, and the call would cause the limit on the number of nested user namespaces to be exceeded. See *user_namespaces*(7).

From Linux 3.11 to Linux 4.8, the error diagnosed in this case was **EUSERS**.

ENOSPC (since Linux 4.9)
One of the values in the *flags* mask specified the creation of a new user namespace, but doing so would have caused the limit defined by the corresponding file in */proc/sys/user* to be exceeded. For further details, see *namespaces*(7).

EOPNOTSUPP (**clone3**() only)
CLONE_INTO_CGROUP was specified in *cl_args.flags*, but the file descriptor specified in *cl_args.cgroup* refers to a version 2 cgroup that is in the *domain invalid* state.

EPERM
CLONE_NEWCGROUP, **CLONE_NEWIPC**, **CLONE_NEWNET**, **CLONE_NEWNS**, **CLONE_NEWPID**, or **CLONE_NEWUTS** was specified by an unprivileged process (process without **CAP_SYS_ADMIN**).

EPERM
CLONE_PID was specified by a process other than process 0. (This error occurs only on Linux 2.5.15 and earlier.)

EPERM
CLONE_NEWUSER was specified in the *flags* mask, but either the effective user ID or the effective group ID of the caller does not have a mapping in the parent namespace (see *user_namespaces*(7)).

EPERM (since Linux 3.9)
CLONE_NEWUSER was specified in the *flags* mask and the caller is in a chroot environment (i.e., the caller's root directory does not match the root directory of the mount namespace in which it resides).

EPERM (**clone3**() only)
set_tid_size was greater than zero, and the caller lacks the **CAP_SYS_ADMIN** capability in one or more of the user namespaces that own the corresponding PID namespaces.

ERESTARTNOINTR (since Linux 2.6.17)
System call was interrupted by a signal and will be restarted. (This can be seen only during a trace.)

EUSERS (Linux 3.11 to Linux 4.8)
CLONE_NEWUSER was specified in the *flags* mask, and the limit on the number of nested user namespaces would be exceeded. See the discussion of the **ENOSPC** error above.

VERSIONS

The glibc **clone**() wrapper function makes some changes in the memory pointed to by *stack* (changes required to set the stack up correctly for the child) *before* invoking the **clone**() system call. So, in cases where **clone**() is used to recursively create children, do not use the buffer employed for the parent's stack as the stack of the child.

On i386, **clone**() should not be called through vsyscall, but directly through *int $0x80*.

C library/kernel differences

The raw **clone**() system call corresponds more closely to *fork*(2) in that execution in the child continues from the point of the call. As such, the *fn* and *arg* arguments of the **clone**() wrapper function are omitted.

In contrast to the glibc wrapper, the raw **clone**() system call accepts NULL as a *stack* argument (and **clone3**() likewise allows *cl_args.stack* to be NULL). In this case, the child uses a duplicate of the parent's stack. (Copy-on-write semantics ensure that the child gets separate copies of stack pages when either process modifies the stack.) In this case, for correct operation, the **CLONE_VM** option should not be specified. (If the child *shares* the parent's memory because of the use of the **CLONE_VM** flag, then no copy-on-write duplication occurs and chaos is likely to result.)

The order of the arguments also differs in the raw system call, and there are variations in the arguments across architectures, as detailed in the following paragraphs.

The raw system call interface on x86-64 and some other architectures (including sh, tile, and alpha) is:

```
long clone(unsigned long flags, void *stack,
           int *parent_tid, int *child_tid,
           unsigned long tls);
```

On x86-32, and several other common architectures (including score, ARM, ARM 64, PA-RISC, arc, Power PC, xtensa, and MIPS), the order of the last two arguments is reversed:

```
long clone(unsigned long flags, void *stack,
           int *parent_tid, unsigned long tls,
           int *child_tid);
```

On the cris and s390 architectures, the order of the first two arguments is reversed:

```
long clone(void *stack, unsigned long flags,
           int *parent_tid, int *child_tid,
           unsigned long tls);
```

On the microblaze architecture, an additional argument is supplied:

```
long clone(unsigned long flags, void *stack,
           int stack_size,         /* Size of stack */
           int *parent_tid, int *child_tid,
           unsigned long tls);
```

blackfin, m68k, and sparc

The argument-passing conventions on blackfin, m68k, and sparc are different from the descriptions above. For details, see the kernel (and glibc) source.

ia64

On ia64, a different interface is used:

```
int __clone2(int (*fn)(void *),
             void *stack_base, size_t stack_size,
             int flags, void *arg, ...
            /* pid_t *parent_tid, struct user_desc *tls,
             pid_t *child_tid */ );
```

The prototype shown above is for the glibc wrapper function; for the system call itself, the prototype can be described as follows (it is identical to the **clone**() prototype on microblaze):

```
long clone2(unsigned long flags, void *stack_base,
            int stack_size,         /* Size of stack */
            int *parent_tid, int *child_tid,
            unsigned long tls);
```

__clone2() operates in the same way as **clone**(), except that *stack_base* points to the lowest address of the child's stack area, and *stack_size* specifies the size of the stack pointed to by *stack_base*.

STANDARDS

Linux.

HISTORY

clone3()

Linux 5.3.

Linux 2.4 and earlier

In the Linux 2.4.x series, **CLONE_THREAD** generally does not make the parent of the new thread the same as the parent of the calling process. However, from Linux 2.4.7 to Linux 2.4.18 the **CLONE_THREAD** flag implied the **CLONE_PARENT** flag (as in Linux 2.6.0 and later).

In Linux 2.4 and earlier, **clone**() does not take arguments *parent_tid*, *tls*, and *child_tid*.

NOTES

One use of these system calls is to implement threads: multiple flows of control in a program that run concurrently in a shared address space.

The *kcmp*(2) system call can be used to test whether two processes share various resources such as a file descriptor table, System V semaphore undo operations, or a virtual address space.

Handlers registered using *pthread_atfork*(3) are not executed during a clone call.

BUGS

GNU C library versions 2.3.4 up to and including 2.24 contained a wrapper function for *getpid*(2) that performed caching of PIDs. This caching relied on support in the glibc wrapper for **clone**(), but

limitations in the implementation meant that the cache was not up to date in some circumstances. In particular, if a signal was delivered to the child immediately after the **clone**() call, then a call to *getpid*(2) in a handler for the signal could return the PID of the calling process ("the parent"), if the clone wrapper had not yet had a chance to update the PID cache in the child. (This discussion ignores the case where the child was created using **CLONE_THREAD**, when *getpid*(2) *should* return the same value in the child and in the process that called **clone**(), since the caller and the child are in the same thread group. The stale-cache problem also does not occur if the *flags* argument includes **CLONE_VM**.) To get the truth, it was sometimes necessary to use code such as the following:

```
#include <syscall.h>

pid_t mypid;

mypid = syscall(SYS_getpid);
```

Because of the stale-cache problem, as well as other problems noted in *getpid*(2), the PID caching feature was removed in glibc 2.25.

EXAMPLES

The following program demonstrates the use of **clone**() to create a child process that executes in a separate UTS namespace. The child changes the hostname in its UTS namespace. Both parent and child then display the system hostname, making it possible to see that the hostname differs in the UTS namespaces of the parent and child. For an example of the use of this program, see *setns*(2).

Within the sample program, we allocate the memory that is to be used for the child's stack using *mmap*(2) rather than *malloc*(3) for the following reasons:

- *mmap*(2) allocates a block of memory that starts on a page boundary and is a multiple of the page size. This is useful if we want to establish a guard page (a page with protection **PROT_NONE**) at the end of the stack using *mprotect*(2).
- We can specify the **MAP_STACK** flag to request a mapping that is suitable for a stack. For the moment, this flag is a no-op on Linux, but it exists and has effect on some other systems, so we should include it for portability.

NAME

close − close a file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int close(int *fd***);**

DESCRIPTION

close() closes a file descriptor, so that it no longer refers to any file and may be reused. Any record locks (see *fcntl*(2)) held on the file it was associated with, and owned by the process, are removed regardless of the file descriptor that was used to obtain the lock. This has some unfortunate consequences and one should be extra careful when using advisory record locking. See *fcntl*(2) for discussion of the risks and consequences as well as for the (probably preferred) open file description locks.

If *fd* is the last file descriptor referring to the underlying open file description (see *open*(2)), the resources associated with the open file description are freed; if the file descriptor was the last reference to a file which has been removed using *unlink*(2), the file is deleted.

RETURN VALUE

close() returns zero on success. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
: *fd* isn't a valid open file descriptor.

EINTR
: The **close**() call was interrupted by a signal; see *signal*(7).

EIO An I/O error occurred.

ENOSPC
EDQUOT
: On NFS, these errors are not normally reported against the first write which exceeds the available storage space, but instead against a subsequent *write*(2), *fsync*(2), or **close**().

See NOTES for a discussion of why **close**() should not be retried after an error.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

NOTES

A successful close does not guarantee that the data has been successfully saved to disk, as the kernel uses the buffer cache to defer writes. Typically, filesystems do not flush buffers when a file is closed. If you need to be sure that the data is physically stored on the underlying disk, use *fsync*(2). (It will depend on the disk hardware at this point.)

The close-on-exec file descriptor flag can be used to ensure that a file descriptor is automatically closed upon a successful *execve*(2); see *fcntl*(2) for details.

Multithreaded processes and close()

It is probably unwise to close file descriptors while they may be in use by system calls in other threads in the same process. Since a file descriptor may be reused, there are some obscure race conditions that may cause unintended side effects.

Furthermore, consider the following scenario where two threads are performing operations on the same file descriptor:

(1) One thread is blocked in an I/O system call on the file descriptor. For example, it is trying to *write*(2) to a pipe that is already full, or trying to *read*(2) from a stream socket which currently has no available data.

(2) Another thread closes the file descriptor.

The behavior in this situation varies across systems. On some systems, when the file descriptor is closed, the blocking system call returns immediately with an error.

On Linux (and possibly some other systems), the behavior is different: the blocking I/O system call holds a reference to the underlying open file description, and this reference keeps the description open until the I/O system call completes. (See *open*(2) for a discussion of open file descriptions.) Thus, the blocking system call in the first thread may successfully complete after the **close**() in the second thread.

Dealing with error returns from close()

A careful programmer will check the return value of **close**(), since it is quite possible that errors on a previous *write*(2) operation are reported only on the final **close**() that releases the open file description. Failing to check the return value when closing a file may lead to *silent* loss of data. This can especially be observed with NFS and with disk quota.

Note, however, that a failure return should be used only for diagnostic purposes (i.e., a warning to the application that there may still be I/O pending or there may have been failed I/O) or remedial purposes (e.g., writing the file once more or creating a backup).

Retrying the **close**() after a failure return is the wrong thing to do, since this may cause a reused file descriptor from another thread to be closed. This can occur because the Linux kernel *always* releases the file descriptor early in the close operation, freeing it for reuse; the steps that may return an error, such as flushing data to the filesystem or device, occur only later in the close operation.

Many other implementations similarly always close the file descriptor (except in the case of **EBADF**, meaning that the file descriptor was invalid) even if they subsequently report an error on return from **close**(). POSIX.1 is currently silent on this point, but there are plans to mandate this behavior in the next major release of the standard.

A careful programmer who wants to know about I/O errors may precede **close**() with a call to *fsync*(2).

The **EINTR** error is a somewhat special case. Regarding the **EINTR** error, POSIX.1-2008 says:

> If **close**() is interrupted by a signal that is to be caught, it shall return −1 with *errno* set to **EINTR** and the state of *fildes* is unspecified.

This permits the behavior that occurs on Linux and many other implementations, where, as with other errors that may be reported by **close**(), the file descriptor is guaranteed to be closed. However, it also permits another possibility: that the implementation returns an **EINTR** error and keeps the file descriptor open. (According to its documentation, HP-UX's **close**() does this.) The caller must then once more use **close**() to close the file descriptor, to avoid file descriptor leaks. This divergence in implementation behaviors provides a difficult hurdle for portable applications, since on many implementations, **close**() must not be called again after an **EINTR** error, and on at least one, **close**() must be called again. There are plans to address this conundrum for the next major release of the POSIX.1 standard.

close_range(2), *fcntl*(2), *fsync*(2), *open*(2), *shutdown*(2), *unlink*(2), *fclose*(3)

NAME

close_range − close all file descriptors in a given range

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <unistd.h>

#include <linux/close_range.h> /* Definition of CLOSE_RANGE_* constants */

int close_range(unsigned int first, unsigned int last, int flags);
```

DESCRIPTION

The **close_range**() system call closes all open file descriptors from *first* to *last* (included).

Errors closing a given file descriptor are currently ignored.

flags is a bit mask containing 0 or more of the following:

CLOSE_RANGE_CLOEXEC (since Linux 5.11)
: Set the close-on-exec flag on the specified file descriptors, rather than immediately closing them.

CLOSE_RANGE_UNSHARE
: Unshare the specified file descriptors from any other processes before closing them, avoiding races with other threads sharing the file descriptor table.

RETURN VALUE

On success, **close_range**() returns 0. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EINVAL
: *flags* is not valid, or *first* is greater than *last*.

The following can occur with **CLOSE_RANGE_UNSHARE** (when constructing the new descriptor table):

EMFILE
: The number of open file descriptors exceeds the limit specified in */proc/sys/fs/nr_open* (see *proc*(5)). This error can occur in situations where that limit was lowered before a call to **close_range**() where the **CLOSE_RANGE_UNSHARE** flag is specified.

ENOMEM
: Insufficient kernel memory was available.

STANDARDS

None.

HISTORY

FreeBSD. Linux 5.9, glibc 2.34.

NOTES

Closing all open file descriptors

To avoid blindly closing file descriptors in the range of possible file descriptors, this is sometimes implemented (on Linux) by listing open file descriptors in */proc/self/fd/* and calling *close*(2) on each one. **close_range**() can take care of this without requiring */proc* and within a single system call, which provides significant performance benefits.

Closing file descriptors before exec

File descriptors can be closed safely using

```
/* we don't want anything past stderr here */
close_range(3, ~0U, CLOSE_RANGE_UNSHARE);
execve(....);
```

CLOSE_RANGE_UNSHARE is conceptually equivalent to

```
unshare(CLONE_FILES);
```

```
close_range(first, last, 0);
```

but can be more efficient: if the unshared range extends past the current maximum number of file descriptors allocated in the caller's file descriptor table (the common case when *last* is ~0U), the kernel will unshare a new file descriptor table for the caller up to *first*, copying as few file descriptors as possible. This avoids subsequent *close*(2) calls entirely; the whole operation is complete once the table is unshared.

Closing files on exec

This is particularly useful in cases where multiple pre-**exec** setup steps risk conflicting with each other. For example, setting up a *seccomp*(2) profile can conflict with a **close_range**() call: if the file descriptors are closed before the *seccomp*(2) profile is set up, the profile setup can't use them itself, or control their closure; if the file descriptors are closed afterwards, the seccomp profile can't block the **close_range**() call or any fallbacks. Using **CLOSE_RANGE_CLOEXEC** avoids this: the descriptors can be marked before the *seccomp*(2) profile is set up, and the profile can control access to **close_range**() without affecting the calling process.

EXAMPLES

The program shown below opens the files named in its command-line arguments, displays the list of files that it has opened (by iterating through the entries in */proc/PID/fd*), uses **close_range**() to close all file descriptors greater than or equal to 3, and then once more displays the process's list of open files. The following example demonstrates the use of the program:

```
$ touch /tmp/a /tmp/b /tmp/c
$ ./a.out /tmp/a /tmp/b /tmp/c
/tmp/a opened as FD 3
/tmp/b opened as FD 4
/tmp/c opened as FD 5
/proc/self/fd/0 ==> /dev/pts/1
/proc/self/fd/1 ==> /dev/pts/1
/proc/self/fd/2 ==> /dev/pts/1
/proc/self/fd/3 ==> /tmp/a
/proc/self/fd/4 ==> /tmp/b
/proc/self/fd/5 ==> /tmp/b
/proc/self/fd/6 ==> /proc/9005/fd
========= About to call close_range() =======
/proc/self/fd/0 ==> /dev/pts/1
/proc/self/fd/1 ==> /dev/pts/1
/proc/self/fd/2 ==> /dev/pts/1
/proc/self/fd/3 ==> /proc/9005/fd
```

Note that the lines showing the pathname */proc/9005/fd* result from the calls to *opendir*(3).

Program source

```
#define _GNU_SOURCE
#include <dirent.h>
#include <fcntl.h>
#include <limits.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

/* Show the contents of the symbolic links in /proc/self/fd */

static void
show_fds(void)
{
    DIR           *dirp;
    char          path[PATH_MAX], target[PATH_MAX];
    ssize_t       len;
    struct dirent  *dp;
```

```
        dirp = opendir("/proc/self/fd");
        if (dirp  == NULL) {
            perror("opendir");
            exit(EXIT_FAILURE);
        }

        for (;;) {
            dp = readdir(dirp);
            if (dp == NULL)
                break;

            if (dp->d_type == DT_LNK) {
                snprintf(path, sizeof(path), "/proc/self/fd/%s",
                         dp->d_name);

                len = readlink(path, target, sizeof(target));
                printf("%s ==> %.*s\n", path, (int) len, target);
            }
        }

        closedir(dirp);
    }

    int
    main(int argc, char *argv[])
    {
        int  fd;

        for (size_t j = 1; j < argc; j++) {
            fd = open(argv[j], O_RDONLY);
            if (fd == -1) {
                perror(argv[j]);
                exit(EXIT_FAILURE);
            }
            printf("%s opened as FD %d\n", argv[j], fd);
        }

        show_fds();

        printf("========= About to call close_range() =======\n");

        if (close_range(3, ~0U, 0) == -1) {
            perror("close_range");
            exit(EXIT_FAILURE);
        }

        show_fds();
        exit(EXIT_FAILURE);
    }
```

NAME

connect − initiate a connection on a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/socket.h>

int connect(int sockfd, const struct sockaddr *addr,
            socklen_t addrlen);
```

DESCRIPTION

The **connect**() system call connects the socket referred to by the file descriptor *sockfd* to the address specified by *addr*. The *addrlen* argument specifies the size of *addr*. The format of the address in *addr* is determined by the address space of the socket *sockfd*; see *socket*(2) for further details.

If the socket *sockfd* is of type **SOCK_DGRAM**, then *addr* is the address to which datagrams are sent by default, and the only address from which datagrams are received. If the socket is of type **SOCK_STREAM** or **SOCK_SEQPACKET**, this call attempts to make a connection to the socket that is bound to the address specified by *addr*.

Some protocol sockets (e.g., UNIX domain stream sockets) may successfully **connect**() only once.

Some protocol sockets (e.g., datagram sockets in the UNIX and Internet domains) may use **connect**() multiple times to change their association.

Some protocol sockets (e.g., TCP sockets as well as datagram sockets in the UNIX and Internet domains) may dissolve the association by connecting to an address with the *sa_family* member of *sockaddr* set to **AF_UNSPEC**; thereafter, the socket can be connected to another address. (**AF_UNSPEC** is supported since Linux 2.2.)

RETURN VALUE

If the connection or binding succeeds, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

The following are general socket errors only. There may be other domain-specific error codes.

EACCES
: For UNIX domain sockets, which are identified by pathname: Write permission is denied on the socket file, or search permission is denied for one of the directories in the path prefix. (See also *path_resolution*(7).)

EACCES
EPERM
: The user tried to connect to a broadcast address without having the socket broadcast flag enabled or the connection request failed because of a local firewall rule.

EACCES
: It can also be returned if an SELinux policy denied a connection (for example, if there is a policy saying that an HTTP proxy can only connect to ports associated with HTTP servers, and the proxy tries to connect to a different port).

EADDRINUSE
: Local address is already in use.

EADDRNOTAVAIL
: (Internet domain sockets) The socket referred to by *sockfd* had not previously been bound to an address and, upon attempting to bind it to an ephemeral port, it was determined that all port numbers in the ephemeral port range are currently in use. See the discussion of */proc/sys/net/ipv4/ip_local_port_range* in *ip*(7).

EAFNOSUPPORT
: The passed address didn't have the correct address family in its *sa_family* field.

EAGAIN
: For nonblocking UNIX domain sockets, the socket is nonblocking, and the connection cannot be completed immediately. For other socket families, there are insufficient entries in the

routing cache.

EALREADY
The socket is nonblocking and a previous connection attempt has not yet been completed.

EBADF
sockfd is not a valid open file descriptor.

ECONNREFUSED
A **connect**() on a stream socket found no one listening on the remote address.

EFAULT
The socket structure address is outside the user's address space.

EINPROGRESS
The socket is nonblocking and the connection cannot be completed immediately. (UNIX domain sockets failed with **EAGAIN** instead.) It is possible to *select*(2) or *poll*(2) for completion by selecting the socket for writing. After *select*(2) indicates writability, use *getsockopt*(2) to read the **SO_ERROR** option at level **SOL_SOCKET** to determine whether **connect**() completed successfully (**SO_ERROR** is zero) or unsuccessfully (**SO_ERROR** is one of the usual error codes listed here, explaining the reason for the failure).

EINTR
The system call was interrupted by a signal that was caught; see *signal*(7).

EISCONN
The socket is already connected.

ENETUNREACH
Network is unreachable.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

EPROTOTYPE
The socket type does not support the requested communications protocol. This error can occur, for example, on an attempt to connect a UNIX domain datagram socket to a stream socket.

ETIMEDOUT
Timeout while attempting connection. The server may be too busy to accept new connections. Note that for IP sockets the timeout may be very long when syncookies are enabled on the server.

STANDARDS
POSIX.1-2008.

HISTORY
POSIX.1-2001, SVr4, 4.4BSD, (**connect**() first appeared in 4.2BSD).

NOTES
If **connect**() fails, consider the state of the socket as unspecified. Portable applications should close the socket and create a new one for reconnecting.

EXAMPLES
An example of the use of **connect**() is shown in *getaddrinfo*(3).

SEE ALSO
accept(2), *bind*(2), *getsockname*(2), *listen*(2), *socket*(2), *path_resolution*(7), *selinux*(8)

NAME

copy_file_range − Copy a range of data from one file to another

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE
#define _FILE_OFFSET_BITS 64
#include <unistd.h>

ssize_t copy_file_range(int fd_in, off_t *_Nullable off_in,
                        int fd_out, off_t *_Nullable off_out,
                        size_t len, unsigned int flags);
```

DESCRIPTION

The **copy_file_range**() system call performs an in-kernel copy between two file descriptors without the additional cost of transferring data from the kernel to user space and then back into the kernel. It copies up to *len* bytes of data from the source file descriptor *fd_in* to the target file descriptor *fd_out*, overwriting any data that exists within the requested range of the target file.

The following semantics apply for *off_in*, and similar statements apply to *off_out*:

- If *off_in* is NULL, then bytes are read from *fd_in* starting from the file offset, and the file offset is adjusted by the number of bytes copied.
- If *off_in* is not NULL, then *off_in* must point to a buffer that specifies the starting offset where bytes from *fd_in* will be read. The file offset of *fd_in* is not changed, but *off_in* is adjusted appropriately.

fd_in and *fd_out* can refer to the same file. If they refer to the same file, then the source and target ranges are not allowed to overlap.

The *flags* argument is provided to allow for future extensions and currently must be set to 0.

RETURN VALUE

Upon successful completion, **copy_file_range**() will return the number of bytes copied between files. This could be less than the length originally requested. If the file offset of *fd_in* is at or past the end of file, no bytes are copied, and **copy_file_range**() returns zero.

On error, **copy_file_range**() returns −1 and *errno* is set to indicate the error.

ERRORS

EBADF
One or more file descriptors are not valid.

EBADF
fd_in is not open for reading; or *fd_out* is not open for writing.

EBADF
The **O_APPEND** flag is set for the open file description (see *open*(2)) referred to by the file descriptor *fd_out*.

EFBIG
An attempt was made to write at a position past the maximum file offset the kernel supports.

EFBIG
An attempt was made to write a range that exceeds the allowed maximum file size. The maximum file size differs between filesystem implementations and can be different from the maximum allowed file offset.

EFBIG
An attempt was made to write beyond the process's file size resource limit. This may also result in the process receiving a **SIGXFSZ** signal.

EINVAL
The *flags* argument is not 0.

EINVAL
fd_in and *fd_out* refer to the same file and the source and target ranges overlap.

EINVAL
Either *fd_in* or *fd_out* is not a regular file.

EIO A low-level I/O error occurred while copying.

EISDIR
Either *fd_in* or *fd_out* refers to a directory.

ENOMEM
Out of memory.

ENOSPC
There is not enough space on the target filesystem to complete the copy.

EOPNOTSUPP (since Linux 5.19)
The filesystem does not support this operation.

EOVERFLOW
The requested source or destination range is too large to represent in the specified data types.

EPERM
fd_out refers to an immutable file.

ETXTBSY
Either *fd_in* or *fd_out* refers to an active swap file.

EXDEV (before Linux 5.3)
The files referred to by *fd_in* and *fd_out* are not on the same filesystem.

EXDEV (since Linux 5.19)
The files referred to by *fd_in* and *fd_out* are not on the same filesystem, and the source and target filesystems are not of the same type, or do not support cross-filesystem copy.

VERSIONS

A major rework of the kernel implementation occurred in Linux 5.3. Areas of the API that weren't clearly defined were clarified and the API bounds are much more strictly checked than on earlier kernels.

Since Linux 5.19, cross-filesystem copies can be achieved when both filesystems are of the same type, and that filesystem implements support for it. See BUGS for behavior prior to Linux 5.19.

Applications should target the behaviour and requirements of Linux 5.19, that was also backported to earlier stable kernels.

STANDARDS

Linux, GNU.

HISTORY

Linux 4.5, but glibc 2.27 provides a user-space emulation when it is not available.

NOTES

If *fd_in* is a sparse file, then **copy_file_range**() may expand any holes existing in the requested range. Users may benefit from calling **copy_file_range**() in a loop, and using the *lseek*(2) **SEEK_DATA** and **SEEK_HOLE** operations to find the locations of data segments.

copy_file_range() gives filesystems an opportunity to implement "copy acceleration" techniques, such as the use of reflinks (i.e., two or more inodes that share pointers to the same copy-on-write disk blocks) or server-side-copy (in the case of NFS).

_FILE_OFFSET_BITS should be defined to be 64 in code that uses non-null *off_in* or *off_out* or that takes the address of **copy_file_range**, if the code is intended to be portable to traditional 32-bit x86 and ARM platforms where **off_t**'s width defaults to 32 bits.

BUGS

In Linux 5.3 to Linux 5.18, cross-filesystem copies were implemented by the kernel, if the operation was not supported by individual filesystems. However, on some virtual filesystems, the call failed to copy, while still reporting success.

EXAMPLES

```
#define _GNU_SOURCE
#define _FILE_OFFSET_BITS 64
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/stat.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int          fd_in, fd_out;
    off_t        len, ret;
    struct stat  stat;

    if (argc != 3) {
        fprintf(stderr, "Usage: %s <source> <destination>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    fd_in = open(argv[1], O_RDONLY);
    if (fd_in == -1) {
        perror("open (argv[1])");
        exit(EXIT_FAILURE);
    }

    if (fstat(fd_in, &stat) == -1) {
        perror("fstat");
        exit(EXIT_FAILURE);
    }

    len = stat.st_size;

    fd_out = open(argv[2], O_CREAT | O_WRONLY | O_TRUNC, 0644);
    if (fd_out == -1) {
        perror("open (argv[2])");
        exit(EXIT_FAILURE);
    }

    do {
        ret = copy_file_range(fd_in, NULL, fd_out, NULL, len, 0);
        if (ret == -1) {
            perror("copy_file_range");
            exit(EXIT_FAILURE);
        }

        len -= ret;
    } while (len > 0 && ret > 0);

    close(fd_in);
    close(fd_out);
    exit(EXIT_SUCCESS);
}
```

NAME

create_module − create a loadable module entry

SYNOPSIS

#include <linux/module.h>

[[deprecated]] caddr_t create_module(const char ****name*, size_t** *size***);**

DESCRIPTION

Note: This system call is present only before Linux 2.6.

create_module() attempts to create a loadable module entry and reserve the kernel memory that will be needed to hold the module. This system call requires privilege.

RETURN VALUE

On success, returns the kernel address at which the module will reside. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EEXIST
A module by that name already exists.

EFAULT
name is outside the program's accessible address space.

EINVAL
The requested size is too small even for the module header information.

ENOMEM
The kernel could not allocate a contiguous block of memory large enough for the module.

ENOSYS
create_module() is not supported in this version of the kernel (e.g., Linux 2.6 or later).

EPERM
The caller was not privileged (did not have the **CAP_SYS_MODULE** capability).

STANDARDS

Linux.

HISTORY

Removed in Linux 2.6.

This obsolete system call is not supported by glibc. No declaration is provided in glibc headers, but, through a quirk of history, glibc versions before glibc 2.23 did export an ABI for this system call. Therefore, in order to employ this system call, it was sufficient to manually declare the interface in your code; alternatively, you could invoke the system call using *syscall*(2).

SEE ALSO

delete_module(2), *init_module*(2), *query_module*(2)

NAME

delete_module − unload a kernel module

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <fcntl.h>          /* Definition of O_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_delete_module, const char *name, unsigned int flags);
```

Note: glibc provides no wrapper for **delete_module**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **delete_module**() system call attempts to remove the unused loadable module entry identified by *name*. If the module has an *exit* function, then that function is executed before unloading the module. The *flags* argument is used to modify the behavior of the system call, as described below. This system call requires privilege.

Module removal is attempted according to the following rules:

(1) If there are other loaded modules that depend on (i.e., refer to symbols defined in) this module, then the call fails.

(2) Otherwise, if the reference count for the module (i.e., the number of processes currently using the module) is zero, then the module is immediately unloaded.

(3) If a module has a nonzero reference count, then the behavior depends on the bits set in *flags*. In normal usage (see NOTES), the **O_NONBLOCK** flag is always specified, and the **O_TRUNC** flag may additionally be specified.

The various combinations for *flags* have the following effect:

flags == O_NONBLOCK
The call returns immediately, with an error.

flags == (O_NONBLOCK | O_TRUNC)
The module is unloaded immediately, regardless of whether it has a nonzero reference count.

(flags & O_NONBLOCK) == 0
If *flags* does not specify **O_NONBLOCK**, the following steps occur:

- The module is marked so that no new references are permitted.
- If the module's reference count is nonzero, the caller is placed in an uninterruptible sleep state (**TASK_UNINTERRUPTIBLE**) until the reference count is zero, at which point the call unblocks.
- The module is unloaded in the usual way.

The **O_TRUNC** flag has one further effect on the rules described above. By default, if a module has an *init* function but no *exit* function, then an attempt to remove the module fails. However, if **O_TRUNC** was specified, this requirement is bypassed.

Using the **O_TRUNC** flag is dangerous! If the kernel was not built with **CONFIG_MODULE_FORCE_UNLOAD**, this flag is silently ignored. (Normally, **CONFIG_MODULE_FORCE_UNLOAD** is enabled.) Using this flag taints the kernel (TAINT_FORCED_RMMOD).

RETURN VALUE

On success, zero is returned. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBUSY
The module is not "live" (i.e., it is still being initialized or is already marked for removal); or, the module has an *init* function but has no *exit* function, and **O_TRUNC** was not specified in *flags*.

EFAULT
name refers to a location outside the process's accessible address space.

ENOENT
No module by that name exists.

EPERM
The caller was not privileged (did not have the **CAP_SYS_MODULE** capability), or module unloading is disabled (see */proc/sys/kernel/modules_disabled* in *proc*(5)).

EWOULDBLOCK
Other modules depend on this module; or, **O_NONBLOCK** was specified in *flags*, but the reference count of this module is nonzero and **O_TRUNC** was not specified in *flags*.

STANDARDS
Linux.

HISTORY
The **delete_module**() system call is not supported by glibc. No declaration is provided in glibc headers, but, through a quirk of history, glibc versions before glibc 2.23 did export an ABI for this system call. Therefore, in order to employ this system call, it is (before glibc 2.23) sufficient to manually declare the interface in your code; alternatively, you can invoke the system call using *syscall*(2).

Linux 2.4 and earlier
In Linux 2.4 and earlier, the system call took only one argument:

int delete_module(const char *_name_);

If *name* is NULL, all unused modules marked auto-clean are removed.

Some further details of differences in the behavior of **delete_module**() in Linux 2.4 and earlier are *not* currently explained in this manual page.

NOTES
The uninterruptible sleep that may occur if **O_NONBLOCK** is omitted from *flags* is considered undesirable, because the sleeping process is left in an unkillable state. As at Linux 3.7, specifying **O_NONBLOCK** is optional, but in future kernels it is likely to become mandatory.

NAME

dup, dup2, dup3 − duplicate a file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int dup(int oldfd);
int dup2(int oldfd, int newfd);

#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <fcntl.h>          /* Definition of O_* constants */
#include <unistd.h>

int dup3(int oldfd, int newfd, int  flags);
```

DESCRIPTION

The **dup**() system call allocates a new file descriptor that refers to the same open file description as the descriptor *oldfd*. (For an explanation of open file descriptions, see *open*(2).) The new file descriptor number is guaranteed to be the lowest-numbered file descriptor that was unused in the calling process.

After a successful return, the old and new file descriptors may be used interchangeably. Since the two file descriptors refer to the same open file description, they share file offset and file status flags; for example, if the file offset is modified by using *lseek*(2) on one of the file descriptors, the offset is also changed for the other file descriptor.

The two file descriptors do not share file descriptor flags (the close-on-exec flag). The close-on-exec flag (**FD_CLOEXEC**; see *fcntl*(2)) for the duplicate descriptor is off.

dup2()

The **dup2**() system call performs the same task as **dup**(), but instead of using the lowest-numbered unused file descriptor, it uses the file descriptor number specified in *newfd*. In other words, the file descriptor *newfd* is adjusted so that it now refers to the same open file description as *oldfd*.

If the file descriptor *newfd* was previously open, it is closed before being reused; the close is performed silently (i.e., any errors during the close are not reported by *dup2*())

The steps of closing and reusing the file descriptor *newfd* are performed *atomically*. This is important, because trying to implement equivalent functionality using *close*(2) and **dup**() would be subject to race conditions, whereby *newfd* might be reused between the two steps. Such reuse could happen because the main program is interrupted by a signal handler that allocates a file descriptor, or because a parallel thread allocates a file descriptor.

Note the following points:

- If *oldfd* is not a valid file descriptor, then the call fails, and *newfd* is not closed.
- If *oldfd* is a valid file descriptor, and *newfd* has the same value as *oldfd*, then **dup2**() does nothing, and returns *newfd*.

dup3()

dup3() is the same as **dup2**(), except that:

- The caller can force the close-on-exec flag to be set for the new file descriptor by specifying **O_CLOEXEC** in *flags*. See the description of the same flag in *open*(2) for reasons why this may be useful.
- If *oldfd* equals *newfd*, then **dup3**() fails with the error **EINVAL**.

RETURN VALUE

On success, these system calls return the new file descriptor. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF

oldfd isn't an open file descriptor.

EBADF
newfd is out of the allowed range for file descriptors (see the discussion of **RLIMIT_NOFILE** in *getrlimit*(2)).

EBUSY
(Linux only) This may be returned by **dup2**() or **dup3**() during a race condition with *open*(2) and **dup**().

EINTR
The **dup2**() or **dup3**() call was interrupted by a signal; see *signal*(7).

EINVAL
(**dup3**()) *flags* contain an invalid value.

EINVAL
(**dup3**()) *oldfd* was equal to *newfd*.

EMFILE
The per-process limit on the number of open file descriptors has been reached (see the discussion of **RLIMIT_NOFILE** in *getrlimit*(2)).

STANDARDS

dup()
dup2() POSIX.1-2008.

dup3() Linux.

HISTORY

dup()
dup2() POSIX.1-2001, SVr4, 4.3BSD.

dup3() Linux 2.6.27, glibc 2.9.

NOTES

The error returned by **dup2**() is different from that returned by **fcntl(**..., **F_DUPFD**, ...**)** when *newfd* is out of range. On some systems, **dup2**() also sometimes returns **EINVAL** like **F_DUPFD**.

If *newfd* was open, any errors that would have been reported at *close*(2) time are lost. If this is of concern, then—unless the program is single-threaded and does not allocate file descriptors in signal handlers—the correct approach is *not* to close *newfd* before calling **dup2**(), because of the race condition described above. Instead, code something like the following could be used:

```
/* Obtain a duplicate of 'newfd' that can subsequently
   be used to check for close() errors; an EBADF error
   means that 'newfd' was not open. */

tmpfd = dup(newfd);
if (tmpfd == -1 && errno != EBADF) {
    /* Handle unexpected dup() error. */
}

/* Atomically duplicate 'oldfd' on 'newfd'. */

if (dup2(oldfd, newfd) == -1) {
    /* Handle dup2() error. */
}

/* Now check for close() errors on the file originally
   referred to by 'newfd'. */

if (tmpfd != -1) {
    if (close(tmpfd) == -1) {
        /* Handle errors from close. */
    }
}
```

NAME

epoll_create, epoll_create1 − open an epoll file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/epoll.h>

int epoll_create(int *size***);**
int epoll_create1(int *flags***);**

DESCRIPTION

epoll_create() creates a new *epoll*(7) instance. Since Linux 2.6.8, the *size* argument is ignored, but must be greater than zero; see HISTORY.

epoll_create() returns a file descriptor referring to the new epoll instance. This file descriptor is used for all the subsequent calls to the **epoll** interface. When no longer required, the file descriptor returned by **epoll_create**() should be closed by using *close*(2). When all file descriptors referring to an epoll instance have been closed, the kernel destroys the instance and releases the associated resources for reuse.

epoll_create1()

If *flags* is 0, then, other than the fact that the obsolete *size* argument is dropped, **epoll_create1**() is the same as **epoll_create**(). The following value can be included in *flags* to obtain different behavior:

EPOLL_CLOEXEC
Set the close-on-exec (**FD_CLOEXEC**) flag on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

RETURN VALUE

On success, these system calls return a file descriptor (a nonnegative integer). On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
size is not positive.

EINVAL
(**epoll_create1**()) Invalid value specified in *flags*.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENOMEM
There was insufficient memory to create the kernel object.

STANDARDS

Linux.

HISTORY

epoll_create()
Linux 2.6, glibc 2.3.2.

epoll_create1()
Linux 2.6.27, glibc 2.9.

In the initial **epoll_create**() implementation, the *size* argument informed the kernel of the number of file descriptors that the caller expected to add to the **epoll** instance. The kernel used this information as a hint for the amount of space to initially allocate in internal data structures describing events. (If necessary, the kernel would allocate more space if the caller's usage exceeded the hint given in *size*.) Nowadays, this hint is no longer required (the kernel dynamically sizes the required data structures without needing the hint), but *size* must still be greater than zero, in order to ensure backward compatibility when new **epoll** applications are run on older kernels.

Prior to Linux 2.6.29, a */proc/sys/fs/epoll/max_user_instances* kernel parameter limited live epolls for

each real user ID, and caused **epoll_create**() to fail with **EMFILE** on overrun.

SEE ALSO

close(2), *epoll_ctl*(2), *epoll_wait*(2), *epoll*(7)

NAME

epoll_ctl − control interface for an epoll file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/epoll.h>

int epoll_ctl(int epfd, int op, int fd,
              struct epoll_event *_Nullable event);
```

DESCRIPTION

This system call is used to add, modify, or remove entries in the interest list of the *epoll*(7) instance referred to by the file descriptor *epfd*. It requests that the operation *op* be performed for the target file descriptor, *fd*.

Valid values for the *op* argument are:

EPOLL_CTL_ADD
: Add an entry to the interest list of the epoll file descriptor, *epfd*. The entry includes the file descriptor, *fd*, a reference to the corresponding open file description (see *epoll*(7) and *open*(2)), and the settings specified in *event*.

EPOLL_CTL_MOD
: Change the settings associated with *fd* in the interest list to the new settings specified in *event*.

EPOLL_CTL_DEL
: Remove (deregister) the target file descriptor *fd* from the interest list. The *event* argument is ignored and can be NULL (but see BUGS below).

The *event* argument describes the object linked to the file descriptor *fd*. The *struct epoll_event* is described in *epoll_event*(3type).

The *data* member of the *epoll_event* structure specifies data that the kernel should save and then return (via *epoll_wait*(2)) when this file descriptor becomes ready.

The *events* member of the *epoll_event* structure is a bit mask composed by ORing together zero or more event types, returned by *epoll_wait*(2), and input flags, which affect its behaviour, but aren't returned. The available event types are:

EPOLLIN
: The associated file is available for *read*(2) operations.

EPOLLOUT
: The associated file is available for *write*(2) operations.

EPOLLRDHUP (since Linux 2.6.17)
: Stream socket peer closed connection, or shut down writing half of connection. (This flag is especially useful for writing simple code to detect peer shutdown when using edge-triggered monitoring.)

EPOLLPRI
: There is an exceptional condition on the file descriptor. See the discussion of **POLLPRI** in *poll*(2).

EPOLLERR
: Error condition happened on the associated file descriptor. This event is also reported for the write end of a pipe when the read end has been closed.

  epoll_wait(2) will always report for this event; it is not necessary to set it in *events* when calling **epoll_ctl**().

EPOLLHUP
: Hang up happened on the associated file descriptor.

  epoll_wait(2) will always wait for this event; it is not necessary to set it in *events* when calling **epoll_ctl**().

  Note that when reading from a channel such as a pipe or a stream socket, this event merely indicates that the peer closed its end of the channel. Subsequent reads from the channel will

return 0 (end of file) only after all outstanding data in the channel has been consumed.

And the available input flags are:

EPOLLET
Requests edge-triggered notification for the associated file descriptor. The default behavior for **epoll** is level-triggered. See *epoll*(7) for more detailed information about edge-triggered and level-triggered notification.

EPOLLONESHOT (since Linux 2.6.2)
Requests one-shot notification for the associated file descriptor. This means that after an event notified for the file descriptor by *epoll_wait*(2), the file descriptor is disabled in the interest list and no other events will be reported by the **epoll** interface. The user must call **epoll_ctl**() with **EPOLL_CTL_MOD** to rearm the file descriptor with a new event mask.

EPOLLWAKEUP (since Linux 3.5)
If **EPOLLONESHOT** and **EPOLLET** are clear and the process has the **CAP_BLOCK_SUSPEND** capability, ensure that the system does not enter "suspend" or "hibernate" while this event is pending or being processed. The event is considered as being "processed" from the time when it is returned by a call to *epoll_wait*(2) until the next call to *epoll_wait*(2) on the same *epoll*(7) file descriptor, the closure of that file descriptor, the removal of the event file descriptor with **EPOLL_CTL_DEL**, or the clearing of **EPOLLWAKEUP** for the event file descriptor with **EPOLL_CTL_MOD**. See also BUGS.

EPOLLEXCLUSIVE (since Linux 4.5)
Sets an exclusive wakeup mode for the epoll file descriptor that is being attached to the target file descriptor, *fd*. When a wakeup event occurs and multiple epoll file descriptors are attached to the same target file using **EPOLLEXCLUSIVE**, one or more of the epoll file descriptors will receive an event with *epoll_wait*(2). The default in this scenario (when **EPOLLEXCLUSIVE** is not set) is for all epoll file descriptors to receive an event. **EPOLLEXCLUSIVE** is thus useful for avoiding thundering herd problems in certain scenarios.

If the same file descriptor is in multiple epoll instances, some with the **EPOLLEXCLUSIVE** flag, and others without, then events will be provided to all epoll instances that did not specify **EPOLLEXCLUSIVE**, and at least one of the epoll instances that did specify **EPOLLEXCLUSIVE**.

The following values may be specified in conjunction with **EPOLLEXCLUSIVE**: **EPOLLIN**, **EPOLLOUT**, **EPOLLWAKEUP**, and **EPOLLET**. **EPOLLHUP** and **EPOLLERR** can also be specified, but this is not required: as usual, these events are always reported if they occur, regardless of whether they are specified in *events*. Attempts to specify other values in *events* yield the error **EINVAL**.

EPOLLEXCLUSIVE may be used only in an **EPOLL_CTL_ADD** operation; attempts to employ it with **EPOLL_CTL_MOD** yield an error. If **EPOLLEXCLUSIVE** has been set using **epoll_ctl**(), then a subsequent **EPOLL_CTL_MOD** on the same *epfd*, *fd* pair yields an error. A call to **epoll_ctl**() that specifies **EPOLLEXCLUSIVE** in *events* and specifies the target file descriptor *fd* as an epoll instance will likewise fail. The error in all of these cases is **EINVAL**.

RETURN VALUE
When successful, **epoll_ctl**() returns zero. When an error occurs, **epoll_ctl**() returns −1 and *errno* is set to indicate the error.

ERRORS
EBADF
epfd or *fd* is not a valid file descriptor.

EEXIST
op was **EPOLL_CTL_ADD**, and the supplied file descriptor *fd* is already registered with this epoll instance.

EINVAL
epfd is not an **epoll** file descriptor, or *fd* is the same as *epfd*, or the requested operation *op* is not supported by this interface.

EINVAL
An invalid event type was specified along with **EPOLLEXCLUSIVE** in *events*.

EINVAL
op was **EPOLL_CTL_MOD** and *events* included **EPOLLEXCLUSIVE**.

EINVAL
op was **EPOLL_CTL_MOD** and the **EPOLLEXCLUSIVE** flag has previously been applied to this *epfd*, *fd* pair.

EINVAL
EPOLLEXCLUSIVE was specified in *event* and *fd* refers to an epoll instance.

ELOOP
fd refers to an epoll instance and this **EPOLL_CTL_ADD** operation would result in a circular loop of epoll instances monitoring one another or a nesting depth of epoll instances greater than 5.

ENOENT
op was **EPOLL_CTL_MOD** or **EPOLL_CTL_DEL**, and *fd* is not registered with this epoll instance.

ENOMEM
There was insufficient memory to handle the requested *op* control operation.

ENOSPC
The limit imposed by */proc/sys/fs/epoll/max_user_watches* was encountered while trying to register (**EPOLL_CTL_ADD**) a new file descriptor on an epoll instance. See *epoll*(7) for further details.

EPERM
The target file *fd* does not support **epoll**. This error can occur if *fd* refers to, for example, a regular file or a directory.

STANDARDS
Linux.

HISTORY
Linux 2.6, glibc 2.3.2.

NOTES
The **epoll** interface supports all file descriptors that support *poll*(2).

BUGS
Before Linux 2.6.9, the **EPOLL_CTL_DEL** operation required a non-null pointer in *event*, even though this argument is ignored. Since Linux 2.6.9, *event* can be specified as NULL when using **EPOLL_CTL_DEL**. Applications that need to be portable to kernels before Linux 2.6.9 should specify a non-null pointer in *event*.

If **EPOLLWAKEUP** is specified in *flags*, but the caller does not have the **CAP_BLOCK_SUSPEND** capability, then the **EPOLLWAKEUP** flag is *silently ignored*. This unfortunate behavior is necessary because no validity checks were performed on the *flags* argument in the original implementation, and the addition of the **EPOLLWAKEUP** with a check that caused the call to fail if the caller did not have the **CAP_BLOCK_SUSPEND** capability caused a breakage in at least one existing user-space application that happened to randomly (and uselessly) specify this bit. A robust application should therefore double check that it has the **CAP_BLOCK_SUSPEND** capability if attempting to use the **EPOLLWAKEUP** flag.

NAME

epoll_wait, epoll_pwait, epoll_pwait2 − wait for an I/O event on an epoll file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/epoll.h>

int epoll_wait(int epfd, struct epoll_event *events,
               int maxevents, int timeout);
int epoll_pwait(int epfd, struct epoll_event *events,
               int maxevents, int timeout,
               const sigset_t *_Nullable sigmask);
int epoll_pwait2(int epfd, struct epoll_event *events,
               int maxevents, const struct timespec *_Nullable timeout,
               const sigset_t *_Nullable sigmask);
```

DESCRIPTION

The **epoll_wait**() system call waits for events on the *epoll*(7) instance referred to by the file descriptor *epfd*. The buffer pointed to by *events* is used to return information from the ready list about file descriptors in the interest list that have some events available. Up to *maxevents* are returned by **epoll_wait**(). The *maxevents* argument must be greater than zero.

The *timeout* argument specifies the number of milliseconds that **epoll_wait**() will block. Time is measured against the **CLOCK_MONOTONIC** clock.

A call to **epoll_wait**() will block until either:

- a file descriptor delivers an event;
- the call is interrupted by a signal handler; or
- the timeout expires.

Note that the *timeout* interval will be rounded up to the system clock granularity, and kernel scheduling delays mean that the blocking interval may overrun by a small amount. Specifying a *timeout* of −1 causes **epoll_wait**() to block indefinitely, while specifying a *timeout* equal to zero causes **epoll_wait**() to return immediately, even if no events are available.

The *struct epoll_event* is described in *epoll_event*(3type).

The *data* field of each returned *epoll_event* structure contains the same data as was specified in the most recent call to *epoll_ctl*(2) (**EPOLL_CTL_ADD**, **EPOLL_CTL_MOD**) for the corresponding open file descriptor.

The *events* field is a bit mask that indicates the events that have occurred for the corresponding open file description. See *epoll_ctl*(2) for a list of the bits that may appear in this mask.

epoll_pwait()

The relationship between **epoll_wait**() and **epoll_pwait**() is analogous to the relationship between *select*(2) and *pselect*(2): like *pselect*(2), **epoll_pwait**() allows an application to safely wait until either a file descriptor becomes ready or until a signal is caught.

The following **epoll_pwait**() call:

```
ready = epoll_pwait(epfd, &events, maxevents, timeout, &sigmask);
```

is equivalent to *atomically* executing the following calls:

```
sigset_t origmask;

pthread_sigmask(SIG_SETMASK, &sigmask, &origmask);
ready = epoll_wait(epfd, &events, maxevents, timeout);
pthread_sigmask(SIG_SETMASK, &origmask, NULL);
```

The *sigmask* argument may be specified as NULL, in which case **epoll_pwait**() is equivalent to **epoll_wait**().

epoll_pwait2()
The **epoll_pwait2**() system call is equivalent to **epoll_pwait**() except for the *timeout* argument. It takes an argument of type *timespec* to be able to specify nanosecond resolution timeout. This argument functions the same as in *pselect*(2) and *ppoll*(2). If *timeout* is NULL, then **epoll_pwait2**() can block indefinitely.

RETURN VALUE
On success, **epoll_wait**() returns the number of file descriptors ready for the requested I/O operation, or zero if no file descriptor became ready during the requested *timeout* milliseconds. On failure, **epoll_wait**() returns −1 and *errno* is set to indicate the error.

ERRORS
EBADF
epfd is not a valid file descriptor.

EFAULT
The memory area pointed to by *events* is not accessible with write permissions.

EINTR
The call was interrupted by a signal handler before either (1) any of the requested events occurred or (2) the *timeout* expired; see *signal*(7).

EINVAL
epfd is not an **epoll** file descriptor, or *maxevents* is less than or equal to zero.

STANDARDS
Linux.

HISTORY
epoll_wait()
Linux 2.6, glibc 2.3.2.

epoll_pwait()
Linux 2.6.19, glibc 2.6.

epoll_pwait2()
Linux 5.11.

NOTES
While one thread is blocked in a call to **epoll_wait**(), it is possible for another thread to add a file descriptor to the waited-upon **epoll** instance. If the new file descriptor becomes ready, it will cause the **epoll_wait**() call to unblock.

If more than *maxevents* file descriptors are ready when **epoll_wait**() is called, then successive **epoll_wait**() calls will round robin through the set of ready file descriptors. This behavior helps avoid starvation scenarios, where a process fails to notice that additional file descriptors are ready because it focuses on a set of file descriptors that are already known to be ready.

Note that it is possible to call **epoll_wait**() on an **epoll** instance whose interest list is currently empty (or whose interest list becomes empty because file descriptors are closed or removed from the interest in another thread). The call will block until some file descriptor is later added to the interest list (in another thread) and that file descriptor becomes ready.

C library/kernel differences
The raw **epoll_pwait**() and **epoll_pwait2**() system calls have a sixth argument, *size_t sigsetsize*, which specifies the size in bytes of the *sigmask* argument. The glibc **epoll_pwait**() wrapper function specifies this argument as a fixed value (equal to *sizeof(sigset_t)*).

BUGS
Before Linux 2.6.37, a *timeout* value larger than approximately *LONG_MAX / HZ* milliseconds is treated as −1 (i.e., infinity). Thus, for example, on a system where *sizeof(long)* is 4 and the kernel *HZ* value is 1000, this means that timeouts greater than 35.79 minutes are treated as infinity.

NAME

eventfd − create a file descriptor for event notification

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/eventfd.h>

int eventfd(unsigned int *initval***, int** *flags***);**

DESCRIPTION

eventfd() creates an "eventfd object" that can be used as an event wait/notify mechanism by user-space applications, and by the kernel to notify user-space applications of events. The object contains an unsigned 64-bit integer (*uint64_t*) counter that is maintained by the kernel. This counter is initialized with the value specified in the argument *initval*.

As its return value, **eventfd**() returns a new file descriptor that can be used to refer to the eventfd object.

The following values may be bitwise ORed in *flags* to change the behavior of **eventfd**():

EFD_CLOEXEC (since Linux 2.6.27)
: Set the close-on-exec (**FD_CLOEXEC**) flag on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

EFD_NONBLOCK (since Linux 2.6.27)
: Set the **O_NONBLOCK** file status flag on the open file description (see *open*(2)) referred to by the new file descriptor. Using this flag saves extra calls to *fcntl*(2) to achieve the same result.

EFD_SEMAPHORE (since Linux 2.6.30)
: Provide semaphore-like semantics for reads from the new file descriptor. See below.

Up to Linux 2.6.26, the *flags* argument is unused, and must be specified as zero.

The following operations can be performed on the file descriptor returned by **eventfd**():

read(2) Each successful *read*(2) returns an 8-byte integer. A *read*(2) fails with the error **EINVAL** if the size of the supplied buffer is less than 8 bytes.

The value returned by *read*(2) is in host byte order—that is, the native byte order for integers on the host machine.

The semantics of *read*(2) depend on whether the eventfd counter currently has a nonzero value and whether the **EFD_SEMAPHORE** flag was specified when creating the eventfd file descriptor:

- If **EFD_SEMAPHORE** was not specified and the eventfd counter has a nonzero value, then a *read*(2) returns 8 bytes containing that value, and the counter's value is reset to zero.
- If **EFD_SEMAPHORE** was specified and the eventfd counter has a nonzero value, then a *read*(2) returns 8 bytes containing the value 1, and the counter's value is decremented by 1.
- If the eventfd counter is zero at the time of the call to *read*(2), then the call either blocks until the counter becomes nonzero (at which time, the *read*(2) proceeds as described above) or fails with the error **EAGAIN** if the file descriptor has been made nonblocking.

write(2)
: A *write*(2) call adds the 8-byte integer value supplied in its buffer to the counter. The maximum value that may be stored in the counter is the largest unsigned 64-bit value minus 1 (i.e., 0xfffffffffffffffe). If the addition would cause the counter's value to exceed the maximum, then the *write*(2) either blocks until a *read*(2) is performed on the file descriptor, or fails with the error **EAGAIN** if the file descriptor has been made nonblocking.

A *write*(2) fails with the error **EINVAL** if the size of the supplied buffer is less than 8 bytes, or if an attempt is made to write the value 0xffffffffffffffff.

poll(2)

select(2)
(and similar)
The returned file descriptor supports *poll*(2) (and analogously *epoll*(7)) and *select*(2), as follows:

- The file descriptor is readable (the *select*(2) *readfds* argument; the *poll*(2) **POLLIN** flag) if the counter has a value greater than 0.
- The file descriptor is writable (the *select*(2) *writefds* argument; the *poll*(2) **POLLOUT** flag) if it is possible to write a value of at least "1" without blocking.
- If an overflow of the counter value was detected, then *select*(2) indicates the file descriptor as being both readable and writable, and *poll*(2) returns a **POLLERR** event. As noted above, *write*(2) can never overflow the counter. However an overflow can occur if 2^64 eventfd "signal posts" were performed by the KAIO subsystem (theoretically possible, but practically unlikely). If an overflow has occurred, then *read*(2) will return that maximum *uint64_t* value (i.e., 0xffffffffffffffff).

The eventfd file descriptor also supports the other file-descriptor multiplexing APIs: *pselect*(2) and *ppoll*(2).

close(2)
When the file descriptor is no longer required it should be closed. When all file descriptors associated with the same eventfd object have been closed, the resources for object are freed by the kernel.

A copy of the file descriptor created by **eventfd**() is inherited by the child produced by *fork*(2). The duplicate file descriptor is associated with the same eventfd object. File descriptors created by **eventfd**() are preserved across *execve*(2), unless the close-on-exec flag has been set.

RETURN VALUE

On success, **eventfd**() returns a new eventfd file descriptor. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EINVAL
An unsupported value was specified in *flags*.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENODEV
Could not mount (internal) anonymous inode device.

ENOMEM
There was insufficient memory to create a new eventfd file descriptor.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
eventfd()	Thread safety	MT-Safe

VERSIONS

C library/kernel differences

There are two underlying Linux system calls: **eventfd**() and the more recent **eventfd2**(). The former system call does not implement a *flags* argument. The latter system call implements the *flags* values described above. The glibc wrapper function will use **eventfd2**() where it is available.

Additional glibc features

The GNU C library defines an additional type, and two functions that attempt to abstract some of the details of reading and writing on an eventfd file descriptor:

```
typedef uint64_t eventfd_t;

int eventfd_read(int fd, eventfd_t *value);
```

```
int eventfd_write(int fd, eventfd_t value);
```

The functions perform the read and write operations on an eventfd file descriptor, returning 0 if the correct number of bytes was transferred, or −1 otherwise.

STANDARDS

Linux, GNU.

HISTORY

eventfd()
: Linux 2.6.22, glibc 2.8.

eventfd2()
: Linux 2.6.27 (see VERSIONS). Since glibc 2.9, the **eventfd**() wrapper will employ the **eventfd2**() system call, if it is supported by the kernel.

NOTES

Applications can use an eventfd file descriptor instead of a pipe (see *pipe*(2)) in all cases where a pipe is used simply to signal events. The kernel overhead of an eventfd file descriptor is much lower than that of a pipe, and only one file descriptor is required (versus the two required for a pipe).

When used in the kernel, an eventfd file descriptor can provide a bridge from kernel to user space, allowing, for example, functionalities like KAIO (kernel AIO) to signal to a file descriptor that some operation is complete.

A key point about an eventfd file descriptor is that it can be monitored just like any other file descriptor using *select*(2), *poll*(2), or *epoll*(7). This means that an application can simultaneously monitor the readiness of "traditional" files and the readiness of other kernel mechanisms that support the eventfd interface. (Without the **eventfd**() interface, these mechanisms could not be multiplexed via *select*(2), *poll*(2), or *epoll*(7).)

The current value of an eventfd counter can be viewed via the entry for the corresponding file descriptor in the process's */proc/*pid*/fdinfo* directory. See *proc*(5) for further details.

EXAMPLES

The following program creates an eventfd file descriptor and then forks to create a child process. While the parent briefly sleeps, the child writes each of the integers supplied in the program's command-line arguments to the eventfd file descriptor. When the parent has finished sleeping, it reads from the eventfd file descriptor.

The following shell session shows a sample run of the program:

```
$ ./a.out 1 2 4 7 14
Child writing 1 to efd
Child writing 2 to efd
Child writing 4 to efd
Child writing 7 to efd
Child writing 14 to efd
Child completed write loop
Parent about to read
Parent read 28 (0x1c) from efd
```

Program source

```
#include <err.h>
#include <inttypes.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/eventfd.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int       efd;
    uint64_t  u;
```

```
        ssize_t   s;

        if (argc < 2) {
            fprintf(stderr, "Usage: %s <num>...\n", argv[0]);
            exit(EXIT_FAILURE);
        }

        efd = eventfd(0, 0);
        if (efd == -1)
            err(EXIT_FAILURE, "eventfd");

        switch (fork()) {
        case 0:
            for (size_t j = 1; j < argc; j++) {
                printf("Child writing %s to efd\n", argv[j]);
                u = strtoull(argv[j], NULL, 0);
                        /* strtoull() allows various bases */
                s = write(efd, &u, sizeof(uint64_t));
                if (s != sizeof(uint64_t))
                    err(EXIT_FAILURE, "write");
            }
            printf("Child completed write loop\n");

            exit(EXIT_SUCCESS);

        default:
            sleep(2);

            printf("Parent about to read\n");
            s = read(efd, &u, sizeof(uint64_t));
            if (s != sizeof(uint64_t))
                err(EXIT_FAILURE, "read");
            printf("Parent read %"PRIu64" (%#"PRIx64") from efd\n", u, u);
            exit(EXIT_SUCCESS);

        case -1:
            err(EXIT_FAILURE, "fork");
        }
    }
```

NAME

execve − execute program

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int execve(const char ****pathname*, char *const _Nullable** *argv***[],**
char *const _Nullable *envp***[]);**

DESCRIPTION

execve() executes the program referred to by *pathname*. This causes the program that is currently being run by the calling process to be replaced with a new program, with newly initialized stack, heap, and (initialized and uninitialized) data segments.

pathname must be either a binary executable, or a script starting with a line of the form:

```
#!interpreter [optional-arg]
```

For details of the latter case, see "Interpreter scripts" below.

argv is an array of pointers to strings passed to the new program as its command-line arguments. By convention, the first of these strings (i.e., *argv[0]*) should contain the filename associated with the file being executed. The *argv* array must be terminated by a null pointer. (Thus, in the new program, *argv[argc]* will be a null pointer.)

envp is an array of pointers to strings, conventionally of the form **key=value**, which are passed as the environment of the new program. The *envp* array must be terminated by a null pointer.

This manual page describes the Linux system call in detail; for an overview of the nomenclature and the many, often preferable, standardised variants of this function provided by libc, including ones that search the **PATH** environment variable, see *exec*(3).

The argument vector and environment can be accessed by the new program's main function, when it is defined as:

```
int main(int argc, char *argv[], char *envp[])
```

Note, however, that the use of a third argument to the main function is not specified in POSIX.1; according to POSIX.1, the environment should be accessed via the external variable *environ*(7).

execve() does not return on success, and the text, initialized data, uninitialized data (bss), and stack of the calling process are overwritten according to the contents of the newly loaded program.

If the current program is being ptraced, a **SIGTRAP** signal is sent to it after a successful **execve**().

If the set-user-ID bit is set on the program file referred to by *pathname*, then the effective user ID of the calling process is changed to that of the owner of the program file. Similarly, if the set-group-ID bit is set on the program file, then the effective group ID of the calling process is set to the group of the program file.

The aforementioned transformations of the effective IDs are *not* performed (i.e., the set-user-ID and set-group-ID bits are ignored) if any of the following is true:

- the *no_new_privs* attribute is set for the calling thread (see *prctl*(2));
- the underlying filesystem is mounted *nosuid* (the **MS_NOSUID** flag for *mount*(2)); or
- the calling process is being ptraced.

The capabilities of the program file (see *capabilities*(7)) are also ignored if any of the above are true.

The effective user ID of the process is copied to the saved set-user-ID; similarly, the effective group ID is copied to the saved set-group-ID. This copying takes place after any effective ID changes that occur because of the set-user-ID and set-group-ID mode bits.

The process's real UID and real GID, as well as its supplementary group IDs, are unchanged by a call to **execve**().

If the executable is an a.out dynamically linked binary executable containing shared-library stubs, the Linux dynamic linker *ld.so*(8) is called at the start of execution to bring needed shared objects into

memory and link the executable with them.

If the executable is a dynamically linked ELF executable, the interpreter named in the PT_INTERP segment is used to load the needed shared objects. This interpreter is typically */lib/ld−linux.so.2* for binaries linked with glibc (see *ld-linux.so*(8)).

Effect on process attributes

All process attributes are preserved during an **execve**(), except the following:

- The dispositions of any signals that are being caught are reset to the default (**signal**(7)).
- Any alternate signal stack is not preserved (**sigaltstack**(2)).
- Memory mappings are not preserved (**mmap**(2)).
- Attached System V shared memory segments are detached (**shmat**(2)).
- POSIX shared memory regions are unmapped (**shm_open**(3)).
- Open POSIX message queue descriptors are closed (**mq_overview**(7)).
- Any open POSIX named semaphores are closed (**sem_overview**(7)).
- POSIX timers are not preserved (**timer_create**(2)).
- Any open directory streams are closed (**opendir**(3)).
- Memory locks are not preserved (**mlock**(2), *mlockall*(2)).
- Exit handlers are not preserved (**atexit**(3), *on_exit*(3)).
- The floating-point environment is reset to the default (see *fenv*(3)).

The process attributes in the preceding list are all specified in POSIX.1. The following Linux-specific process attributes are also not preserved during an **execve**():

- The process's "dumpable" attribute is set to the value 1, unless a set-user-ID program, a set-group-ID program, or a program with capabilities is being executed, in which case the dumpable flag may instead be reset to the value in */proc/sys/fs/suid_dumpable*, in the circumstances described under **PR_SET_DUMPABLE** in *prctl*(2). Note that changes to the "dumpable" attribute may cause ownership of files in the process's */proc/*pid directory to change to *root:root*, as described in *proc*(5).
- The *prctl*(2) **PR_SET_KEEPCAPS** flag is cleared.
- (Since Linux 2.4.36 / 2.6.23) If a set-user-ID or set-group-ID program is being executed, then the parent death signal set by *prctl*(2) **PR_SET_PDEATHSIG** flag is cleared.
- The process name, as set by *prctl*(2) **PR_SET_NAME** (and displayed by *ps −o comm*), is reset to the name of the new executable file.
- The **SECBIT_KEEP_CAPS** *securebits* flag is cleared. See *capabilities*(7).
- The termination signal is reset to **SIGCHLD** (see *clone*(2)).
- The file descriptor table is unshared, undoing the effect of the **CLONE_FILES** flag of *clone*(2).

Note the following further points:

- All threads other than the calling thread are destroyed during an **execve**(). Mutexes, condition variables, and other pthreads objects are not preserved.
- The equivalent of *setlocale(LC_ALL, "C")* is executed at program start-up.
- POSIX.1 specifies that the dispositions of any signals that are ignored or set to the default are left unchanged. POSIX.1 specifies one exception: if **SIGCHLD** is being ignored, then an implementation may leave the disposition unchanged or reset it to the default; Linux does the former.
- Any outstanding asynchronous I/O operations are canceled (**aio_read**(3), *aio_write*(3)).
- For the handling of capabilities during **execve**(), see *capabilities*(7).
- By default, file descriptors remain open across an **execve**(). File descriptors that are marked close-on-exec are closed; see the description of **FD_CLOEXEC** in *fcntl*(2). (If a file descriptor is closed, this will cause the release of all record locks obtained on the underlying file by this process. See *fcntl*(2) for details.) POSIX.1 says that if file descriptors 0, 1, and 2 would otherwise be closed after a successful **execve**(), and the process would gain privilege because the set-user-ID or set-group-ID

mode bit was set on the executed file, then the system may open an unspecified file for each of these file descriptors. As a general principle, no portable program, whether privileged or not, can assume that these three file descriptors will remain closed across an **execve**().

Interpreter scripts

An interpreter script is a text file that has execute permission enabled and whose first line is of the form:

```
#!interpreter [optional-arg]
```

The *interpreter* must be a valid pathname for an executable file.

If the *pathname* argument of **execve**() specifies an interpreter script, then *interpreter* will be invoked with the following arguments:

```
interpreter [optional-arg] pathname arg...
```

where *pathname* is the pathname of the file specified as the first argument of **execve**(), and *arg...* is the series of words pointed to by the *argv* argument of **execve**(), starting at *argv[1]*. Note that there is no way to get the *argv[0]* that was passed to the **execve**() call.

For portable use, *optional-arg* should either be absent, or be specified as a single word (i.e., it should not contain white space); see NOTES below.

Since Linux 2.6.28, the kernel permits the interpreter of a script to itself be a script. This permission is recursive, up to a limit of four recursions, so that the interpreter may be a script which is interpreted by a script, and so on.

Limits on size of arguments and environment

Most UNIX implementations impose some limit on the total size of the command-line argument (*argv*) and environment (*envp*) strings that may be passed to a new program. POSIX.1 allows an implementation to advertise this limit using the **ARG_MAX** constant (either defined in <*limits.h*> or available at run time using the call *sysconf(_SC_ARG_MAX)*).

Before Linux 2.6.23, the memory used to store the environment and argument strings was limited to 32 pages (defined by the kernel constant **MAX_ARG_PAGES**). On architectures with a 4-kB page size, this yields a maximum size of 128 kB.

On Linux 2.6.23 and later, most architectures support a size limit derived from the soft **RLIMIT_STACK** resource limit (see *getrlimit*(2)) that is in force at the time of the **execve**() call. (Architectures with no memory management unit are excepted: they maintain the limit that was in effect before Linux 2.6.23.) This change allows programs to have a much larger argument and/or environment list. For these architectures, the total size is limited to 1/4 of the allowed stack size. (Imposing the 1/4-limit ensures that the new program always has some stack space.) Additionally, the total size is limited to 3/4 of the value of the kernel constant **_STK_LIM** (8 MiB). Since Linux 2.6.25, the kernel also places a floor of 32 pages on this size limit, so that, even when **RLIMIT_STACK** is set very low, applications are guaranteed to have at least as much argument and environment space as was provided by Linux 2.6.22 and earlier. (This guarantee was not provided in Linux 2.6.23 and 2.6.24.) Additionally, the limit per string is 32 pages (the kernel constant **MAX_ARG_STRLEN**), and the maximum number of strings is 0x7FFFFFFF.

RETURN VALUE

On success, **execve**() does not return, on error −1 is returned, and *errno* is set to indicate the error.

ERRORS

E2BIG The total number of bytes in the environment (*envp*) and argument list (*argv*) is too large, an argument or environment string is too long, or the full *pathname* of the executable is too long. The terminating null byte is counted as part of the string length.

EACCES

Search permission is denied on a component of the path prefix of *pathname* or the name of a script interpreter. (See also *path_resolution*(7).)

EACCES

The file or a script interpreter is not a regular file.

EACCES
Execute permission is denied for the file or a script or ELF interpreter.

EACCES
The filesystem is mounted *noexec*.

EAGAIN (since Linux 3.1)
Having changed its real UID using one of the **set*uid**() calls, the caller was—and is now still—above its **RLIMIT_NPROC** resource limit (see *setrlimit*(2)). For a more detailed explanation of this error, see NOTES.

EFAULT
pathname or one of the pointers in the vectors *argv* or *envp* points outside your accessible address space.

EINVAL
An ELF executable had more than one PT_INTERP segment (i.e., tried to name more than one interpreter).

EIO An I/O error occurred.

EISDIR
An ELF interpreter was a directory.

ELIBBAD
An ELF interpreter was not in a recognized format.

ELOOP
Too many symbolic links were encountered in resolving *pathname* or the name of a script or ELF interpreter.

ELOOP
The maximum recursion limit was reached during recursive script interpretation (see "Interpreter scripts", above). Before Linux 3.8, the error produced for this case was **ENOEXEC**.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENAMETOOLONG
pathname is too long.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENOENT
The file *pathname* or a script or ELF interpreter does not exist.

ENOEXEC
An executable is not in a recognized format, is for the wrong architecture, or has some other format error that means it cannot be executed.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component of the path prefix of *pathname* or a script or ELF interpreter is not a directory.

EPERM
The filesystem is mounted *nosuid*, the user is not the superuser, and the file has the set-user-ID or set-group-ID bit set.

EPERM
The process is being traced, the user is not the superuser and the file has the set-user-ID or set-group-ID bit set.

EPERM
A "capability-dumb" applications would not obtain the full set of permitted capabilities granted by the executable file. See *capabilities*(7).

ETXTBSY
The specified executable was open for writing by one or more processes.

VERSIONS

POSIX does not document the #! behavior, but it exists (with some variations) on other UNIX systems.

On Linux, *argv* and *envp* can be specified as NULL. In both cases, this has the same effect as specifying the argument as a pointer to a list containing a single null pointer. **Do not take advantage of this nonstandard and nonportable misfeature!** On many other UNIX systems, specifying *argv* as NULL will result in an error (**EFAULT**). *Some* other UNIX systems treat the *envp==NULL* case the same as Linux.

POSIX.1 says that values returned by *sysconf*(3) should be invariant over the lifetime of a process. However, since Linux 2.6.23, if the **RLIMIT_STACK** resource limit changes, then the value reported by **_SC_ARG_MAX** will also change, to reflect the fact that the limit on space for holding command-line arguments and environment variables has changed.

Interpreter scripts

The kernel imposes a maximum length on the text that follows the "#!" characters at the start of a script; characters beyond the limit are ignored. Before Linux 5.1, the limit is 127 characters. Since Linux 5.1, the limit is 255 characters.

The semantics of the *optional-arg* argument of an interpreter script vary across implementations. On Linux, the entire string following the *interpreter* name is passed as a single argument to the interpreter, and this string can include white space. However, behavior differs on some other systems. Some systems use the first white space to terminate *optional-arg*. On some systems, an interpreter script can have multiple arguments, and white spaces in *optional-arg* are used to delimit the arguments.

Linux (like most other modern UNIX systems) ignores the set-user-ID and set-group-ID bits on scripts.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

With UNIX V6, the argument list of an **exec**() call was ended by 0, while the argument list of *main* was ended by −1. Thus, this argument list was not directly usable in a further **exec**() call. Since UNIX V7, both are NULL.

NOTES

One sometimes sees **execve**() (and the related functions described in *exec*(3)) described as "executing a *new* process" (or similar). This is a highly misleading description: there is no new process; many attributes of the calling process remain unchanged (in particular, its PID). All that **execve**() does is arrange for an existing process (the calling process) to execute a new program.

Set-user-ID and set-group-ID processes can not be *ptrace*(2)d.

The result of mounting a filesystem *nosuid* varies across Linux kernel versions: some will refuse execution of set-user-ID and set-group-ID executables when this would give the user powers they did not have already (and return **EPERM**), some will just ignore the set-user-ID and set-group-ID bits and **exec**() successfully.

In most cases where **execve**() fails, control returns to the original executable image, and the caller of **execve**() can then handle the error. However, in (rare) cases (typically caused by resource exhaustion), failure may occur past the point of no return: the original executable image has been torn down, but the new image could not be completely built. In such cases, the kernel kills the process with a **SIGSEGV** (**SIGKILL** until Linux 3.17) signal.

execve() and EAGAIN

A more detailed explanation of the **EAGAIN** error that can occur (since Linux 3.1) when calling **execve**() is as follows.

The **EAGAIN** error can occur when a *preceding* call to *setuid*(2), *setreuid*(2), or *setresuid*(2) caused the real user ID of the process to change, and that change caused the process to exceed its **RLIMIT_NPROC** resource limit (i.e., the number of processes belonging to the new real UID exceeds the resource limit). From Linux 2.6.0 to Linux 3.0, this caused the **set*uid**() call to fail. (Before Linux 2.6, the resource limit was not imposed on processes that changed their user IDs.)

Since Linux 3.1, the scenario just described no longer causes the **set*uid**() call to fail, because it too often led to security holes where buggy applications didn't check the return status and assumed that—if the caller had root privileges—the call would always succeed. Instead, the **set*uid**() calls now successfully change the real UID, but the kernel sets an internal flag, named **PF_NPROC_EXCEEDED**, to note that the **RLIMIT_NPROC** resource limit has been exceeded. If the **PF_NPROC_EXCEEDED** flag is set and the resource limit is still exceeded at the time of a subsequent **execve**() call, that call fails with the error **EAGAIN**. This kernel logic ensures that the **RLIMIT_NPROC** resource limit is still enforced for the common privileged daemon workflow—namely, *fork*(2) + **set*uid**() + **execve**().

If the resource limit was not still exceeded at the time of the **execve**() call (because other processes belonging to this real UID terminated between the **set*uid**() call and the **execve**() call), then the **execve**() call succeeds and the kernel clears the **PF_NPROC_EXCEEDED** process flag. The flag is also cleared if a subsequent call to *fork*(2) by this process succeeds.

EXAMPLES

The following program is designed to be execed by the second program below. It just echoes its command-line arguments, one per line.

```
/* myecho.c */

#include <stdio.h>
#include <stdlib.h>

int
main(int argc, char *argv[])
{
    for (size_t j = 0; j < argc; j++)
        printf("argv[%zu]: %s\n", j, argv[j]);

    exit(EXIT_SUCCESS);
}
```

This program can be used to exec the program named in its command-line argument:

```
/* execve.c */

#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    static char *newargv[] = { NULL, "hello", "world", NULL };
    static char *newenviron[] = { NULL };

    if (argc != 2) {
        fprintf(stderr, "Usage: %s <file-to-exec>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    newargv[0] = argv[1];

    execve(argv[1], newargv, newenviron);
    perror("execve");   /* execve() returns only on error */
    exit(EXIT_FAILURE);
}
```

We can use the second program to exec the first as follows:

```
$ cc myecho.c -o myecho
$ cc execve.c -o execve
$ ./execve ./myecho
```

```
argv[0]: ./myecho
argv[1]: hello
argv[2]: world
```

We can also use these programs to demonstrate the use of a script interpreter. To do this we create a script whose "interpreter" is our *myecho* program:

```
$ cat > script
#!./myecho script-arg
^D
$ chmod +x script
```

We can then use our program to exec the script:

```
$ ./execve ./script
argv[0]: ./myecho
argv[1]: script-arg
argv[2]: ./script
argv[3]: hello
argv[4]: world
```

NAME

execveat − execute program relative to a directory file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/fcntl.h>      /* Definition of AT_* constants */
#include <unistd.h>

int execveat(int dirfd, const char *pathname,
             char *const _Nullable argv[],
             char *const _Nullable envp[],
             int flags);
```

DESCRIPTION

The **execveat**() system call executes the program referred to by the combination of *dirfd* and *pathname*. It operates in exactly the same way as *execve*(2), except for the differences described in this manual page.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by *execve*(2) for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *execve*(2)).

If *pathname* is absolute, then *dirfd* is ignored.

If *pathname* is an empty string and the **AT_EMPTY_PATH** flag is specified, then the file descriptor *dirfd* specifies the file to be executed (i.e., *dirfd* refers to an executable file, rather than a directory).

The *flags* argument is a bit mask that can include zero or more of the following flags:

AT_EMPTY_PATH
: If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the *open*(2) **O_PATH** flag).

AT_SYMLINK_NOFOLLOW
: If the file identified by *dirfd* and a non-NULL *pathname* is a symbolic link, then the call fails with the error **ELOOP**.

RETURN VALUE

On success, **execveat**() does not return. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

The same errors that occur for *execve*(2) can also occur for **execveat**(). The following additional errors can occur for **execveat**():

pathname
: is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EINVAL
: Invalid flag specified in *flags*.

ELOOP
: *flags* includes **AT_SYMLINK_NOFOLLOW** and the file identified by *dirfd* and a non-NULL *pathname* is a symbolic link.

ENOENT
: The program identified by *dirfd* and *pathname* requires the use of an interpreter program (such as a script starting with "#!"), but the file descriptor *dirfd* was opened with the **O_CLOEXEC** flag, with the result that the program file is inaccessible to the launched interpreter. See BUGS.

ENOTDIR
: *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

STANDARDS

Linux.

HISTORY

Linux 3.19, glibc 2.34.

NOTES

In addition to the reasons explained in *openat*(2), the **execveat**() system call is also needed to allow *fexecve*(3) to be implemented on systems that do not have the */proc* filesystem mounted.

When asked to execute a script file, the *argv[0]* that is passed to the script interpreter is a string of the form */dev/fd/N* or */dev/fd/N/P*, where *N* is the number of the file descriptor passed via the *dirfd* argument. A string of the first form occurs when **AT_EMPTY_PATH** is employed. A string of the second form occurs when the script is specified via both *dirfd* and *pathname*; in this case, *P* is the value given in *pathname*.

For the same reasons described in *fexecve*(3), the natural idiom when using **execveat**() is to set the close-on-exec flag on *dirfd*. (But see BUGS.)

BUGS

The **ENOENT** error described above means that it is not possible to set the close-on-exec flag on the file descriptor given to a call of the form:

```
execveat(fd, "", argv, envp, AT_EMPTY_PATH);
```

However, the inability to set the close-on-exec flag means that a file descriptor referring to the script leaks through to the script itself. As well as wasting a file descriptor, this leakage can lead to file-descriptor exhaustion in scenarios where scripts recursively employ **execveat**().

execve(2), *openat*(2), *fexecve*(3)

NAME

_exit, _Exit − terminate the calling process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

[[noreturn]] void _exit(int status);

#include <stdlib.h>

[[noreturn]] void _Exit(int status);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

_Exit():
_ISOC99_SOURCE || _POSIX_C_SOURCE >= 200112L

DESCRIPTION

_exit() terminates the calling process "immediately". Any open file descriptors belonging to the process are closed. Any children of the process are inherited by *init*(1) (or by the nearest "subreaper" process as defined through the use of the *prctl*(2) **PR_SET_CHILD_SUBREAPER** operation). The process's parent is sent a **SIGCHLD** signal.

The value *status & 0xFF* is returned to the parent process as the process's exit status, and can be collected by the parent using one of the *wait*(2) family of calls.

The function **_Exit**() is equivalent to **_exit**().

RETURN VALUE

These functions do not return.

STANDARDS

_exit() POSIX.1-2008.

_Exit() C11, POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

_Exit() was introduced by C99.

NOTES

For a discussion on the effects of an exit, the transmission of exit status, zombie processes, signals sent, and so on, see *exit*(3).

The function **_exit**() is like *exit*(3), but does not call any functions registered with *atexit*(3) or *on_exit*(3). Open *stdio*(3) streams are not flushed. On the other hand, **_exit**() does close open file descriptors, and this may cause an unknown delay, waiting for pending output to finish. If the delay is undesired, it may be useful to call functions like *tcflush*(3) before calling **_exit**(). Whether any pending I/O is canceled, and which pending I/O may be canceled upon **_exit**(), is implementation-dependent.

C library/kernel differences

The text above in DESCRIPTION describes the traditional effect of **_exit**(), which is to terminate a process, and these are the semantics specified by POSIX.1 and implemented by the C library wrapper function. On modern systems, this means termination of all threads in the process.

By contrast with the C library wrapper function, the raw Linux **_exit**() system call terminates only the calling thread, and actions such as reparenting child processes or sending **SIGCHLD** to the parent process are performed only if this is the last thread in the thread group.

Up to glibc 2.3, the **_exit**() wrapper function invoked the kernel system call of the same name. Since glibc 2.3, the wrapper function invokes *exit_group*(2), in order to terminate all of the threads in a process.

SEE ALSO

execve(2), *exit_group*(2), *fork*(2), *kill*(2), *wait*(2), *wait4*(2), *waitpid*(2), *atexit*(3), *exit*(3), *on_exit*(3), *termios*(3)

NAME

exit_group − exit all threads in a process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

[[noreturn]] void syscall(SYS_exit_group, int status);
```

Note: glibc provides no wrapper for **exit_group**(), necessitating the use of *syscall*(2).

DESCRIPTION

This system call terminates all threads in the calling process's thread group.

RETURN VALUE

This system call does not return.

STANDARDS

Linux.

HISTORY

Linux 2.5.35.

NOTES

Since glibc 2.3, this is the system call invoked when the *_exit*(2) wrapper function is called.

SEE ALSO

_exit(2)

NAME

fallocate − manipulate file space

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <fcntl.h>

int fallocate(int fd, int mode, off_t offset, off_t len);
```

DESCRIPTION

This is a nonportable, Linux-specific system call. For the portable, POSIX.1-specified method of ensuring that space is allocated for a file, see *posix_fallocate*(3).

fallocate() allows the caller to directly manipulate the allocated disk space for the file referred to by *fd* for the byte range starting at *offset* and continuing for *len* bytes.

The *mode* argument determines the operation to be performed on the given range. Details of the supported operations are given in the subsections below.

Allocating disk space

The default operation (i.e., *mode* is zero) of **fallocate**() allocates the disk space within the range specified by *offset* and *len*. The file size (as reported by *stat*(2)) will be changed if *offset*+*len* is greater than the file size. Any subregion within the range specified by *offset* and *len* that did not contain data before the call will be initialized to zero. This default behavior closely resembles the behavior of the *posix_fallocate*(3) library function, and is intended as a method of optimally implementing that function.

After a successful call, subsequent writes into the range specified by *offset* and *len* are guaranteed not to fail because of lack of disk space.

If the **FALLOC_FL_KEEP_SIZE** flag is specified in *mode*, the behavior of the call is similar, but the file size will not be changed even if *offset*+*len* is greater than the file size. Preallocating zeroed blocks beyond the end of the file in this manner is useful for optimizing append workloads.

If the **FALLOC_FL_UNSHARE_RANGE** flag is specified in *mode*, shared file data extents will be made private to the file to guarantee that a subsequent write will not fail due to lack of space. Typically, this will be done by performing a copy-on-write operation on all shared data in the file. This flag may not be supported by all filesystems.

Because allocation is done in block size chunks, **fallocate**() may allocate a larger range of disk space than was specified.

Deallocating file space

Specifying the **FALLOC_FL_PUNCH_HOLE** flag (available since Linux 2.6.38) in *mode* deallocates space (i.e., creates a hole) in the byte range starting at *offset* and continuing for *len* bytes. Within the specified range, partial filesystem blocks are zeroed, and whole filesystem blocks are removed from the file. After a successful call, subsequent reads from this range will return zeros.

The **FALLOC_FL_PUNCH_HOLE** flag must be ORed with **FALLOC_FL_KEEP_SIZE** in *mode*; in other words, even when punching off the end of the file, the file size (as reported by *stat*(2)) does not change.

Not all filesystems support **FALLOC_FL_PUNCH_HOLE**; if a filesystem doesn't support the operation, an error is returned. The operation is supported on at least the following filesystems:

- XFS (since Linux 2.6.38)
- ext4 (since Linux 3.0)
- Btrfs (since Linux 3.7)
- *tmpfs*(5) (since Linux 3.5)
- *gfs2*(5) (since Linux 4.16)

Collapsing file space

Specifying the **FALLOC_FL_COLLAPSE_RANGE** flag (available since Linux 3.15) in *mode* removes a byte range from a file, without leaving a hole. The byte range to be collapsed starts at *offset*

and continues for *len* bytes. At the completion of the operation, the contents of the file starting at the location *offset*+*len* will be appended at the location *offset*, and the file will be *len* bytes smaller.

A filesystem may place limitations on the granularity of the operation, in order to ensure efficient implementation. Typically, *offset* and *len* must be a multiple of the filesystem logical block size, which varies according to the filesystem type and configuration. If a filesystem has such a requirement, **fallocate**() fails with the error **EINVAL** if this requirement is violated.

If the region specified by *offset* plus *len* reaches or passes the end of file, an error is returned; instead, use *ftruncate*(2) to truncate a file.

No other flags may be specified in *mode* in conjunction with **FALLOC_FL_COLLAPSE_RANGE**.

As at Linux 3.15, **FALLOC_FL_COLLAPSE_RANGE** is supported by ext4 (only for extent-based files) and XFS.

Zeroing file space

Specifying the **FALLOC_FL_ZERO_RANGE** flag (available since Linux 3.15) in *mode* zeros space in the byte range starting at *offset* and continuing for *len* bytes. Within the specified range, blocks are preallocated for the regions that span the holes in the file. After a successful call, subsequent reads from this range will return zeros.

Zeroing is done within the filesystem preferably by converting the range into unwritten extents. This approach means that the specified range will not be physically zeroed out on the device (except for partial blocks at the either end of the range), and I/O is (otherwise) required only to update metadata.

If the **FALLOC_FL_KEEP_SIZE** flag is additionally specified in *mode*, the behavior of the call is similar, but the file size will not be changed even if *offset*+*len* is greater than the file size. This behavior is the same as when preallocating space with **FALLOC_FL_KEEP_SIZE** specified.

Not all filesystems support **FALLOC_FL_ZERO_RANGE**; if a filesystem doesn't support the operation, an error is returned. The operation is supported on at least the following filesystems:

- XFS (since Linux 3.15)
- ext4, for extent-based files (since Linux 3.15)
- SMB3 (since Linux 3.17)
- Btrfs (since Linux 4.16)

Increasing file space

Specifying the **FALLOC_FL_INSERT_RANGE** flag (available since Linux 4.1) in *mode* increases the file space by inserting a hole within the file size without overwriting any existing data. The hole will start at *offset* and continue for *len* bytes. When inserting the hole inside file, the contents of the file starting at *offset* will be shifted upward (i.e., to a higher file offset) by *len* bytes. Inserting a hole inside a file increases the file size by *len* bytes.

This mode has the same limitations as **FALLOC_FL_COLLAPSE_RANGE** regarding the granularity of the operation. If the granularity requirements are not met, **fallocate**() fails with the error **EINVAL**. If the *offset* is equal to or greater than the end of file, an error is returned. For such operations (i.e., inserting a hole at the end of file), *ftruncate*(2) should be used.

No other flags may be specified in *mode* in conjunction with **FALLOC_FL_INSERT_RANGE**.

FALLOC_FL_INSERT_RANGE requires filesystem support. Filesystems that support this operation include XFS (since Linux 4.1) and ext4 (since Linux 4.2).

RETURN VALUE

On success, **fallocate**() returns zero. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF

fd is not a valid file descriptor, or is not opened for writing.

EFBIG

offset+*len* exceeds the maximum file size.

EFBIG

mode is **FALLOC_FL_INSERT_RANGE**, and the current file size+*len* exceeds the maximum file size.

EINTR
A signal was caught during execution; see *signal*(7).

EINVAL
offset was less than 0, or *len* was less than or equal to 0.

EINVAL
mode is **FALLOC_FL_COLLAPSE_RANGE** and the range specified by *offset* plus *len* reaches or passes the end of the file.

EINVAL
mode is **FALLOC_FL_INSERT_RANGE** and the range specified by *offset* reaches or passes the end of the file.

EINVAL
mode is **FALLOC_FL_COLLAPSE_RANGE** or **FALLOC_FL_INSERT_RANGE**, but either *offset* or *len* is not a multiple of the filesystem block size.

EINVAL
mode contains one of **FALLOC_FL_COLLAPSE_RANGE** or **FALLOC_FL_INSERT_RANGE** and also other flags; no other flags are permitted with **FALLOC_FL_COLLAPSE_RANGE** or **FALLOC_FL_INSERT_RANGE**.

EINVAL
mode is **FALLOC_FL_COLLAPSE_RANGE**, **FALLOC_FL_ZERO_RANGE**, or **FALLOC_FL_INSERT_RANGE**, but the file referred to by *fd* is not a regular file.

EIO An I/O error occurred while reading from or writing to a filesystem.

ENODEV
fd does not refer to a regular file or a directory. (If *fd* is a pipe or FIFO, a different error results.)

ENOSPC
There is not enough space left on the device containing the file referred to by *fd*.

ENOSYS
This kernel does not implement **fallocate**().

EOPNOTSUPP
The filesystem containing the file referred to by *fd* does not support this operation; or the *mode* is not supported by the filesystem containing the file referred to by *fd*.

EPERM
The file referred to by *fd* is marked immutable (see *chattr*(1)).

EPERM
mode specifies **FALLOC_FL_PUNCH_HOLE**, **FALLOC_FL_COLLAPSE_RANGE**, or **FALLOC_FL_INSERT_RANGE** and the file referred to by *fd* is marked append-only (see *chattr*(1)).

EPERM
The operation was prevented by a file seal; see *fcntl*(2).

ESPIPE
fd refers to a pipe or FIFO.

ETXTBSY
mode specifies **FALLOC_FL_COLLAPSE_RANGE** or **FALLOC_FL_INSERT_RANGE**, but the file referred to by *fd* is currently being executed.

STANDARDS
Linux.

HISTORY
fallocate()
Linux 2.6.23, glibc 2.10.

FALLOC_FL_*
glibc 2.18.

NAME

fanotify_init − create and initialize fanotify group

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <fcntl.h> /* Definition of **O_*** constants */
#include <sys/fanotify.h>

int fanotify_init(unsigned int *flags***, unsigned int** *event_f_flags***);**

DESCRIPTION

For an overview of the fanotify API, see *fanotify*(7).

fanotify_init() initializes a new fanotify group and returns a file descriptor for the event queue associated with the group.

The file descriptor is used in calls to *fanotify_mark*(2) to specify the files, directories, mounts, or filesystems for which fanotify events shall be created. These events are received by reading from the file descriptor. Some events are only informative, indicating that a file has been accessed. Other events can be used to determine whether another application is permitted to access a file or directory. Permission to access filesystem objects is granted by writing to the file descriptor.

Multiple programs may be using the fanotify interface at the same time to monitor the same files.

The number of fanotify groups per user is limited. See *fanotify*(7) for details about this limit.

The *flags* argument contains a multi-bit field defining the notification class of the listening application and further single bit fields specifying the behavior of the file descriptor.

If multiple listeners for permission events exist, the notification class is used to establish the sequence in which the listeners receive the events.

Only one of the following notification classes may be specified in *flags*:

FAN_CLASS_PRE_CONTENT
: This value allows the receipt of events notifying that a file has been accessed and events for permission decisions if a file may be accessed. It is intended for event listeners that need to access files before they contain their final data. This notification class might be used by hierarchical storage managers, for example. Use of this flag requires the **CAP_SYS_ADMIN** capability.

FAN_CLASS_CONTENT
: This value allows the receipt of events notifying that a file has been accessed and events for permission decisions if a file may be accessed. It is intended for event listeners that need to access files when they already contain their final content. This notification class might be used by malware detection programs, for example. Use of this flag requires the **CAP_SYS_ADMIN** capability.

FAN_CLASS_NOTIF
: This is the default value. It does not need to be specified. This value only allows the receipt of events notifying that a file has been accessed. Permission decisions before the file is accessed are not possible.

Listeners with different notification classes will receive events in the order **FAN_CLASS_PRE_CONTENT**, **FAN_CLASS_CONTENT**, **FAN_CLASS_NOTIF**. The order of notification for listeners in the same notification class is undefined.

The following bits can additionally be set in *flags*:

FAN_CLOEXEC
: Set the close-on-exec flag (**FD_CLOEXEC**) on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2).

FAN_NONBLOCK
: Enable the nonblocking flag (**O_NONBLOCK**) for the file descriptor. Reading from the file descriptor will not block. Instead, if no data is available, *read*(2) fails with the error **EAGAIN**.

FAN_UNLIMITED_QUEUE
Remove the limit on the number of events in the event queue. See *fanotify*(7) for details about this limit. Use of this flag requires the **CAP_SYS_ADMIN** capability.

FAN_UNLIMITED_MARKS
Remove the limit on the number of fanotify marks per user. See *fanotify*(7) for details about this limit. Use of this flag requires the **CAP_SYS_ADMIN** capability.

FAN_REPORT_TID (since Linux 4.20)
Report thread ID (TID) instead of process ID (PID) in the *pid* field of the *struct fanotify_event_metadata* supplied to *read*(2) (see *fanotify*(7)). Use of this flag requires the **CAP_SYS_ADMIN** capability.

FAN_ENABLE_AUDIT (since Linux 4.15)
Enable generation of audit log records about access mediation performed by permission events. The permission event response has to be marked with the **FAN_AUDIT** flag for an audit log record to be generated. Use of this flag requires the **CAP_AUDIT_WRITE** capability.

FAN_REPORT_FID (since Linux 5.1)
This value allows the receipt of events which contain additional information about the underlying filesystem object correlated to an event. An additional record of type **FAN_EVENT_INFO_TYPE_FID** encapsulates the information about the object and is included alongside the generic event metadata structure. The file descriptor that is used to represent the object correlated to an event is instead substituted with a file handle. It is intended for applications that may find the use of a file handle to identify an object more suitable than a file descriptor. Additionally, it may be used for applications monitoring a directory or a filesystem that are interested in the directory entry modification events **FAN_CREATE**, **FAN_DELETE**, **FAN_MOVE**, and **FAN_RENAME**, or in events such as **FAN_ATTRIB**, **FAN_DELETE_SELF**, and **FAN_MOVE_SELF**. All the events above require an fanotify group that identifies filesystem objects by file handles. Note that without the flag **FAN_REPORT_TARGET_FID**, for the directory entry modification events, there is an information record that identifies the modified directory and not the created/deleted/moved child object. The use of **FAN_CLASS_CONTENT** or **FAN_CLASS_PRE_CONTENT** is not permitted with this flag and will result in the error **EINVAL**. See *fanotify*(7) for additional details.

FAN_REPORT_DIR_FID (since Linux 5.9)
Events for fanotify groups initialized with this flag will contain (see exceptions below) additional information about a directory object correlated to an event. An additional record of type **FAN_EVENT_INFO_TYPE_DFID** encapsulates the information about the directory object and is included alongside the generic event metadata structure. For events that occur on a non-directory object, the additional structure includes a file handle that identifies the parent directory filesystem object. Note that there is no guarantee that the directory filesystem object will be found at the location described by the file handle information at the time the event is received. When combined with the flag **FAN_REPORT_FID**, two records may be reported with events that occur on a non-directory object, one to identify the non-directory object itself and one to identify the parent directory object. Note that in some cases, a filesystem object does not have a parent, for example, when an event occurs on an unlinked but open file. In that case, with the **FAN_REPORT_FID** flag, the event will be reported with only one record to identify the non-directory object itself, because there is no directory associated with the event. Without the **FAN_REPORT_FID** flag, no event will be reported. See *fanotify*(7) for additional details.

FAN_REPORT_NAME (since Linux 5.9)
Events for fanotify groups initialized with this flag will contain additional information about the name of the directory entry correlated to an event. This flag must be provided in conjunction with the flag **FAN_REPORT_DIR_FID**. Providing this flag value without **FAN_REPORT_DIR_FID** will result in the error **EINVAL**. This flag may be combined with the flag **FAN_REPORT_FID**. An additional record of type **FAN_EVENT_INFO_TYPE_DFID_NAME**, which encapsulates the information about the directory entry, is included alongside the generic event metadata structure and substitutes the additional information record of type **FAN_EVENT_INFO_TYPE_DFID**. The additional record includes a file handle that identifies a directory filesystem object followed by a name

that identifies an entry in that directory. For the directory entry modification events **FAN_CREATE**, **FAN_DELETE**, and **FAN_MOVE**, the reported name is that of the created/deleted/moved directory entry. The event **FAN_RENAME** may contain two information records. One of type **FAN_EVENT_INFO_TYPE_OLD_DFID_NAME** identifying the old directory entry, and another of type **FAN_EVENT_INFO_TYPE_NEW_DFID_NAME** identifying the new directory entry. For other events that occur on a directory object, the reported file handle is that of the directory object itself and the reported name is '.'. For other events that occur on a non-directory object, the reported file handle is that of the parent directory object and the reported name is the name of a directory entry where the object was located at the time of the event. The rationale behind this logic is that the reported directory file handle can be passed to *open_by_handle_at*(2) to get an open directory file descriptor and that file descriptor along with the reported name can be used to call *fstatat*(2). The same rule that applies to record type **FAN_EVENT_INFO_TYPE_DFID** also applies to record type **FAN_EVENT_INFO_TYPE_DFID_NAME**: if a non-directory object has no parent, either the event will not be reported or it will be reported without the directory entry information. Note that there is no guarantee that the filesystem object will be found at the location described by the directory entry information at the time the event is received. See *fanotify*(7) for additional details.

FAN_REPORT_DFID_NAME
This is a synonym for (**FAN_REPORT_DIR_FID**|**FAN_REPORT_NAME**).

FAN_REPORT_TARGET_FID (since Linux 5.17)
Events for fanotify groups initialized with this flag will contain additional information about the child correlated with directory entry modification events. This flag must be provided in conjunction with the flags **FAN_REPORT_FID**, **FAN_REPORT_DIR_FID** and **FAN_REPORT_NAME**. or else the error **EINVAL** will be returned. For the directory entry modification events **FAN_CREATE**, **FAN_DELETE**, **FAN_MOVE**, and **FAN_RENAME**, an additional record of type **FAN_EVENT_INFO_TYPE_FID**, is reported in addition to the information records of type **FAN_EVENT_INFO_TYPE_DFID**, **FAN_EVENT_INFO_TYPE_DFID_NAME**, **FAN_EVENT_INFO_TYPE_OLD_DFID_NAME**, and **FAN_EVENT_INFO_TYPE_NEW_DFID_NAME**. The additional record includes a file handle that identifies the filesystem child object that the directory entry is referring to.

FAN_REPORT_DFID_NAME_TARGET
This is a synonym for (**FAN_REPORT_DFID_NAME**|**FAN_REPORT_FID**|**FAN_REPORT_TARGET_FID**).

FAN_REPORT_PIDFD (since Linux 5.15)
Events for fanotify groups initialized with this flag will contain an additional information record alongside the generic *fanotify_event_metadata* structure. This information record will be of type **FAN_EVENT_INFO_TYPE_PIDFD** and will contain a pidfd for the process that was responsible for generating an event. A pidfd returned in this information record object is no different to the pidfd that is returned when calling *pidfd_open*(2). Usage of this information record are for applications that may be interested in reliably determining whether the process responsible for generating an event has been recycled or terminated. The use of the **FAN_REPORT_TID** flag along with **FAN_REPORT_PIDFD** is currently not supported and attempting to do so will result in the error **EINVAL** being returned. This limitation is currently imposed by the pidfd API as it currently only supports the creation of pidfds for thread-group leaders. Creating pidfds for non-thread-group leaders may be supported at some point in the future, so this restriction may eventually be lifted. For more details on information records, see *fanotify*(7).

The *event_f_flags* argument defines the file status flags that will be set on the open file descriptions that are created for fanotify events. For details of these flags, see the description of the *flags* values in *open*(2). *event_f_flags* includes a multi-bit field for the access mode. This field can take the following values:

O_RDONLY
This value allows only read access.

O_WRONLY
This value allows only write access.

O_RDWR
This value allows read and write access.

Additional bits can be set in *event_f_flags*. The most useful values are:

O_LARGEFILE
Enable support for files exceeding 2 GB. Failing to set this flag will result in an **EOVERFLOW** error when trying to open a large file which is monitored by an fanotify group on a 32-bit system.

O_CLOEXEC (since Linux 3.18)
Enable the close-on-exec flag for the file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

The following are also allowable: **O_APPEND**, **O_DSYNC**, **O_NOATIME**, **O_NONBLOCK**, and **O_SYNC**. Specifying any other flag in *event_f_flags* yields the error **EINVAL** (but see BUGS).

RETURN VALUE

On success, **fanotify_init**() returns a new file descriptor. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
An invalid value was passed in *flags* or *event_f_flags*. **FAN_ALL_INIT_FLAGS** (deprecated since Linux 4.20) defines all allowable bits for *flags*.

EMFILE
The number of fanotify groups for this user exceeds the limit. See *fanotify*(7) for details about this limit.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENOMEM
The allocation of memory for the notification group failed.

ENOSYS
This kernel does not implement **fanotify_init**(). The fanotify API is available only if the kernel was configured with **CONFIG_FANOTIFY**.

EPERM
The operation is not permitted because the caller lacks a required capability.

VERSIONS

Prior to Linux 5.13, calling **fanotify_init**() required the **CAP_SYS_ADMIN** capability. Since Linux 5.13, users may call **fanotify_init**() without the **CAP_SYS_ADMIN** capability to create and initialize an fanotify group with limited functionality.

The limitations imposed on an event listener created by a user without the **CAP_SYS_ADMIN** capability are as follows:

- The user cannot request for an unlimited event queue by using **FAN_UNLIMITED_QUEUE**.
- The user cannot request for an unlimited number of marks by using **FAN_UNLIMITED_MARKS**.
- The user cannot request to use either notification classes **FAN_CLASS_CONTENT** or **FAN_CLASS_PRE_CONTENT**. This means that user cannot request permission events.
- The user is required to create a group that identifies filesystem objects by file handles, for example, by providing the **FAN_REPORT_FID** flag.
- The user is limited to only mark inodes. The ability to mark a mount or filesystem via **fanotify_mark**() through the use of **FAN_MARK_MOUNT** or **FAN_MARK_FILESYSTEM** is not permitted.

- The event object in the event queue is limited in terms of the information that is made available to the unprivileged user. A user will also not receive the pid that generated the event, unless the listening process itself generated the event.

STANDARDS

Linux.

HISTORY

Linux 2.6.37.

BUGS

The following bug was present before Linux 3.18:

- The **O_CLOEXEC** is ignored when passed in *event_f_flags*.

The following bug was present before Linux 3.14:

- The *event_f_flags* argument is not checked for invalid flags. Flags that are intended only for internal use, such as **FMODE_EXEC**, can be set, and will consequently be set for the file descriptors returned when reading from the fanotify file descriptor.

SEE ALSO

fanotify_mark(2), *fanotify*(7)

NAME

fanotify_mark − add, remove, or modify an fanotify mark on a filesystem object

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/fanotify.h>

int fanotify_mark(int fanotify_fd, unsigned int flags,
                  uint64_t mask, int dirfd,
                  const char *_Nullable pathname);
```

DESCRIPTION

For an overview of the fanotify API, see *fanotify*(7).

fanotify_mark() adds, removes, or modifies an fanotify mark on a filesystem object. The caller must have read permission on the filesystem object that is to be marked.

The *fanotify_fd* argument is a file descriptor returned by *fanotify_init*(2).

flags is a bit mask describing the modification to perform. It must include exactly one of the following values:

FAN_MARK_ADD
: The events in *mask* will be added to the mark mask (or to the ignore mask). *mask* must be nonempty or the error **EINVAL** will occur.

FAN_MARK_REMOVE
: The events in argument *mask* will be removed from the mark mask (or from the ignore mask). *mask* must be nonempty or the error **EINVAL** will occur.

FAN_MARK_FLUSH
: Remove either all marks for filesystems, all marks for mounts, or all marks for directories and files from the fanotify group. If *flags* contains **FAN_MARK_MOUNT**, all marks for mounts are removed from the group. If *flags* contains **FAN_MARK_FILESYSTEM**, all marks for filesystems are removed from the group. Otherwise, all marks for directories and files are removed. No flag other than, and at most one of, the flags **FAN_MARK_MOUNT** or **FAN_MARK_FILESYSTEM** can be used in conjunction with **FAN_MARK_FLUSH**. *mask* is ignored.

If none of the values above is specified, or more than one is specified, the call fails with the error **EINVAL**.

In addition, zero or more of the following values may be ORed into *flags*:

FAN_MARK_DONT_FOLLOW
: If *pathname* is a symbolic link, mark the link itself, rather than the file to which it refers. (By default, **fanotify_mark**() dereferences *pathname* if it is a symbolic link.)

FAN_MARK_ONLYDIR
: If the filesystem object to be marked is not a directory, the error **ENOTDIR** shall be raised.

FAN_MARK_MOUNT
: Mark the mount specified by *pathname*. If *pathname* is not itself a mount point, the mount containing *pathname* will be marked. All directories, subdirectories, and the contained files of the mount will be monitored. The events which require that filesystem objects are identified by file handles, such as **FAN_CREATE**, **FAN_ATTRIB**, **FAN_MOVE**, and **FAN_DELETE_SELF**, cannot be provided as a *mask* when *flags* contains **FAN_MARK_MOUNT**. Attempting to do so will result in the error **EINVAL** being returned. Use of this flag requires the **CAP_SYS_ADMIN** capability.

FAN_MARK_FILESYSTEM (since Linux 4.20)
: Mark the filesystem specified by *pathname*. The filesystem containing *pathname* will be marked. All the contained files and directories of the filesystem from any mount point will be monitored. Use of this flag requires the **CAP_SYS_ADMIN** capability.

FAN_MARK_IGNORED_MASK
The events in *mask* shall be added to or removed from the ignore mask. Note that the flags **FAN_ONDIR**, and **FAN_EVENT_ON_CHILD** have no effect when provided with this flag. The effect of setting the flags **FAN_ONDIR**, and **FAN_EVENT_ON_CHILD** in the mark mask on the events that are set in the ignore mask is undefined and depends on the Linux kernel version. Specifically, prior to Linux 5.9, setting a mark mask on a file and a mark with ignore mask on its parent directory would not result in ignoring events on the file, regardless of the **FAN_EVENT_ON_CHILD** flag in the parent directory's mark mask. When the ignore mask is updated with the **FAN_MARK_IGNORED_MASK** flag on a mark that was previously updated with the **FAN_MARK_IGNORE** flag, the update fails with **EEXIST** error.

FAN_MARK_IGNORE (since Linux 6.0)
This flag has a similar effect as setting the **FAN_MARK_IGNORED_MASK** flag. The events in *mask* shall be added to or removed from the ignore mask. Unlike the **FAN_MARK_IGNORED_MASK** flag, this flag also has the effect that the **FAN_ONDIR**, and **FAN_EVENT_ON_CHILD** flags take effect on the ignore mask. Specifically, unless the **FAN_ONDIR** flag is set with **FAN_MARK_IGNORE**, events on directories will not be ignored. If the flag **FAN_EVENT_ON_CHILD** is set with **FAN_MARK_IGNORE**, events on children will be ignored. For example, a mark on a directory with combination of a mask with **FAN_CREATE** event and **FAN_ONDIR** flag and an ignore mask with **FAN_CREATE** event and without **FAN_ONDIR** flag, will result in getting only the events for creation of sub-directories. When using the **FAN_MARK_IGNORE** flag to add to an ignore mask of a mount, filesystem, or directory inode mark, the **FAN_MARK_IGNORED_SURV_MODIFY** flag must be specified. Failure to do so will results with **EINVAL** or **EISDIR** error.

FAN_MARK_IGNORED_SURV_MODIFY
The ignore mask shall survive modify events. If this flag is not set, the ignore mask is cleared when a modify event occurs on the marked object. Omitting this flag is typically used to suppress events (e.g., **FAN_OPEN**) for a specific file, until that specific file's content has been modified. It is far less useful to suppress events on an entire filesystem, or mount, or on all files inside a directory, until some file's content has been modified. For this reason, the **FAN_MARK_IGNORE** flag requires the **FAN_MARK_IGNORED_SURV_MODIFY** flag on a mount, filesystem, or directory inode mark. This flag cannot be removed from a mark once set. When the ignore mask is updated without this flag on a mark that was previously updated with the **FAN_MARK_IGNORE** and **FAN_MARK_IGNORED_SURV_MODIFY** flags, the update fails with **EEXIST** error.

FAN_MARK_IGNORE_SURV
This is a synonym for (**FAN_MARK_IGNORE**|**FAN_MARK_IGNORED_SURV_MODIFY**).

FAN_MARK_EVICTABLE (since Linux 5.19)
When an inode mark is created with this flag, the inode object will not be pinned to the inode cache, therefore, allowing the inode object to be evicted from the inode cache when the memory pressure on the system is high. The eviction of the inode object results in the evictable mark also being lost. When the mask of an evictable inode mark is updated without using the **FAN_MARK_EVICATBLE** flag, the marked inode is pinned to inode cache and the mark is no longer evictable. When the mask of a non-evictable inode mark is updated with the **FAN_MARK_EVICTABLE** flag, the inode mark remains non-evictable and the update fails with **EEXIST** error. Mounts and filesystems are not evictable objects, therefore, an attempt to create a mount mark or a filesystem mark with the **FAN_MARK_EVICTABLE** flag, will result in the error **EINVAL**. For example, inode marks can be used in combination with mount marks to reduce the amount of events from noninteresting paths. The event listener reads events, checks if the path reported in the event is of interest, and if it is not, the listener sets a mark with an ignore mask on the directory. Evictable inode marks allow using this method for a large number of directories without the concern of pinning all inodes and exhausting the system's memory.

mask defines which events shall be listened for (or which shall be ignored). It is a bit mask composed of the following values:

FAN_ACCESS
Create an event when a file or directory (but see BUGS) is accessed (read).

FAN_MODIFY
Create an event when a file is modified (write).

FAN_CLOSE_WRITE
Create an event when a writable file is closed.

FAN_CLOSE_NOWRITE
Create an event when a read-only file or directory is closed.

FAN_OPEN
Create an event when a file or directory is opened.

FAN_OPEN_EXEC (since Linux 5.0)
Create an event when a file is opened with the intent to be executed. See NOTES for additional details.

FAN_ATTRIB (since Linux 5.1)
Create an event when the metadata for a file or directory has changed. An fanotify group that identifies filesystem objects by file handles is required.

FAN_CREATE (since Linux 5.1)
Create an event when a file or directory has been created in a marked parent directory. An fanotify group that identifies filesystem objects by file handles is required.

FAN_DELETE (since Linux 5.1)
Create an event when a file or directory has been deleted in a marked parent directory. An fanotify group that identifies filesystem objects by file handles is required.

FAN_DELETE_SELF (since Linux 5.1)
Create an event when a marked file or directory itself is deleted. An fanotify group that identifies filesystem objects by file handles is required.

FAN_FS_ERROR (since Linux 5.16)
Create an event when a filesystem error leading to inconsistent filesystem metadata is detected. An additional information record of type **FAN_EVENT_INFO_TYPE_ERROR** is returned for each event in the read buffer. An fanotify group that identifies filesystem objects by file handles is required.

Events of such type are dependent on support from the underlying filesystem. At the time of writing, only the **ext4** filesystem reports **FAN_FS_ERROR** events.

See *fanotify*(7) for additional details.

FAN_MOVED_FROM (since Linux 5.1)
Create an event when a file or directory has been moved from a marked parent directory. An fanotify group that identifies filesystem objects by file handles is required.

FAN_MOVED_TO (since Linux 5.1)
Create an event when a file or directory has been moved to a marked parent directory. An fanotify group that identifies filesystem objects by file handles is required.

FAN_RENAME (since Linux 5.17)
This event contains the same information provided by events **FAN_MOVED_FROM** and **FAN_MOVED_TO**, however is represented by a single event with up to two information records. An fanotify group that identifies filesystem objects by file handles is required. If the filesystem object to be marked is not a directory, the error **ENOTDIR** shall be raised.

FAN_MOVE_SELF (since Linux 5.1)
Create an event when a marked file or directory itself has been moved. An fanotify group that identifies filesystem objects by file handles is required.

FAN_OPEN_PERM
Create an event when a permission to open a file or directory is requested. An fanotify file descriptor created with **FAN_CLASS_PRE_CONTENT** or **FAN_CLASS_CONTENT** is required.

FAN_OPEN_EXEC_PERM (since Linux 5.0)
Create an event when a permission to open a file for execution is requested. An fanotify file descriptor created with **FAN_CLASS_PRE_CONTENT** or **FAN_CLASS_CONTENT** is required. See NOTES for additional details.

FAN_ACCESS_PERM
Create an event when a permission to read a file or directory is requested. An fanotify file descriptor created with **FAN_CLASS_PRE_CONTENT** or **FAN_CLASS_CONTENT** is required.

FAN_ONDIR
Create events for directories—for example, when *opendir*(3), *readdir*(3) (but see BUGS), and *closedir*(3) are called. Without this flag, events are created only for files. In the context of directory entry events, such as **FAN_CREATE**, **FAN_DELETE**, **FAN_MOVED_FROM**, and **FAN_MOVED_TO**, specifying the flag **FAN_ONDIR** is required in order to create events when subdirectory entries are modified (i.e., *mkdir*(2)/ *rmdir*(2)).

FAN_EVENT_ON_CHILD
Events for the immediate children of marked directories shall be created. The flag has no effect when marking mounts and filesystems. Note that events are not generated for children of the subdirectories of marked directories. More specifically, the directory entry modification events **FAN_CREATE**, **FAN_DELETE**, **FAN_MOVED_FROM**, and **FAN_MOVED_TO** are not generated for any entry modifications performed inside subdirectories of marked directories. Note that the events **FAN_DELETE_SELF** and **FAN_MOVE_SELF** are not generated for children of marked directories. To monitor complete directory trees it is necessary to mark the relevant mount or filesystem.

The following composed values are defined:

FAN_CLOSE
A file is closed (**FAN_CLOSE_WRITE**|**FAN_CLOSE_NOWRITE**).

FAN_MOVE
A file or directory has been moved (**FAN_MOVED_FROM**|**FAN_MOVED_TO**).

The filesystem object to be marked is determined by the file descriptor *dirfd* and the pathname specified in *pathname*:

- If *pathname* is NULL, *dirfd* defines the filesystem object to be marked.
- If *pathname* is NULL, and *dirfd* takes the special value **AT_FDCWD**, the current working directory is to be marked.
- If *pathname* is absolute, it defines the filesystem object to be marked, and *dirfd* is ignored.
- If *pathname* is relative, and *dirfd* does not have the value **AT_FDCWD**, then the filesystem object to be marked is determined by interpreting *pathname* relative the directory referred to by *dirfd*.
- If *pathname* is relative, and *dirfd* has the value **AT_FDCWD**, then the filesystem object to be marked is determined by interpreting *pathname* relative to the current working directory. (See *openat*(2) for an explanation of why the *dirfd* argument is useful.)

RETURN VALUE
On success, **fanotify_mark**() returns 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS
EBADF
An invalid file descriptor was passed in *fanotify_fd*.

EBADF
pathname is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EEXIST
The filesystem object indicated by *dirfd* and *pathname* has a mark that was updated without the **FAN_MARK_EVICTABLE** flag, and the user attempted to update the mark with **FAN_MARK_EVICTABLE** flag.

EEXIST
The filesystem object indicated by *dirfd* and *pathname* has a mark that was updated with the **FAN_MARK_IGNORE** flag, and the user attempted to update the mark with **FAN_MARK_IGNORED_MASK** flag.

EEXIST
The filesystem object indicated by *dirfd* and *pathname* has a mark that was updated with the **FAN_MARK_IGNORE** and **FAN_MARK_IGNORED_SURV_MODIFY** flags, and the user attempted to update the mark only with **FAN_MARK_IGNORE** flag.

EINVAL
An invalid value was passed in *flags* or *mask*, or *fanotify_fd* was not an fanotify file descriptor.

EINVAL
The fanotify file descriptor was opened with **FAN_CLASS_NOTIF** or the fanotify group identifies filesystem objects by file handles and mask contains a flag for permission events (**FAN_OPEN_PERM** or **FAN_ACCESS_PERM**).

EINVAL
The group was initialized without **FAN_REPORT_FID** but one or more event types specified in the *mask* require it.

EINVAL
flags contains **FAN_MARK_IGNORE**, and either **FAN_MARK_MOUNT** or **FAN_MARK_FILESYSTEM**, but does not contain **FAN_MARK_IGNORED_SURV_MODIFY**.

EISDIR
flags contains **FAN_MARK_IGNORE**, but does not contain **FAN_MARK_IGNORED_SURV_MODIFY**, and *dirfd* and *pathname* specify a directory.

ENODEV
The filesystem object indicated by *dirfd* and *pathname* is not associated with a filesystem that supports *fsid* (e.g., *fuse*(4)). *tmpfs*(5) did not support *fsid* prior to Linux 5.13. This error can be returned only with an fanotify group that identifies filesystem objects by file handles.

ENOENT
The filesystem object indicated by *dirfd* and *pathname* does not exist. This error also occurs when trying to remove a mark from an object which is not marked.

ENOMEM
The necessary memory could not be allocated.

ENOSPC
The number of marks for this user exceeds the limit and the **FAN_UNLIMITED_MARKS** flag was not specified when the fanotify file descriptor was created with *fanotify_init*(2). See *fanotify*(7) for details about this limit.

ENOSYS
This kernel does not implement **fanotify_mark**(). The fanotify API is available only if the kernel was configured with **CONFIG_FANOTIFY**.

ENOTDIR
flags contains **FAN_MARK_ONLYDIR**, and *dirfd* and *pathname* do not specify a directory.

ENOTDIR
mask contains **FAN_RENAME**, and *dirfd* and *pathname* do not specify a directory.

ENOTDIR
flags contains **FAN_MARK_IGNORE**, or the fanotify group was initialized with flag **FAN_REPORT_TARGET_FID**, and *mask* contains directory entry modification events (e.g., **FAN_CREATE**, **FAN_DELETE**), or directory event flags (e.g., **FAN_ONDIR**, **FAN_EVENT_ON_CHILD**), and *dirfd* and *pathname* do not specify a directory.

EOPNOTSUPP
The object indicated by *pathname* is associated with a filesystem that does not support the encoding of file handles. This error can be returned only with an fanotify group that identifies

filesystem objects by file handles. Calling *name_to_handle_at*(2) with the flag **AT_HANDLE_FID** (since Linux 6.5) can be used as a test to check if a filesystem supports reporting events with file handles.

EPERM
The operation is not permitted because the caller lacks a required capability.

EXDEV
The filesystem object indicated by *pathname* resides within a filesystem subvolume (e.g., *btrfs*(5)) which uses a different *fsid* than its root superblock. This error can be returned only with an fanotify group that identifies filesystem objects by file handles.

STANDARDS
Linux.

HISTORY
Linux 2.6.37.

NOTES
FAN_OPEN_EXEC and FAN_OPEN_EXEC_PERM
When using either **FAN_OPEN_EXEC** or **FAN_OPEN_EXEC_PERM** within the *mask*, events of these types will be returned only when the direct execution of a program occurs. More specifically, this means that events of these types will be generated for files that are opened using *execve*(2), *execveat*(2), or *uselib*(2). Events of these types will not be raised in the situation where an interpreter is passed (or reads) a file for interpretation.

Additionally, if a mark has also been placed on the Linux dynamic linker, a user should also expect to receive an event for it when an ELF object has been successfully opened using *execve*(2) or *execveat*(2).

For example, if the following ELF binary were to be invoked and a **FAN_OPEN_EXEC** mark has been placed on /:

```
$ /bin/echo foo
```

The listening application in this case would receive **FAN_OPEN_EXEC** events for both the ELF binary and interpreter, respectively:

```
/bin/echo
/lib64/ld-linux-x86-64.so.2
```

BUGS
The following bugs were present in before Linux 3.16:

- If *flags* contains **FAN_MARK_FLUSH**, *dirfd*, and *pathname* must specify a valid filesystem object, even though this object is not used.
- *readdir*(2) does not generate a **FAN_ACCESS** event.
- If **fanotify_mark**() is called with **FAN_MARK_FLUSH**, *flags* is not checked for invalid values.

NAME

fcntl − manipulate file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <fcntl.h>

int fcntl(int *fd***, int** *op***, ... /*** *arg* ***/);**

DESCRIPTION

fcntl() performs one of the operations described below on the open file descriptor *fd*. The operation is determined by *op*.

fcntl() can take an optional third argument. Whether or not this argument is required is determined by *op*. The required argument type is indicated in parentheses after each *op* name (in most cases, the required type is *int*, and we identify the argument using the name *arg*), or *void* is specified if the argument is not required.

Certain of the operations below are supported only since a particular Linux kernel version. The preferred method of checking whether the host kernel supports a particular operation is to invoke **fcntl**() with the desired *op* value and then test whether the call failed with **EINVAL**, indicating that the kernel does not recognize this value.

Duplicating a file descriptor

F_DUPFD (*int*)

Duplicate the file descriptor *fd* using the lowest-numbered available file descriptor greater than or equal to *arg*. This is different from *dup2*(2), which uses exactly the file descriptor specified.

On success, the new file descriptor is returned.

See *dup*(2) for further details.

F_DUPFD_CLOEXEC (*int*; since Linux 2.6.24)

As for **F_DUPFD**, but additionally set the close-on-exec flag for the duplicate file descriptor. Specifying this flag permits a program to avoid an additional **fcntl**() **F_SETFD** operation to set the **FD_CLOEXEC** flag. For an explanation of why this flag is useful, see the description of **O_CLOEXEC** in *open*(2).

File descriptor flags

The following operations manipulate the flags associated with a file descriptor. Currently, only one such flag is defined: **FD_CLOEXEC**, the close-on-exec flag. If the **FD_CLOEXEC** bit is set, the file descriptor will automatically be closed during a successful *execve*(2). (If the *execve*(2) fails, the file descriptor is left open.) If the **FD_CLOEXEC** bit is not set, the file descriptor will remain open across an *execve*(2).

F_GETFD (*void*)

Return (as the function result) the file descriptor flags; *arg* is ignored.

F_SETFD (*int*)

Set the file descriptor flags to the value specified by *arg*.

In multithreaded programs, using **fcntl**() **F_SETFD** to set the close-on-exec flag at the same time as another thread performs a *fork*(2) plus *execve*(2) is vulnerable to a race condition that may unintentionally leak the file descriptor to the program executed in the child process. See the discussion of the **O_CLOEXEC** flag in *open*(2) for details and a remedy to the problem.

File status flags

Each open file description has certain associated status flags, initialized by *open*(2) and possibly modified by **fcntl**(). Duplicated file descriptors (made with *dup*(2), *fcntl*(F_DUPFD), *fork*(2), etc.) refer to the same open file description, and thus share the same file status flags.

The file status flags and their semantics are described in *open*(2).

F_GETFL (*void*)

Return (as the function result) the file access mode and the file status flags; *arg* is ignored.

F_SETFL (*int*)
Set the file status flags to the value specified by *arg*. File access mode (**O_RDONLY**, **O_WRONLY**, **O_RDWR**) and file creation flags (i.e., **O_CREAT**, **O_EXCL**, **O_NOCTTY**, **O_TRUNC**) in *arg* are ignored. On Linux, this operation can change only the **O_APPEND**, **O_ASYNC**, **O_DIRECT**, **O_NOATIME**, and **O_NONBLOCK** flags. It is not possible to change the **O_DSYNC** and **O_SYNC** flags; see BUGS, below.

Advisory record locking
Linux implements traditional ("process-associated") UNIX record locks, as standardized by POSIX. For a Linux-specific alternative with better semantics, see the discussion of open file description locks below.

F_SETLK, **F_SETLKW**, and **F_GETLK** are used to acquire, release, and test for the existence of record locks (also known as byte-range, file-segment, or file-region locks). The third argument, *lock*, is a pointer to a structure that has at least the following fields (in unspecified order).

```
struct flock {
    ...
    short l_type;    /* Type of lock: F_RDLCK,
                        F_WRLCK, F_UNLCK */
    short l_whence;  /* How to interpret l_start:
                        SEEK_SET, SEEK_CUR, SEEK_END */
    off_t l_start;   /* Starting offset for lock */
    off_t l_len;     /* Number of bytes to lock */
    pid_t l_pid;     /* PID of process blocking our lock
                        (set by F_GETLK and F_OFD_GETLK) */
    ...
};
```

The *l_whence*, *l_start*, and *l_len* fields of this structure specify the range of bytes we wish to lock. Bytes past the end of the file may be locked, but not bytes before the start of the file.

l_start is the starting offset for the lock, and is interpreted relative to either: the start of the file (if *l_whence* is **SEEK_SET**); the current file offset (if *l_whence* is **SEEK_CUR**); or the end of the file (if *l_whence* is **SEEK_END**). In the final two cases, *l_start* can be a negative number provided the offset does not lie before the start of the file.

l_len specifies the number of bytes to be locked. If *l_len* is positive, then the range to be locked covers bytes *l_start* up to and including *l_start*+*l_len*−1. Specifying 0 for *l_len* has the special meaning: lock all bytes starting at the location specified by *l_whence* and *l_start* through to the end of file, no matter how large the file grows.

POSIX.1-2001 allows (but does not require) an implementation to support a negative *l_len* value; if *l_len* is negative, the interval described by *lock* covers bytes *l_start*+*l_len* up to and including *l_start*−1. This is supported since Linux 2.4.21 and Linux 2.5.49.

The *l_type* field can be used to place a read (**F_RDLCK**) or a write (**F_WRLCK**) lock on a file. Any number of processes may hold a read lock (shared lock) on a file region, but only one process may hold a write lock (exclusive lock). An exclusive lock excludes all other locks, both shared and exclusive. A single process can hold only one type of lock on a file region; if a new lock is applied to an already-locked region, then the existing lock is converted to the new lock type. (Such conversions may involve splitting, shrinking, or coalescing with an existing lock if the byte range specified by the new lock does not precisely coincide with the range of the existing lock.)

F_SETLK (*struct flock* *)
Acquire a lock (when *l_type* is **F_RDLCK** or **F_WRLCK**) or release a lock (when *l_type* is **F_UNLCK**) on the bytes specified by the *l_whence*, *l_start*, and *l_len* fields of *lock*. If a conflicting lock is held by another process, this call returns −1 and sets *errno* to **EACCES** or **EAGAIN**. (The error returned in this case differs across implementations, so POSIX requires a portable application to check for both errors.)

F_SETLKW (*struct flock* *)
As for **F_SETLK**, but if a conflicting lock is held on the file, then wait for that lock to be released. If a signal is caught while waiting, then the call is interrupted and (after the signal handler has returned) returns immediately (with return value −1 and *errno* set to **EINTR**; see

signal(7)).

F_GETLK (*struct flock* *)
On input to this call, *lock* describes a lock we would like to place on the file. If the lock could be placed, **fcntl**() does not actually place it, but returns **F_UNLCK** in the *l_type* field of *lock* and leaves the other fields of the structure unchanged.

If one or more incompatible locks would prevent this lock being placed, then **fcntl**() returns details about one of those locks in the *l_type*, *l_whence*, *l_start*, and *l_len* fields of *lock*. If the conflicting lock is a traditional (process-associated) record lock, then the *l_pid* field is set to the PID of the process holding that lock. If the conflicting lock is an open file description lock, then *l_pid* is set to −1. Note that the returned information may already be out of date by the time the caller inspects it.

In order to place a read lock, *fd* must be open for reading. In order to place a write lock, *fd* must be open for writing. To place both types of lock, open a file read-write.

When placing locks with **F_SETLKW**, the kernel detects *deadlocks*, whereby two or more processes have their lock requests mutually blocked by locks held by the other processes. For example, suppose process A holds a write lock on byte 100 of a file, and process B holds a write lock on byte 200. If each process then attempts to lock the byte already locked by the other process using **F_SETLKW**, then, without deadlock detection, both processes would remain blocked indefinitely. When the kernel detects such deadlocks, it causes one of the blocking lock requests to immediately fail with the error **EDEADLK**; an application that encounters such an error should release some of its locks to allow other applications to proceed before attempting regain the locks that it requires. Circular deadlocks involving more than two processes are also detected. Note, however, that there are limitations to the kernel's deadlock-detection algorithm; see BUGS.

As well as being removed by an explicit **F_UNLCK**, record locks are automatically released when the process terminates.

Record locks are not inherited by a child created via *fork*(2), but are preserved across an *execve*(2).

Because of the buffering performed by the *stdio*(3) library, the use of record locking with routines in that package should be avoided; use *read*(2) and *write*(2) instead.

The record locks described above are associated with the process (unlike the open file description locks described below). This has some unfortunate consequences:

- If a process closes *any* file descriptor referring to a file, then all of the process's locks on that file are released, regardless of the file descriptor(s) on which the locks were obtained. This is bad: it means that a process can lose its locks on a file such as */etc/passwd* or */etc/mtab* when for some reason a library function decides to open, read, and close the same file.
- The threads in a process share locks. In other words, a multithreaded program can't use record locking to ensure that threads don't simultaneously access the same region of a file.

Open file description locks solve both of these problems.

Open file description locks (non-POSIX)
Open file description locks are advisory byte-range locks whose operation is in most respects identical to the traditional record locks described above. This lock type is Linux-specific, and available since Linux 3.15. (There is a proposal with the Austin Group to include this lock type in the next revision of POSIX.1.) For an explanation of open file descriptions, see *open*(2).

The principal difference between the two lock types is that whereas traditional record locks are associated with a process, open file description locks are associated with the open file description on which they are acquired, much like locks acquired with *flock*(2). Consequently (and unlike traditional advisory record locks), open file description locks are inherited across *fork*(2) (and *clone*(2) with **CLONE_FILES**), and are only automatically released on the last close of the open file description, instead of being released on any close of the file.

Conflicting lock combinations (i.e., a read lock and a write lock or two write locks) where one lock is an open file description lock and the other is a traditional record lock conflict even when they are acquired by the same process on the same file descriptor.

Open file description locks placed via the same open file description (i.e., via the same file descriptor, or via a duplicate of the file descriptor created by *fork*(2), *dup*(2), **fcntl**() **F_DUPFD**, and so on) are

always compatible: if a new lock is placed on an already locked region, then the existing lock is converted to the new lock type. (Such conversions may result in splitting, shrinking, or coalescing with an existing lock as discussed above.)

On the other hand, open file description locks may conflict with each other when they are acquired via different open file descriptions. Thus, the threads in a multithreaded program can use open file description locks to synchronize access to a file region by having each thread perform its own *open*(2) on the file and applying locks via the resulting file descriptor.

As with traditional advisory locks, the third argument to **fcntl**(), *lock*, is a pointer to an *flock* structure. By contrast with traditional record locks, the *l_pid* field of that structure must be set to zero when using the operations described below.

The operations for working with open file description locks are analogous to those used with traditional locks:

F_OFD_SETLK (*struct flock* *)
: Acquire an open file description lock (when *l_type* is **F_RDLCK** or **F_WRLCK**) or release an open file description lock (when *l_type* is **F_UNLCK**) on the bytes specified by the *l_whence*, *l_start*, and *l_len* fields of *lock*. If a conflicting lock is held by another process, this call returns −1 and sets *errno* to **EAGAIN**.

F_OFD_SETLKW (*struct flock* *)
: As for **F_OFD_SETLK**, but if a conflicting lock is held on the file, then wait for that lock to be released. If a signal is caught while waiting, then the call is interrupted and (after the signal handler has returned) returns immediately (with return value −1 and *errno* set to **EINTR**; see *signal*(7)).

F_OFD_GETLK (*struct flock* *)
: On input to this call, *lock* describes an open file description lock we would like to place on the file. If the lock could be placed, **fcntl**() does not actually place it, but returns **F_UNLCK** in the *l_type* field of *lock* and leaves the other fields of the structure unchanged. If one or more incompatible locks would prevent this lock being placed, then details about one of these locks are returned via *lock*, as described above for **F_GETLK**.

In the current implementation, no deadlock detection is performed for open file description locks. (This contrasts with process-associated record locks, for which the kernel does perform deadlock detection.)

Mandatory locking

Warning: the Linux implementation of mandatory locking is unreliable. See BUGS below. Because of these bugs, and the fact that the feature is believed to be little used, since Linux 4.5, mandatory locking has been made an optional feature, governed by a configuration option (**CONFIG_MANDATORY_FILE_LOCKING**). This feature is no longer supported at all in Linux 5.15 and above.

By default, both traditional (process-associated) and open file description record locks are advisory. Advisory locks are not enforced and are useful only between cooperating processes.

Both lock types can also be mandatory. Mandatory locks are enforced for all processes. If a process tries to perform an incompatible access (e.g., *read*(2) or *write*(2)) on a file region that has an incompatible mandatory lock, then the result depends upon whether the **O_NONBLOCK** flag is enabled for its open file description. If the **O_NONBLOCK** flag is not enabled, then the system call is blocked until the lock is removed or converted to a mode that is compatible with the access. If the **O_NONBLOCK** flag is enabled, then the system call fails with the error **EAGAIN**.

To make use of mandatory locks, mandatory locking must be enabled both on the filesystem that contains the file to be locked, and on the file itself. Mandatory locking is enabled on a filesystem using the "−o mand" option to *mount*(8), or the **MS_MANDLOCK** flag for *mount*(2). Mandatory locking is enabled on a file by disabling group execute permission on the file and enabling the set-group-ID permission bit (see *chmod*(1) and *chmod*(2)).

Mandatory locking is not specified by POSIX. Some other systems also support mandatory locking, although the details of how to enable it vary across systems.

Lost locks

When an advisory lock is obtained on a networked filesystem such as NFS it is possible that the lock might get lost. This may happen due to administrative action on the server, or due to a network partition (i.e., loss of network connectivity with the server) which lasts long enough for the server to assume that the client is no longer functioning.

When the filesystem determines that a lock has been lost, future *read*(2) or *write*(2) requests may fail with the error **EIO**. This error will persist until the lock is removed or the file descriptor is closed. Since Linux 3.12, this happens at least for NFSv4 (including all minor versions).

Some versions of UNIX send a signal (**SIGLOST**) in this circumstance. Linux does not define this signal, and does not provide any asynchronous notification of lost locks.

Managing signals

F_GETOWN, **F_SETOWN**, **F_GETOWN_EX**, **F_SETOWN_EX**, **F_GETSIG**, and **F_SETSIG** are used to manage I/O availability signals:

F_GETOWN (*void*)

Return (as the function result) the process ID or process group ID currently receiving **SIGIO** and **SIGURG** signals for events on file descriptor *fd*. Process IDs are returned as positive values; process group IDs are returned as negative values (but see BUGS below). *arg* is ignored.

F_SETOWN (*int*)

Set the process ID or process group ID that will receive **SIGIO** and **SIGURG** signals for events on the file descriptor *fd*. The target process or process group ID is specified in *arg*. A process ID is specified as a positive value; a process group ID is specified as a negative value. Most commonly, the calling process specifies itself as the owner (that is, *arg* is specified as *getpid*(2)).

As well as setting the file descriptor owner, one must also enable generation of signals on the file descriptor. This is done by using the **fcntl**() **F_SETFL** operation to set the **O_ASYNC** file status flag on the file descriptor. Subsequently, a **SIGIO** signal is sent whenever input or output becomes possible on the file descriptor. The **fcntl**() **F_SETSIG** operation can be used to obtain delivery of a signal other than **SIGIO**.

Sending a signal to the owner process (group) specified by **F_SETOWN** is subject to the same permissions checks as are described for *kill*(2), where the sending process is the one that employs **F_SETOWN** (but see BUGS below). If this permission check fails, then the signal is silently discarded. *Note*: The **F_SETOWN** operation records the caller's credentials at the time of the **fcntl**() call, and it is these saved credentials that are used for the permission checks.

If the file descriptor *fd* refers to a socket, **F_SETOWN** also selects the recipient of **SIGURG** signals that are delivered when out-of-band data arrives on that socket. (**SIGURG** is sent in any situation where *select*(2) would report the socket as having an "exceptional condition".)

The following was true in Linux 2.6.x up to and including Linux 2.6.11:

> If a nonzero value is given to **F_SETSIG** in a multithreaded process running with a threading library that supports thread groups (e.g., NPTL), then a positive value given to **F_SETOWN** has a different meaning: instead of being a process ID identifying a whole process, it is a thread ID identifying a specific thread within a process. Consequently, it may be necessary to pass **F_SETOWN** the result of *gettid*(2) instead of *getpid*(2) to get sensible results when **F_SETSIG** is used. (In current Linux threading implementations, a main thread's thread ID is the same as its process ID. This means that a single-threaded program can equally use *gettid*(2) or *getpid*(2) in this scenario.) Note, however, that the statements in this paragraph do not apply to the **SIGURG** signal generated for out-of-band data on a socket: this signal is always sent to either a process or a process group, depending on the value given to **F_SETOWN**.

The above behavior was accidentally dropped in Linux 2.6.12, and won't be restored. From Linux 2.6.32 onward, use **F_SETOWN_EX** to target **SIGIO** and **SIGURG** signals at a particular thread.

F_GETOWN_EX (*struct f_owner_ex* *) (since Linux 2.6.32)
Return the current file descriptor owner settings as defined by a previous **F_SETOWN_EX** operation. The information is returned in the structure pointed to by *arg*, which has the following form:

```
struct f_owner_ex {
    int   type;
    pid_t pid;
};
```

The *type* field will have one of the values **F_OWNER_TID**, **F_OWNER_PID**, or **F_OWNER_PGRP**. The *pid* field is a positive integer representing a thread ID, process ID, or process group ID. See **F_SETOWN_EX** for more details.

F_SETOWN_EX (*struct f_owner_ex* *) (since Linux 2.6.32)
This operation performs a similar task to **F_SETOWN**. It allows the caller to direct I/O availability signals to a specific thread, process, or process group. The caller specifies the target of signals via *arg*, which is a pointer to a *f_owner_ex* structure. The *type* field has one of the following values, which define how *pid* is interpreted:

F_OWNER_TID
Send the signal to the thread whose thread ID (the value returned by a call to *clone*(2) or *gettid*(2)) is specified in *pid*.

F_OWNER_PID
Send the signal to the process whose ID is specified in *pid*.

F_OWNER_PGRP
Send the signal to the process group whose ID is specified in *pid*. (Note that, unlike with **F_SETOWN**, a process group ID is specified as a positive value here.)

F_GETSIG (*void*)
Return (as the function result) the signal sent when input or output becomes possible. A value of zero means **SIGIO** is sent. Any other value (including **SIGIO**) is the signal sent instead, and in this case additional info is available to the signal handler if installed with **SA_SIGINFO**. *arg* is ignored.

F_SETSIG (*int*)
Set the signal sent when input or output becomes possible to the value given in *arg*. A value of zero means to send the default **SIGIO** signal. Any other value (including **SIGIO**) is the signal to send instead, and in this case additional info is available to the signal handler if installed with **SA_SIGINFO**.

By using **F_SETSIG** with a nonzero value, and setting **SA_SIGINFO** for the signal handler (see *sigaction*(2)), extra information about I/O events is passed to the handler in a *siginfo_t* structure. If the *si_code* field indicates the source is **SI_SIGIO**, the *si_fd* field gives the file descriptor associated with the event. Otherwise, there is no indication which file descriptors are pending, and you should use the usual mechanisms (**select**(2), *poll*(2), *read*(2) with **O_NONBLOCK** set etc.) to determine which file descriptors are available for I/O.

Note that the file descriptor provided in *si_fd* is the one that was specified during the **F_SETSIG** operation. This can lead to an unusual corner case. If the file descriptor is duplicated (**dup**(2) or similar), and the original file descriptor is closed, then I/O events will continue to be generated, but the *si_fd* field will contain the number of the now closed file descriptor.

By selecting a real time signal (value >= **SIGRTMIN**), multiple I/O events may be queued using the same signal numbers. (Queuing is dependent on available memory.) Extra information is available if **SA_SIGINFO** is set for the signal handler, as above.

Note that Linux imposes a limit on the number of real-time signals that may be queued to a process (see *getrlimit*(2) and *signal*(7)) and if this limit is reached, then the kernel reverts to delivering **SIGIO**, and this signal is delivered to the entire process rather than to a specific thread.

Using these mechanisms, a program can implement fully asynchronous I/O without using *select*(2) or *poll*(2) most of the time.

The use of **O_ASYNC** is specific to BSD and Linux. The only use of **F_GETOWN** and **F_SETOWN** specified in POSIX.1 is in conjunction with the use of the **SIGURG** signal on sockets. (POSIX does not specify the **SIGIO** signal.) **F_GETOWN_EX**, **F_SETOWN_EX**, **F_GETSIG**, and **F_SETSIG** are Linux-specific. POSIX has asynchronous I/O and the *aio_sigevent* structure to achieve similar things; these are also available in Linux as part of the GNU C Library (glibc).

Leases

F_SETLEASE and **F_GETLEASE** (Linux 2.4 onward) are used to establish a new lease, and retrieve the current lease, on the open file description referred to by the file descriptor *fd*. A file lease provides a mechanism whereby the process holding the lease (the "lease holder") is notified (via delivery of a signal) when a process (the "lease breaker") tries to *open*(2) or *truncate*(2) the file referred to by that file descriptor.

F_SETLEASE (*int*)

Set or remove a file lease according to which of the following values is specified in the integer *arg*:

F_RDLCK

Take out a read lease. This will cause the calling process to be notified when the file is opened for writing or is truncated. A read lease can be placed only on a file descriptor that is opened read-only.

F_WRLCK

Take out a write lease. This will cause the caller to be notified when the file is opened for reading or writing or is truncated. A write lease may be placed on a file only if there are no other open file descriptors for the file.

F_UNLCK

Remove our lease from the file.

Leases are associated with an open file description (see *open*(2)). This means that duplicate file descriptors (created by, for example, *fork*(2) or *dup*(2)) refer to the same lease, and this lease may be modified or released using any of these descriptors. Furthermore, the lease is released by either an explicit **F_UNLCK** operation on any of these duplicate file descriptors, or when all such file descriptors have been closed.

Leases may be taken out only on regular files. An unprivileged process may take out a lease only on a file whose UID (owner) matches the filesystem UID of the process. A process with the **CAP_LEASE** capability may take out leases on arbitrary files.

F_GETLEASE (*void*)

Indicates what type of lease is associated with the file descriptor *fd* by returning either **F_RDLCK**, **F_WRLCK**, or **F_UNLCK**, indicating, respectively, a read lease , a write lease, or no lease. *arg* is ignored.

When a process (the "lease breaker") performs an *open*(2) or *truncate*(2) that conflicts with a lease established via **F_SETLEASE**, the system call is blocked by the kernel and the kernel notifies the lease holder by sending it a signal (**SIGIO** by default). The lease holder should respond to receipt of this signal by doing whatever cleanup is required in preparation for the file to be accessed by another process (e.g., flushing cached buffers) and then either remove or downgrade its lease. A lease is removed by performing an **F_SETLEASE** operation specifying *arg* as **F_UNLCK**. If the lease holder currently holds a write lease on the file, and the lease breaker is opening the file for reading, then it is sufficient for the lease holder to downgrade the lease to a read lease. This is done by performing an **F_SETLEASE** operation specifying *arg* as **F_RDLCK**.

If the lease holder fails to downgrade or remove the lease within the number of seconds specified in */proc/sys/fs/lease-break-time*, then the kernel forcibly removes or downgrades the lease holder's lease.

Once a lease break has been initiated, **F_GETLEASE** returns the target lease type (either **F_RDLCK** or **F_UNLCK**, depending on what would be compatible with the lease breaker) until the lease holder voluntarily downgrades or removes the lease or the kernel forcibly does so after the lease break timer expires.

Once the lease has been voluntarily or forcibly removed or downgraded, and assuming the lease breaker has not unblocked its system call, the kernel permits the lease breaker's system call to proceed.

If the lease breaker's blocked *open*(2) or *truncate*(2) is interrupted by a signal handler, then the system call fails with the error **EINTR**, but the other steps still occur as described above. If the lease breaker is killed by a signal while blocked in *open*(2) or *truncate*(2), then the other steps still occur as described above. If the lease breaker specifies the **O_NONBLOCK** flag when calling *open*(2), then the call immediately fails with the error **EWOULDBLOCK**, but the other steps still occur as described above.

The default signal used to notify the lease holder is **SIGIO**, but this can be changed using the **F_SETSIG** operation to **fcntl**(). If a **F_SETSIG** operation is performed (even one specifying **SIGIO**), and the signal handler is established using **SA_SIGINFO**, then the handler will receive a *siginfo_t* structure as its second argument, and the *si_fd* field of this argument will hold the file descriptor of the leased file that has been accessed by another process. (This is useful if the caller holds leases against multiple files.)

File and directory change notification (dnotify)

F_NOTIFY (*int*)

(Linux 2.4 onward) Provide notification when the directory referred to by *fd* or any of the files that it contains is changed. The events to be notified are specified in *arg*, which is a bit mask specified by ORing together zero or more of the following bits:

DN_ACCESS
A file was accessed (**read**(2), *pread*(2), *readv*(2), and similar)

DN_MODIFY
A file was modified (**write**(2), *pwrite*(2), *writev*(2), *truncate*(2), *ftruncate*(2), and similar).

DN_CREATE
A file was created (**open**(2), *creat*(2), *mknod*(2), *mkdir*(2), *link*(2), *symlink*(2), *rename*(2) into this directory).

DN_DELETE
A file was unlinked (**unlink**(2), *rename*(2) to another directory, *rmdir*(2)).

DN_RENAME
A file was renamed within this directory (**rename**(2)).

DN_ATTRIB
The attributes of a file were changed (**chown**(2), *chmod*(2), *utime*(2), *utimensat*(2), and similar).

(In order to obtain these definitions, the **_GNU_SOURCE** feature test macro must be defined before including *any* header files.)

Directory notifications are normally "one-shot", and the application must reregister to receive further notifications. Alternatively, if **DN_MULTISHOT** is included in *arg*, then notification will remain in effect until explicitly removed.

A series of **F_NOTIFY** requests is cumulative, with the events in *arg* being added to the set already monitored. To disable notification of all events, make an **F_NOTIFY** call specifying *arg* as 0.

Notification occurs via delivery of a signal. The default signal is **SIGIO**, but this can be changed using the **F_SETSIG** operation to **fcntl**(). (Note that **SIGIO** is one of the nonqueuing standard signals; switching to the use of a real-time signal means that multiple notifications can be queued to the process.) In the latter case, the signal handler receives a *siginfo_t* structure as its second argument (if the handler was established using **SA_SIGINFO**) and the *si_fd* field of this structure contains the file descriptor which generated the notification (useful when establishing notification on multiple directories).

Especially when using **DN_MULTISHOT**, a real time signal should be used for notification, so that multiple notifications can be queued.

NOTE: New applications should use the *inotify* interface (available since Linux 2.6.13), which provides a much superior interface for obtaining notifications of filesystem events. See *inotify*(7).

Changing the capacity of a pipe

F_SETPIPE_SZ (*int*; since Linux 2.6.35)

Change the capacity of the pipe referred to by *fd* to be at least *arg* bytes. An unprivileged process can adjust the pipe capacity to any value between the system page size and the limit

defined in */proc/sys/fs/pipe-max-size* (see *proc*(5)). Attempts to set the pipe capacity below the page size are silently rounded up to the page size. Attempts by an unprivileged process to set the pipe capacity above the limit in */proc/sys/fs/pipe-max-size* yield the error **EPERM**; a privileged process (**CAP_SYS_RESOURCE**) can override the limit.

When allocating the buffer for the pipe, the kernel may use a capacity larger than *arg*, if that is convenient for the implementation. (In the current implementation, the allocation is the next higher power-of-two page-size multiple of the requested size.) The actual capacity (in bytes) that is set is returned as the function result.

Attempting to set the pipe capacity smaller than the amount of buffer space currently used to store data produces the error **EBUSY**.

Note that because of the way the pages of the pipe buffer are employed when data is written to the pipe, the number of bytes that can be written may be less than the nominal size, depending on the size of the writes.

F_GETPIPE_SZ (*void*; since Linux 2.6.35)
Return (as the function result) the capacity of the pipe referred to by *fd*.

File Sealing

File seals limit the set of allowed operations on a given file. For each seal that is set on a file, a specific set of operations will fail with **EPERM** on this file from now on. The file is said to be sealed. The default set of seals depends on the type of the underlying file and filesystem. For an overview of file sealing, a discussion of its purpose, and some code examples, see *memfd_create*(2).

Currently, file seals can be applied only to a file descriptor returned by *memfd_create*(2) (if the **MFD_ALLOW_SEALING** was employed). On other filesystems, all **fcntl**() operations that operate on seals will return **EINVAL**.

Seals are a property of an inode. Thus, all open file descriptors referring to the same inode share the same set of seals. Furthermore, seals can never be removed, only added.

F_ADD_SEALS (*int*; since Linux 3.17)
Add the seals given in the bit-mask argument *arg* to the set of seals of the inode referred to by the file descriptor *fd*. Seals cannot be removed again. Once this call succeeds, the seals are enforced by the kernel immediately. If the current set of seals includes **F_SEAL_SEAL** (see below), then this call will be rejected with **EPERM**. Adding a seal that is already set is a no-op, in case **F_SEAL_SEAL** is not set already. In order to place a seal, the file descriptor *fd* must be writable.

F_GET_SEALS (*void*; since Linux 3.17)
Return (as the function result) the current set of seals of the inode referred to by *fd*. If no seals are set, 0 is returned. If the file does not support sealing, −1 is returned and *errno* is set to **EINVAL**.

The following seals are available:

F_SEAL_SEAL
If this seal is set, any further call to **fcntl**() with **F_ADD_SEALS** fails with the error **EPERM**. Therefore, this seal prevents any modifications to the set of seals itself. If the initial set of seals of a file includes **F_SEAL_SEAL**, then this effectively causes the set of seals to be constant and locked.

F_SEAL_SHRINK
If this seal is set, the file in question cannot be reduced in size. This affects *open*(2) with the **O_TRUNC** flag as well as *truncate*(2) and *ftruncate*(2). Those calls fail with **EPERM** if you try to shrink the file in question. Increasing the file size is still possible.

F_SEAL_GROW
If this seal is set, the size of the file in question cannot be increased. This affects *write*(2) beyond the end of the file, *truncate*(2), *ftruncate*(2), and *fallocate*(2). These calls fail with **EPERM** if you use them to increase the file size. If you keep the size or shrink it, those calls still work as expected.

F_SEAL_WRITE
If this seal is set, you cannot modify the contents of the file. Note that shrinking or growing the size of the file is still possible and allowed. Thus, this seal is normally used in combination with one of the other seals. This seal affects *write*(2) and *fallocate*(2) (only in combination with the **FALLOC_FL_PUNCH_HOLE** flag). Those calls fail with **EPERM** if this seal is set. Furthermore, trying to create new shared, writable memory-mappings via *mmap*(2) will also fail with **EPERM**.

Using the **F_ADD_SEALS** operation to set the **F_SEAL_WRITE** seal fails with **EBUSY** if any writable, shared mapping exists. Such mappings must be unmapped before you can add this seal. Furthermore, if there are any asynchronous I/O operations (**io_submit**(2)) pending on the file, all outstanding writes will be discarded.

F_SEAL_FUTURE_WRITE (since Linux 5.1)
The effect of this seal is similar to **F_SEAL_WRITE**, but the contents of the file can still be modified via shared writable mappings that were created prior to the seal being set. Any attempt to create a new writable mapping on the file via *mmap*(2) will fail with **EPERM**. Likewise, an attempt to write to the file via *write*(2) will fail with **EPERM**.

Using this seal, one process can create a memory buffer that it can continue to modify while sharing that buffer on a "read-only" basis with other processes.

File read/write hints
Write lifetime hints can be used to inform the kernel about the relative expected lifetime of writes on a given inode or via a particular open file description. (See *open*(2) for an explanation of open file descriptions.) In this context, the term "write lifetime" means the expected time the data will live on media, before being overwritten or erased.

An application may use the different hint values specified below to separate writes into different write classes, so that multiple users or applications running on a single storage back-end can aggregate their I/O patterns in a consistent manner. However, there are no functional semantics implied by these flags, and different I/O classes can use the write lifetime hints in arbitrary ways, so long as the hints are used consistently.

The following operations can be applied to the file descriptor, *fd*:

F_GET_RW_HINT (*uint64_t* *; since Linux 4.13)
Returns the value of the read/write hint associated with the underlying inode referred to by *fd*.

F_SET_RW_HINT (*uint64_t* *; since Linux 4.13)
Sets the read/write hint value associated with the underlying inode referred to by *fd*. This hint persists until either it is explicitly modified or the underlying filesystem is unmounted.

F_GET_FILE_RW_HINT (*uint64_t* *; since Linux 4.13)
Returns the value of the read/write hint associated with the open file description referred to by *fd*.

F_SET_FILE_RW_HINT (*uint64_t* *; since Linux 4.13)
Sets the read/write hint value associated with the open file description referred to by *fd*.

If an open file description has not been assigned a read/write hint, then it shall use the value assigned to the inode, if any.

The following read/write hints are valid since Linux 4.13:

RWH_WRITE_LIFE_NOT_SET
No specific hint has been set. This is the default value.

RWH_WRITE_LIFE_NONE
No specific write lifetime is associated with this file or inode.

RWH_WRITE_LIFE_SHORT
Data written to this inode or via this open file description is expected to have a short lifetime.

RWH_WRITE_LIFE_MEDIUM
Data written to this inode or via this open file description is expected to have a lifetime longer than data written with **RWH_WRITE_LIFE_SHORT**.

RWH_WRITE_LIFE_LONG
Data written to this inode or via this open file description is expected to have a lifetime longer than data written with **RWH_WRITE_LIFE_MEDIUM**.

RWH_WRITE_LIFE_EXTREME
Data written to this inode or via this open file description is expected to have a lifetime longer than data written with **RWH_WRITE_LIFE_LONG**.

All the write-specific hints are relative to each other, and no individual absolute meaning should be attributed to them.

RETURN VALUE

For a successful call, the return value depends on the operation:

F_DUPFD
The new file descriptor.

F_GETFD
Value of file descriptor flags.

F_GETFL
Value of file status flags.

F_GETLEASE
Type of lease held on file descriptor.

F_GETOWN
Value of file descriptor owner.

F_GETSIG
Value of signal sent when read or write becomes possible, or zero for traditional **SIGIO** behavior.

F_GETPIPE_SZ
F_SETPIPE_SZ
The pipe capacity.

F_GET_SEALS
A bit mask identifying the seals that have been set for the inode referred to by *fd*.

All other operations
Zero.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES or **EAGAIN**
Operation is prohibited by locks held by other processes.

EAGAIN
The operation is prohibited because the file has been memory-mapped by another process.

EBADF
fd is not an open file descriptor

EBADF
op is **F_SETLK** or **F_SETLKW** and the file descriptor open mode doesn't match with the type of lock requested.

EBUSY
op is **F_SETPIPE_SZ** and the new pipe capacity specified in *arg* is smaller than the amount of buffer space currently used to store data in the pipe.

EBUSY
op is **F_ADD_SEALS**, *arg* includes **F_SEAL_WRITE**, and there exists a writable, shared mapping on the file referred to by *fd*.

EDEADLK
It was detected that the specified **F_SETLKW** operation would cause a deadlock.

EFAULT
lock is outside your accessible address space.

EINTR
op is **F_SETLKW** or **F_OFD_SETLKW** and the operation was interrupted by a signal; see *signal*(7).

EINTR
op is **F_GETLK**, **F_SETLK**, **F_OFD_GETLK**, or **F_OFD_SETLK**, and the operation was interrupted by a signal before the lock was checked or acquired. Most likely when locking a remote file (e.g., locking over NFS), but can sometimes happen locally.

EINVAL
The value specified in *op* is not recognized by this kernel.

EINVAL
op is **F_ADD_SEALS** and *arg* includes an unrecognized sealing bit.

EINVAL
op is **F_ADD_SEALS** or **F_GET_SEALS** and the filesystem containing the inode referred to by *fd* does not support sealing.

EINVAL
op is **F_DUPFD** and *arg* is negative or is greater than the maximum allowable value (see the discussion of **RLIMIT_NOFILE** in *getrlimit*(2)).

EINVAL
op is **F_SETSIG** and *arg* is not an allowable signal number.

EINVAL
op is **F_OFD_SETLK**, **F_OFD_SETLKW**, or **F_OFD_GETLK**, and *l_pid* was not specified as zero.

EMFILE
op is **F_DUPFD** and the per-process limit on the number of open file descriptors has been reached.

ENOLCK
Too many segment locks open, lock table is full, or a remote locking protocol failed (e.g., locking over NFS).

ENOTDIR
F_NOTIFY was specified in *op*, but *fd* does not refer to a directory.

EPERM
op is **F_SETPIPE_SZ** and the soft or hard user pipe limit has been reached; see *pipe*(7).

EPERM
Attempted to clear the **O_APPEND** flag on a file that has the append-only attribute set.

EPERM
op was **F_ADD_SEALS**, but *fd* was not open for writing or the current set of seals on the file already includes **F_SEAL_SEAL**.

STANDARDS

POSIX.1-2008.

F_GETOWN_EX, **F_SETOWN_EX**, **F_SETPIPE_SZ**, **F_GETPIPE_SZ**, **F_GETSIG**, **F_SETSIG**, **F_NOTIFY**, **F_GETLEASE**, and **F_SETLEASE** are Linux-specific. (Define the **_GNU_SOURCE** macro to obtain these definitions.)

F_OFD_SETLK, **F_OFD_SETLKW**, and **F_OFD_GETLK** are Linux-specific (and one must define **_GNU_SOURCE** to obtain their definitions), but work is being done to have them included in the next version of POSIX.1.

F_ADD_SEALS and **F_GET_SEALS** are Linux-specific.

HISTORY

SVr4, 4.3BSD, POSIX.1-2001.

Only the operations **F_DUPFD**, **F_GETFD**, **F_SETFD**, **F_GETFL**, **F_SETFL**, **F_GETLK**,

F_SETLK, and **F_SETLKW** are specified in POSIX.1-2001.

F_GETOWN and **F_SETOWN** are specified in POSIX.1-2001. (To get their definitions, define either **_XOPEN_SOURCE** with the value 500 or greater, or **_POSIX_C_SOURCE** with the value 200809L or greater.)

F_DUPFD_CLOEXEC is specified in POSIX.1-2008. (To get this definition, define **_POSIX_C_SOURCE** with the value 200809L or greater, or **_XOPEN_SOURCE** with the value 700 or greater.)

NOTES

The errors returned by *dup2*(2) are different from those returned by **F_DUPFD**.

File locking

The original Linux **fcntl**() system call was not designed to handle large file offsets (in the *flock* structure). Consequently, an **fcntl64**() system call was added in Linux 2.4. The newer system call employs a different structure for file locking, *flock64*, and corresponding operations, **F_GETLK64**, **F_SETLK64**, and **F_SETLKW64**. However, these details can be ignored by applications using glibc, whose **fcntl**() wrapper function transparently employs the more recent system call where it is available.

Record locks

Since Linux 2.0, there is no interaction between the types of lock placed by *flock*(2) and **fcntl**().

Several systems have more fields in *struct flock* such as, for example, *l_sysid* (to identify the machine where the lock is held). Clearly, *l_pid* alone is not going to be very useful if the process holding the lock may live on a different machine; on Linux, while present on some architectures (such as MIPS32), this field is not used.

The original Linux **fcntl**() system call was not designed to handle large file offsets (in the *flock* structure). Consequently, an **fcntl64**() system call was added in Linux 2.4. The newer system call employs a different structure for file locking, *flock64*, and corresponding operations, **F_GETLK64**, **F_SETLK64**, and **F_SETLKW64**. However, these details can be ignored by applications using glibc, whose **fcntl**() wrapper function transparently employs the more recent system call where it is available.

Record locking and NFS

Before Linux 3.12, if an NFSv4 client loses contact with the server for a period of time (defined as more than 90 seconds with no communication), it might lose and regain a lock without ever being aware of the fact. (The period of time after which contact is assumed lost is known as the NFSv4 lease-time. On a Linux NFS server, this can be determined by looking at */proc/fs/nfsd/nfsv4leasetime*, which expresses the period in seconds. The default value for this file is 90.) This scenario potentially risks data corruption, since another process might acquire a lock in the intervening period and perform file I/O.

Since Linux 3.12, if an NFSv4 client loses contact with the server, any I/O to the file by a process which "thinks" it holds a lock will fail until that process closes and reopens the file. A kernel parameter, *nfs.recover_lost_locks*, can be set to 1 to obtain the pre-3.12 behavior, whereby the client will attempt to recover lost locks when contact is reestablished with the server. Because of the attendant risk of data corruption, this parameter defaults to 0 (disabled).

BUGS

F_SETFL

It is not possible to use **F_SETFL** to change the state of the **O_DSYNC** and **O_SYNC** flags. Attempts to change the state of these flags are silently ignored.

F_GETOWN

A limitation of the Linux system call conventions on some architectures (notably i386) means that if a (negative) process group ID to be returned by **F_GETOWN** falls in the range −1 to −4095, then the return value is wrongly interpreted by glibc as an error in the system call; that is, the return value of **fcntl**() will be −1, and *errno* will contain the (positive) process group ID. The Linux-specific **F_GETOWN_EX** operation avoids this problem. Since glibc 2.11, glibc makes the kernel **F_GETOWN** problem invisible by implementing **F_GETOWN** using **F_GETOWN_EX**.

F_SETOWN

In Linux 2.4 and earlier, there is bug that can occur when an unprivileged process uses **F_SETOWN** to specify the owner of a socket file descriptor as a process (group) other than the caller. In this case, **fcntl**() can return −1 with *errno* set to **EPERM**, even when the owner process (group) is one that the

caller has permission to send signals to. Despite this error return, the file descriptor owner is set, and signals will be sent to the owner.

Deadlock detection

The deadlock-detection algorithm employed by the kernel when dealing with **F_SETLKW** requests can yield both false negatives (failures to detect deadlocks, leaving a set of deadlocked processes blocked indefinitely) and false positives (**EDEADLK** errors when there is no deadlock). For example, the kernel limits the lock depth of its dependency search to 10 steps, meaning that circular deadlock chains that exceed that size will not be detected. In addition, the kernel may falsely indicate a deadlock when two or more processes created using the *clone*(2) **CLONE_FILES** flag place locks that appear (to the kernel) to conflict.

Mandatory locking

The Linux implementation of mandatory locking is subject to race conditions which render it unreliable: a *write*(2) call that overlaps with a lock may modify data after the mandatory lock is acquired; a *read*(2) call that overlaps with a lock may detect changes to data that were made only after a write lock was acquired. Similar races exist between mandatory locks and *mmap*(2). It is therefore inadvisable to rely on mandatory locking.

NAME

flock − apply or remove an advisory lock on an open file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/file.h>

int flock(int *fd***, int** *op***);**

DESCRIPTION

Apply or remove an advisory lock on the open file specified by *fd*. The argument *op* is one of the following:

LOCK_SH
Place a shared lock. More than one process may hold a shared lock for a given file at a given time.

LOCK_EX
Place an exclusive lock. Only one process may hold an exclusive lock for a given file at a given time.

LOCK_UN
Remove an existing lock held by this process.

A call to **flock**() may block if an incompatible lock is held by another process. To make a nonblocking request, include **LOCK_NB** (by ORing) with any of the above operations.

A single file may not simultaneously have both shared and exclusive locks.

Locks created by **flock**() are associated with an open file description (see *open*(2)). This means that duplicate file descriptors (created by, for example, *fork*(2) or *dup*(2)) refer to the same lock, and this lock may be modified or released using any of these file descriptors. Furthermore, the lock is released either by an explicit **LOCK_UN** operation on any of these duplicate file descriptors, or when all such file descriptors have been closed.

If a process uses *open*(2) (or similar) to obtain more than one file descriptor for the same file, these file descriptors are treated independently by **flock**(). An attempt to lock the file using one of these file descriptors may be denied by a lock that the calling process has already placed via another file descriptor.

A process may hold only one type of lock (shared or exclusive) on a file. Subsequent **flock**() calls on an already locked file will convert an existing lock to the new lock mode.

Locks created by **flock**() are preserved across an *execve*(2).

A shared or exclusive lock can be placed on a file regardless of the mode in which the file was opened.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
fd is not an open file descriptor.

EINTR
While waiting to acquire a lock, the call was interrupted by delivery of a signal caught by a handler; see *signal*(7).

EINVAL
op is invalid.

ENOLCK
The kernel ran out of memory for allocating lock records.

EWOULDBLOCK
The file is locked and the **LOCK_NB** flag was selected.

VERSIONS

Since Linux 2.0, **flock**() is implemented as a system call in its own right rather than being emulated in the GNU C library as a call to *fcntl*(2). With this implementation, there is no interaction between the

types of lock placed by **flock**() and *fcntl*(2), and **flock**() does not detect deadlock. (Note, however, that on some systems, such as the modern BSDs, **flock**() and *fcntl*(2) locks *do* interact with one another.)

CIFS details

Up to Linux 5.4, **flock**() is not propagated over SMB. A file with such locks will not appear locked for remote clients.

Since Linux 5.5, **flock**() locks are emulated with SMB byte-range locks on the entire file. Similarly to NFS, this means that *fcntl*(2) and **flock**() locks interact with one another. Another important side-effect is that the locks are not advisory anymore: any IO on a locked file will always fail with **EACCES** when done from a separate file descriptor. This difference originates from the design of locks in the SMB protocol, which provides mandatory locking semantics.

Remote and mandatory locking semantics may vary with SMB protocol, mount options and server type. See *mount.cifs*(8) for additional information.

STANDARDS

BSD.

HISTORY

4.4BSD (the **flock**() call first appeared in 4.2BSD). A version of **flock**(), possibly implemented in terms of *fcntl*(2), appears on most UNIX systems.

NFS details

Up to Linux 2.6.11, **flock**() does not lock files over NFS (i.e., the scope of locks was limited to the local system). Instead, one could use *fcntl*(2) byte-range locking, which does work over NFS, given a sufficiently recent version of Linux and a server which supports locking.

Since Linux 2.6.12, NFS clients support **flock**() locks by emulating them as *fcntl*(2) byte-range locks on the entire file. This means that *fcntl*(2) and **flock**() locks *do* interact with one another over NFS. It also means that in order to place an exclusive lock, the file must be opened for writing.

Since Linux 2.6.37, the kernel supports a compatibility mode that allows **flock**() locks (and also *fcntl*(2) byte region locks) to be treated as local; see the discussion of the *local_lock* option in *nfs*(5)

NOTES

flock() places advisory locks only; given suitable permissions on a file, a process is free to ignore the use of **flock**() and perform I/O on the file.

flock() and *fcntl*(2) locks have different semantics with respect to forked processes and *dup*(2). On systems that implement **flock**() using *fcntl*(2), the semantics of **flock**() will be different from those described in this manual page.

Converting a lock (shared to exclusive, or vice versa) is not guaranteed to be atomic: the existing lock is first removed, and then a new lock is established. Between these two steps, a pending lock request by another process may be granted, with the result that the conversion either blocks, or fails if **LOCK_NB** was specified. (This is the original BSD behavior, and occurs on many other implementations.)

NAME

fork − create a child process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

pid_t fork(void);

DESCRIPTION

fork() creates a new process by duplicating the calling process. The new process is referred to as the *child* process. The calling process is referred to as the *parent* process.

The child process and the parent process run in separate memory spaces. At the time of **fork**() both memory spaces have the same content. Memory writes, file mappings (**mmap**(2)), and unmappings (**munmap**(2)) performed by one of the processes do not affect the other.

The child process is an exact duplicate of the parent process except for the following points:

- The child has its own unique process ID, and this PID does not match the ID of any existing process group (**setpgid**(2)) or session.
- The child's parent process ID is the same as the parent's process ID.
- The child does not inherit its parent's memory locks (**mlock**(2), *mlockall*(2)).
- Process resource utilizations (**getrusage**(2)) and CPU time counters (**times**(2)) are reset to zero in the child.
- The child's set of pending signals is initially empty (**sigpending**(2)).
- The child does not inherit semaphore adjustments from its parent (**semop**(2)).
- The child does not inherit process-associated record locks from its parent (**fcntl**(2)). (On the other hand, it does inherit *fcntl*(2) open file description locks and *flock*(2) locks from its parent.)
- The child does not inherit timers from its parent (**setitimer**(2), *alarm*(2), *timer_create*(2)).
- The child does not inherit outstanding asynchronous I/O operations from its parent (**aio_read**(3), *aio_write*(3)), nor does it inherit any asynchronous I/O contexts from its parent (see *io_setup*(2)).

The process attributes in the preceding list are all specified in POSIX.1. The parent and child also differ with respect to the following Linux-specific process attributes:

- The child does not inherit directory change notifications (dnotify) from its parent (see the description of **F_NOTIFY** in *fcntl*(2)).
- The *prctl*(2) **PR_SET_PDEATHSIG** setting is reset so that the child does not receive a signal when its parent terminates.
- The default timer slack value is set to the parent's current timer slack value. See the description of **PR_SET_TIMERSLACK** in *prctl*(2).
- Memory mappings that have been marked with the *madvise*(2) **MADV_DONTFORK** flag are not inherited across a **fork**().
- Memory in address ranges that have been marked with the *madvise*(2) **MADV_WIPEONFORK** flag is zeroed in the child after a **fork**(). (The **MADV_WIPEONFORK** setting remains in place for those address ranges in the child.)
- The termination signal of the child is always **SIGCHLD** (see *clone*(2)).
- The port access permission bits set by *ioperm*(2) are not inherited by the child; the child must turn on any bits that it requires using *ioperm*(2).

Note the following further points:

- The child process is created with a single thread—the one that called **fork**(). The entire virtual address space of the parent is replicated in the child, including the states of mutexes, condition variables, and other pthreads objects; the use of *pthread_atfork*(3) may be helpful for dealing with problems that this can cause.

- After a **fork**() in a multithreaded program, the child can safely call only async-signal-safe functions (see *signal-safety*(7)) until such time as it calls *execve*(2).
- The child inherits copies of the parent's set of open file descriptors. Each file descriptor in the child refers to the same open file description (see *open*(2)) as the corresponding file descriptor in the parent. This means that the two file descriptors share open file status flags, file offset, and signal-driven I/O attributes (see the description of **F_SETOWN** and **F_SETSIG** in *fcntl*(2)).
- The child inherits copies of the parent's set of open message queue descriptors (see *mq_overview*(7)). Each file descriptor in the child refers to the same open message queue description as the corresponding file descriptor in the parent. This means that the two file descriptors share the same flags (*mq_flags*).
- The child inherits copies of the parent's set of open directory streams (see *opendir*(3)). POSIX.1 says that the corresponding directory streams in the parent and child *may* share the directory stream positioning; on Linux/glibc they do not.

RETURN VALUE

On success, the PID of the child process is returned in the parent, and 0 is returned in the child. On failure, −1 is returned in the parent, no child process is created, and *errno* is set to indicate the error.

ERRORS

EAGAIN

A system-imposed limit on the number of threads was encountered. There are a number of limits that may trigger this error:

- the **RLIMIT_NPROC** soft resource limit (set via *setrlimit*(2)), which limits the number of processes and threads for a real user ID, was reached;
- the kernel's system-wide limit on the number of processes and threads, */proc/sys/kernel/threads-max*, was reached (see *proc*(5));
- the maximum number of PIDs, */proc/sys/kernel/pid_max*, was reached (see *proc*(5)); or
- the PID limit (*pids.max*) imposed by the cgroup "process number" (PIDs) controller was reached.

EAGAIN

The caller is operating under the **SCHED_DEADLINE** scheduling policy and does not have the reset-on-fork flag set. See *sched*(7).

ENOMEM

fork() failed to allocate the necessary kernel structures because memory is tight.

ENOMEM

An attempt was made to create a child process in a PID namespace whose "init" process has terminated. See *pid_namespaces*(7).

ENOSYS

fork() is not supported on this platform (for example, hardware without a Memory-Management Unit).

ERESTARTNOINTR (since Linux 2.6.17)

System call was interrupted by a signal and will be restarted. (This can be seen only during a trace.)

VERSIONS

C library/kernel differences

Since glibc 2.3.3, rather than invoking the kernel's **fork**() system call, the glibc **fork**() wrapper that is provided as part of the NPTL threading implementation invokes *clone*(2) with flags that provide the same effect as the traditional system call. (A call to **fork**() is equivalent to a call to *clone*(2) specifying *flags* as just **SIGCHLD**.) The glibc wrapper invokes any fork handlers that have been established using *pthread_atfork*(3).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

NOTES

Under Linux, **fork**() is implemented using copy-on-write pages, so the only penalty that it incurs is the time and memory required to duplicate the parent's page tables, and to create a unique task structure for the child.

EXAMPLES

See *pipe*(2) and *wait*(2) for more examples.

```
#include <signal.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

int
main(void)
{
    pid_t pid;

    if (signal(SIGCHLD, SIG_IGN) == SIG_ERR) {
        perror("signal");
        exit(EXIT_FAILURE);
    }
    pid = fork();
    switch (pid) {
    case -1:
        perror("fork");
        exit(EXIT_FAILURE);
    case 0:
        puts("Child exiting.");
        exit(EXIT_SUCCESS);
    default:
        printf("Child is PID %jd\n", (intmax_t) pid);
        puts("Parent exiting.");
        exit(EXIT_SUCCESS);
    }
}
```

NAME

fsync, fdatasync − synchronize a file's in-core state with storage device

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int fsync(int fd);

int fdatasync(int fd);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

fsync():
glibc 2.16 and later:
No feature test macros need be defined
glibc up to and including 2.15:
_BSD_SOURCE || _XOPEN_SOURCE
|| /* Since glibc 2.8: */ _POSIX_C_SOURCE >= 200112L

fdatasync():
_POSIX_C_SOURCE >= 199309L || _XOPEN_SOURCE >= 500

DESCRIPTION

fsync() transfers ("flushes") all modified in-core data of (i.e., modified buffer cache pages for) the file referred to by the file descriptor *fd* to the disk device (or other permanent storage device) so that all changed information can be retrieved even if the system crashes or is rebooted. This includes writing through or flushing a disk cache if present. The call blocks until the device reports that the transfer has completed.

As well as flushing the file data, **fsync**() also flushes the metadata information associated with the file (see *inode*(7)).

Calling **fsync**() does not necessarily ensure that the entry in the directory containing the file has also reached disk. For that an explicit **fsync**() on a file descriptor for the directory is also needed.

fdatasync() is similar to **fsync**(), but does not flush modified metadata unless that metadata is needed in order to allow a subsequent data retrieval to be correctly handled. For example, changes to *st_atime* or *st_mtime* (respectively, time of last access and time of last modification; see *inode*(7)) do not require flushing because they are not necessary for a subsequent data read to be handled correctly. On the other hand, a change to the file size (*st_size*, as made by say *ftruncate*(2)), would require a metadata flush.

The aim of **fdatasync**() is to reduce disk activity for applications that do not require all metadata to be synchronized with the disk.

RETURN VALUE

On success, these system calls return zero. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
fd is not a valid open file descriptor.

EINTR
The function was interrupted by a signal; see *signal*(7).

EIO An error occurred during synchronization. This error may relate to data written to some other file descriptor on the same file. Since Linux 4.13, errors from write-back will be reported to all file descriptors that might have written the data which triggered the error. Some filesystems (e.g., NFS) keep close track of which data came through which file descriptor, and give more precise reporting. Other filesystems (e.g., most local filesystems) will report errors to all file descriptors that were open on the file when the error was recorded.

ENOSPC
Disk space was exhausted while synchronizing.

EROFS
EINVAL
fd is bound to a special file (e.g., a pipe, FIFO, or socket) which does not support synchronization.

ENOSPC
EDQUOT
fd is bound to a file on NFS or another filesystem which does not allocate space at the time of a *write*(2) system call, and some previous write failed due to insufficient storage space.

VERSIONS

On POSIX systems on which **fdatasync**() is available, **_POSIX_SYNCHRONIZED_IO** is defined in *<unistd.h>* to a value greater than 0. (See also *sysconf*(3).)

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.2BSD.

In Linux 2.2 and earlier, **fdatasync**() is equivalent to **fsync**(), and so has no performance advantage.

The **fsync**() implementations in older kernels and lesser used filesystems do not know how to flush disk caches. In these cases disk caches need to be disabled using *hdparm*(8) or *sdparm*(8) to guarantee safe operation.

Under AT&T UNIX System V Release 4 *fd* needs to be opened for writing. This is by itself incompatible with the original BSD interface and forbidden by POSIX, but nevertheless survives in HP-UX and AIX.

NAME

futex − fast user-space locking

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/futex.h>      /* Definition of FUTEX_* constants */
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

long syscall(SYS_futex, uint32_t *uaddr, int  futex_op, uint32_t val,
             const struct timespec *timeout,   /* or: uint32_t val2 */
             uint32_t *uaddr2, uint32_t val3);
```

Note: glibc provides no wrapper for **futex**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **futex**() system call provides a method for waiting until a certain condition becomes true. It is typically used as a blocking construct in the context of shared-memory synchronization. When using futexes, the majority of the synchronization operations are performed in user space. A user-space program employs the **futex**() system call only when it is likely that the program has to block for a longer time until the condition becomes true. Other **futex**() operations can be used to wake any processes or threads waiting for a particular condition.

A futex is a 32-bit value—referred to below as a *futex word*—whose address is supplied to the **futex**() system call. (Futexes are 32 bits in size on all platforms, including 64-bit systems.) All futex operations are governed by this value. In order to share a futex between processes, the futex is placed in a region of shared memory, created using (for example) *mmap*(2) or *shmat*(2). (Thus, the futex word may have different virtual addresses in different processes, but these addresses all refer to the same location in physical memory.) In a multithreaded program, it is sufficient to place the futex word in a global variable shared by all threads.

When executing a futex operation that requests to block a thread, the kernel will block only if the futex word has the value that the calling thread supplied (as one of the arguments of the **futex**() call) as the expected value of the futex word. The loading of the futex word's value, the comparison of that value with the expected value, and the actual blocking will happen atomically and will be totally ordered with respect to concurrent operations performed by other threads on the same futex word. Thus, the futex word is used to connect the synchronization in user space with the implementation of blocking by the kernel. Analogously to an atomic compare-and-exchange operation that potentially changes shared memory, blocking via a futex is an atomic compare-and-block operation.

One use of futexes is for implementing locks. The state of the lock (i.e., acquired or not acquired) can be represented as an atomically accessed flag in shared memory. In the uncontended case, a thread can access or modify the lock state with atomic instructions, for example atomically changing it from not acquired to acquired using an atomic compare-and-exchange instruction. (Such instructions are performed entirely in user mode, and the kernel maintains no information about the lock state.) On the other hand, a thread may be unable to acquire a lock because it is already acquired by another thread. It then may pass the lock's flag as a futex word and the value representing the acquired state as the expected value to a **futex**() wait operation. This **futex**() operation will block if and only if the lock is still acquired (i.e., the value in the futex word still matches the "acquired state"). When releasing the lock, a thread has to first reset the lock state to not acquired and then execute a futex operation that wakes threads blocked on the lock flag used as a futex word (this can be further optimized to avoid unnecessary wake-ups). See *futex*(7) for more detail on how to use futexes.

Besides the basic wait and wake-up futex functionality, there are further futex operations aimed at supporting more complex use cases.

Note that no explicit initialization or destruction is necessary to use futexes; the kernel maintains a futex (i.e., the kernel-internal implementation artifact) only while operations such as **FUTEX_WAIT**, described below, are being performed on a particular futex word.

Arguments

The *uaddr* argument points to the futex word. On all platforms, futexes are four-byte integers that must be aligned on a four-byte boundary. The operation to perform on the futex is specified in the *futex_op*

argument; *val* is a value whose meaning and purpose depends on *futex_op*.

The remaining arguments (*timeout*, *uaddr2*, and *val3*) are required only for certain of the futex operations described below. Where one of these arguments is not required, it is ignored.

For several blocking operations, the *timeout* argument is a pointer to a *timespec* structure that specifies a timeout for the operation. However, notwithstanding the prototype shown above, for some operations, the least significant four bytes of this argument are instead used as an integer whose meaning is determined by the operation. For these operations, the kernel casts the *timeout* value first to *unsigned long*, then to *uint32_t*, and in the remainder of this page, this argument is referred to as *val2* when interpreted in this fashion.

Where it is required, the *uaddr2* argument is a pointer to a second futex word that is employed by the operation.

The interpretation of the final integer argument, *val3*, depends on the operation.

Futex operations

The *futex_op* argument consists of two parts: a command that specifies the operation to be performed, bitwise ORed with zero or more options that modify the behaviour of the operation. The options that may be included in *futex_op* are as follows:

FUTEX_PRIVATE_FLAG (since Linux 2.6.22)

This option bit can be employed with all futex operations. It tells the kernel that the futex is process-private and not shared with another process (i.e., it is being used for synchronization only between threads of the same process). This allows the kernel to make some additional performance optimizations.

As a convenience, <*linux/futex.h*> defines a set of constants with the suffix **_PRIVATE** that are equivalents of all of the operations listed below, but with the **FUTEX_PRIVATE_FLAG** ORed into the constant value. Thus, there are **FUTEX_WAIT_PRIVATE**, **FUTEX_WAKE_PRIVATE**, and so on.

FUTEX_CLOCK_REALTIME (since Linux 2.6.28)

This option bit can be employed only with the **FUTEX_WAIT_BITSET**, **FUTEX_WAIT_REQUEUE_PI**, (since Linux 4.5) **FUTEX_WAIT**, and (since Linux 5.14) **FUTEX_LOCK_PI2** operations.

If this option is set, the kernel measures the *timeout* against the **CLOCK_REALTIME** clock.

If this option is not set, the kernel measures the *timeout* against the **CLOCK_MONOTONIC** clock.

The operation specified in *futex_op* is one of the following:

FUTEX_WAIT (since Linux 2.6.0)

This operation tests that the value at the futex word pointed to by the address *uaddr* still contains the expected value *val*, and if so, then sleeps waiting for a **FUTEX_WAKE** operation on the futex word. The load of the value of the futex word is an atomic memory access (i.e., using atomic machine instructions of the respective architecture). This load, the comparison with the expected value, and starting to sleep are performed atomically and totally ordered with respect to other futex operations on the same futex word. If the thread starts to sleep, it is considered a waiter on this futex word. If the futex value does not match *val*, then the call fails immediately with the error **EAGAIN**.

The purpose of the comparison with the expected value is to prevent lost wake-ups. If another thread changed the value of the futex word after the calling thread decided to block based on the prior value, and if the other thread executed a **FUTEX_WAKE** operation (or similar wake-up) after the value change and before this **FUTEX_WAIT** operation, then the calling thread will observe the value change and will not start to sleep.

If the *timeout* is not NULL, the structure it points to specifies a timeout for the wait. (This interval will be rounded up to the system clock granularity, and is guaranteed not to expire early.) The timeout is by default measured according to the **CLOCK_MONOTONIC** clock, but, since Linux 4.5, the **CLOCK_REALTIME** clock can be selected by specifying **FUTEX_CLOCK_REALTIME** in *futex_op*. If *timeout* is NULL, the call blocks indefinitely.

Note: for **FUTEX_WAIT**, *timeout* is interpreted as a *relative* value. This differs from other futex operations, where *timeout* is interpreted as an absolute value. To obtain the equivalent of **FUTEX_WAIT** with an absolute timeout, employ **FUTEX_WAIT_BITSET** with *val3* specified as **FUTEX_BITSET_MATCH_ANY**.

The arguments *uaddr2* and *val3* are ignored.

FUTEX_WAKE (since Linux 2.6.0)
This operation wakes at most *val* of the waiters that are waiting (e.g., inside **FUTEX_WAIT**) on the futex word at the address *uaddr*. Most commonly, *val* is specified as either 1 (wake up a single waiter) or **INT_MAX** (wake up all waiters). No guarantee is provided about which waiters are awoken (e.g., a waiter with a higher scheduling priority is not guaranteed to be awoken in preference to a waiter with a lower priority).

The arguments *timeout*, *uaddr2*, and *val3* are ignored.

FUTEX_FD (from Linux 2.6.0 up to and including Linux 2.6.25)
This operation creates a file descriptor that is associated with the futex at *uaddr*. The caller must close the returned file descriptor after use. When another process or thread performs a **FUTEX_WAKE** on the futex word, the file descriptor indicates as being readable with *select*(2), *poll*(2), and *epoll*(7)

The file descriptor can be used to obtain asynchronous notifications: if *val* is nonzero, then, when another process or thread executes a **FUTEX_WAKE**, the caller will receive the signal number that was passed in *val*.

The arguments *timeout*, *uaddr2*, and *val3* are ignored.

Because it was inherently racy, **FUTEX_FD** has been removed from Linux 2.6.26 onward.

FUTEX_REQUEUE (since Linux 2.6.0)
This operation performs the same task as **FUTEX_CMP_REQUEUE** (see below), except that no check is made using the value in *val3*. (The argument *val3* is ignored.)

FUTEX_CMP_REQUEUE (since Linux 2.6.7)
This operation first checks whether the location *uaddr* still contains the value *val3*. If not, the operation fails with the error **EAGAIN**. Otherwise, the operation wakes up a maximum of *val* waiters that are waiting on the futex at *uaddr*. If there are more than *val* waiters, then the remaining waiters are removed from the wait queue of the source futex at *uaddr* and added to the wait queue of the target futex at *uaddr2*. The *val2* argument specifies an upper limit on the number of waiters that are requeued to the futex at *uaddr2*.

The load from *uaddr* is an atomic memory access (i.e., using atomic machine instructions of the respective architecture). This load, the comparison with *val3*, and the requeueing of any waiters are performed atomically and totally ordered with respect to other operations on the same futex word.

Typical values to specify for *val* are 0 or 1. (Specifying **INT_MAX** is not useful, because it would make the **FUTEX_CMP_REQUEUE** operation equivalent to **FUTEX_WAKE**.) The limit value specified via *val2* is typically either 1 or **INT_MAX**. (Specifying the argument as 0 is not useful, because it would make the **FUTEX_CMP_REQUEUE** operation equivalent to **FUTEX_WAIT**.)

The **FUTEX_CMP_REQUEUE** operation was added as a replacement for the earlier **FUTEX_REQUEUE**. The difference is that the check of the value at *uaddr* can be used to ensure that requeueing happens only under certain conditions, which allows race conditions to be avoided in certain use cases.

Both **FUTEX_REQUEUE** and **FUTEX_CMP_REQUEUE** can be used to avoid "thundering herd" wake-ups that could occur when using **FUTEX_WAKE** in cases where all of the waiters that are woken need to acquire another futex. Consider the following scenario, where multiple waiter threads are waiting on B, a wait queue implemented using a futex:

```
lock(A)
while (!check_value(V)) {
    unlock(A);
    block_on(B);
```

```
    lock(A);
};
unlock(A);
```

If a waker thread used **FUTEX_WAKE**, then all waiters waiting on B would be woken up, and they would all try to acquire lock A. However, waking all of the threads in this manner would be pointless because all except one of the threads would immediately block on lock A again. By contrast, a requeue operation wakes just one waiter and moves the other waiters to lock A, and when the woken waiter unlocks A then the next waiter can proceed.

FUTEX_WAKE_OP (since Linux 2.6.14)

This operation was added to support some user-space use cases where more than one futex must be handled at the same time. The most notable example is the implementation of *pthread_cond_signal*(3), which requires operations on two futexes, the one used to implement the mutex and the one used in the implementation of the wait queue associated with the condition variable. **FUTEX_WAKE_OP** allows such cases to be implemented without leading to high rates of contention and context switching.

The **FUTEX_WAKE_OP** operation is equivalent to executing the following code atomically and totally ordered with respect to other futex operations on any of the two supplied futex words:

```
uint32_t oldval = *(uint32_t *) uaddr2;
*(uint32_t *) uaddr2 = oldval op oparg;
futex(uaddr, FUTEX_WAKE, val, 0, 0, 0);
if (oldval cmp cmparg)
    futex(uaddr2, FUTEX_WAKE, val2, 0, 0, 0);
```

In other words, **FUTEX_WAKE_OP** does the following:

- saves the original value of the futex word at *uaddr2* and performs an operation to modify the value of the futex at *uaddr2*; this is an atomic read-modify-write memory access (i.e., using atomic machine instructions of the respective architecture)
- wakes up a maximum of *val* waiters on the futex for the futex word at *uaddr*; and
- dependent on the results of a test of the original value of the futex word at *uaddr2*, wakes up a maximum of *val2* waiters on the futex for the futex word at *uaddr2*.

The operation and comparison that are to be performed are encoded in the bits of the argument *val3*. Pictorially, the encoding is:

```
+---+---+-----------+-----------+
|op |cmp|   oparg   |  cmparg   |
+---+---+-----------+-----------+
  4   4       12          12    <== # of bits
```

Expressed in code, the encoding is:

```
#define FUTEX_OP(op, oparg, cmp, cmparg) \
                ((((op & 0xf) << 28) | \
                ((cmp & 0xf) << 24) | \
                ((oparg & 0xfff) << 12) | \
                (cmparg & 0xfff))
```

In the above, *op* and *cmp* are each one of the codes listed below. The *oparg* and *cmparg* components are literal numeric values, except as noted below.

The *op* component has one of the following values:

```
FUTEX_OP_SET        0  /* uaddr2 = oparg; */
FUTEX_OP_ADD        1  /* uaddr2 += oparg; */
FUTEX_OP_OR         2  /* uaddr2 |= oparg; */
FUTEX_OP_ANDN       3  /* uaddr2 &= ~oparg; */
FUTEX_OP_XOR        4  /* uaddr2 ^= oparg; */
```

In addition, bitwise ORing the following value into *op* causes *(1 << oparg)* to be used as the operand:

```
FUTEX_OP_ARG_SHIFT  8  /* Use (1 << oparg) as operand */
```

The *cmp* field is one of the following:

```
FUTEX_OP_CMP_EQ     0  /* if (oldval == cmparg) wake */
FUTEX_OP_CMP_NE     1  /* if (oldval != cmparg) wake */
FUTEX_OP_CMP_LT     2  /* if (oldval < cmparg) wake */
FUTEX_OP_CMP_LE     3  /* if (oldval <= cmparg) wake */
FUTEX_OP_CMP_GT     4  /* if (oldval > cmparg) wake */
FUTEX_OP_CMP_GE     5  /* if (oldval >= cmparg) wake */
```

The return value of **FUTEX_WAKE_OP** is the sum of the number of waiters woken on the futex *uaddr* plus the number of waiters woken on the futex *uaddr2*.

FUTEX_WAIT_BITSET (since Linux 2.6.25)

This operation is like **FUTEX_WAIT** except that *val3* is used to provide a 32-bit bit mask to the kernel. This bit mask, in which at least one bit must be set, is stored in the kernel-internal state of the waiter. See the description of **FUTEX_WAKE_BITSET** for further details.

If *timeout* is not NULL, the structure it points to specifies an absolute timeout for the wait operation. If *timeout* is NULL, the operation can block indefinitely.

The *uaddr2* argument is ignored.

FUTEX_WAKE_BITSET (since Linux 2.6.25)

This operation is the same as **FUTEX_WAKE** except that the *val3* argument is used to provide a 32-bit bit mask to the kernel. This bit mask, in which at least one bit must be set, is used to select which waiters should be woken up. The selection is done by a bitwise AND of the "wake" bit mask (i.e., the value in *val3*) and the bit mask which is stored in the kernel-internal state of the waiter (the "wait" bit mask that is set using **FUTEX_WAIT_BITSET**). All of the waiters for which the result of the AND is nonzero are woken up; the remaining waiters are left sleeping.

The effect of **FUTEX_WAIT_BITSET** and **FUTEX_WAKE_BITSET** is to allow selective wake-ups among multiple waiters that are blocked on the same futex. However, note that, depending on the use case, employing this bit-mask multiplexing feature on a futex can be less efficient than simply using multiple futexes, because employing bit-mask multiplexing requires the kernel to check all waiters on a futex, including those that are not interested in being woken up (i.e., they do not have the relevant bit set in their "wait" bit mask).

The constant **FUTEX_BITSET_MATCH_ANY**, which corresponds to all 32 bits set in the bit mask, can be used as the *val3* argument for **FUTEX_WAIT_BITSET** and **FUTEX_WAKE_BITSET**. Other than differences in the handling of the *timeout* argument, the **FUTEX_WAIT** operation is equivalent to **FUTEX_WAIT_BITSET** with *val3* specified as **FUTEX_BITSET_MATCH_ANY**; that is, allow a wake-up by any waker. The **FUTEX_WAKE** operation is equivalent to **FUTEX_WAKE_BITSET** with *val3* specified as **FUTEX_BITSET_MATCH_ANY**; that is, wake up any waiter(s).

The *uaddr2* and *timeout* arguments are ignored.

Priority-inheritance futexes

Linux supports priority-inheritance (PI) futexes in order to handle priority-inversion problems that can be encountered with normal futex locks. Priority inversion is the problem that occurs when a high-priority task is blocked waiting to acquire a lock held by a low-priority task, while tasks at an intermediate priority continuously preempt the low-priority task from the CPU. Consequently, the low-priority task makes no progress toward releasing the lock, and the high-priority task remains blocked.

Priority inheritance is a mechanism for dealing with the priority-inversion problem. With this mechanism, when a high-priority task becomes blocked by a lock held by a low-priority task, the priority of the low-priority task is temporarily raised to that of the high-priority task, so that it is not preempted by any intermediate level tasks, and can thus make progress toward releasing the lock. To be effective, priority inheritance must be transitive, meaning that if a high-priority task blocks on a lock held by a lower-priority task that is itself blocked by a lock held by another intermediate-priority task (and so on, for chains of arbitrary length), then both of those tasks (or more generally, all of the tasks in a lock chain) have their priorities raised to be the same as the high-priority task.

From a user-space perspective, what makes a futex PI-aware is a policy agreement (described below) between user space and the kernel about the value of the futex word, coupled with the use of the PI-futex operations described below. (Unlike the other futex operations described above, the PI-futex operations are designed for the implementation of very specific IPC mechanisms.)

The PI-futex operations described below differ from the other futex operations in that they impose policy on the use of the value of the futex word:

- If the lock is not acquired, the futex word's value shall be 0.
- If the lock is acquired, the futex word's value shall be the thread ID (TID; see *gettid*(2)) of the owning thread.
- If the lock is owned and there are threads contending for the lock, then the **FUTEX_WAITERS** bit shall be set in the futex word's value; in other words, this value is:

  ```
  FUTEX_WAITERS | TID
  ```

  (Note that is invalid for a PI futex word to have no owner and **FUTEX_WAITERS** set.)

With this policy in place, a user-space application can acquire an unacquired lock or release a lock using atomic instructions executed in user mode (e.g., a compare-and-swap operation such as *cmpxchg* on the x86 architecture). Acquiring a lock simply consists of using compare-and-swap to atomically set the futex word's value to the caller's TID if its previous value was 0. Releasing a lock requires using compare-and-swap to set the futex word's value to 0 if the previous value was the expected TID.

If a futex is already acquired (i.e., has a nonzero value), waiters must employ the **FUTEX_LOCK_PI** or **FUTEX_LOCK_PI2** operations to acquire the lock. If other threads are waiting for the lock, then the **FUTEX_WAITERS** bit is set in the futex value; in this case, the lock owner must employ the **FUTEX_UNLOCK_PI** operation to release the lock.

In the cases where callers are forced into the kernel (i.e., required to perform a **futex**() call), they then deal directly with a so-called RT-mutex, a kernel locking mechanism which implements the required priority-inheritance semantics. After the RT-mutex is acquired, the futex value is updated accordingly, before the calling thread returns to user space.

It is important to note that the kernel will update the futex word's value prior to returning to user space. (This prevents the possibility of the futex word's value ending up in an invalid state, such as having an owner but the value being 0, or having waiters but not having the **FUTEX_WAITERS** bit set.)

If a futex has an associated RT-mutex in the kernel (i.e., there are blocked waiters) and the owner of the futex/RT-mutex dies unexpectedly, then the kernel cleans up the RT-mutex and hands it over to the next waiter. This in turn requires that the user-space value is updated accordingly. To indicate that this is required, the kernel sets the **FUTEX_OWNER_DIED** bit in the futex word along with the thread ID of the new owner. User space can detect this situation via the presence of the **FUTEX_OWNER_DIED** bit and is then responsible for cleaning up the stale state left over by the dead owner.

PI futexes are operated on by specifying one of the values listed below in *futex_op*. Note that the PI futex operations must be used as paired operations and are subject to some additional requirements:

- **FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, and **FUTEX_TRYLOCK_PI** pair with **FUTEX_UNLOCK_PI**. **FUTEX_UNLOCK_PI** must be called only on a futex owned by the calling thread, as defined by the value policy, otherwise the error **EPERM** results.
- **FUTEX_WAIT_REQUEUE_PI** pairs with **FUTEX_CMP_REQUEUE_PI**. This must be performed from a non-PI futex to a distinct PI futex (or the error **EINVAL** results). Additionally, *val* (the number of waiters to be woken) must be 1 (or the error **EINVAL** results).

The PI futex operations are as follows:

FUTEX_LOCK_PI (since Linux 2.6.18)

This operation is used after an attempt to acquire the lock via an atomic user-mode instruction failed because the futex word has a nonzero value—specifically, because it contained the (PID-namespace-specific) TID of the lock owner.

The operation checks the value of the futex word at the address *uaddr*. If the value is 0, then the kernel tries to atomically set the futex value to the caller's TID. If the futex word's value is nonzero, the kernel atomically sets the **FUTEX_WAITERS** bit, which signals the futex owner that it cannot unlock the futex in user space atomically by setting the futex value to 0.

After that, the kernel:

(1) Tries to find the thread which is associated with the owner TID.

(2) Creates or reuses kernel state on behalf of the owner. (If this is the first waiter, there is no kernel state for this futex, so kernel state is created by locking the RT-mutex and the futex owner is made the owner of the RT-mutex. If there are existing waiters, then the existing state is reused.)

(3) Attaches the waiter to the futex (i.e., the waiter is enqueued on the RT-mutex waiter list).

If more than one waiter exists, the enqueueing of the waiter is in descending priority order. (For information on priority ordering, see the discussion of the **SCHED_DEADLINE**, **SCHED_FIFO**, and **SCHED_RR** scheduling policies in *sched*(7).) The owner inherits either the waiter's CPU bandwidth (if the waiter is scheduled under the **SCHED_DEADLINE** policy) or the waiter's priority (if the waiter is scheduled under the **SCHED_RR** or **SCHED_FIFO** policy). This inheritance follows the lock chain in the case of nested locking and performs deadlock detection.

The *timeout* argument provides a timeout for the lock attempt. If *timeout* is not NULL, the structure it points to specifies an absolute timeout, measured against the **CLOCK_REALTIME** clock. If *timeout* is NULL, the operation will block indefinitely.

The *uaddr2*, *val*, and *val3* arguments are ignored.

FUTEX_LOCK_PI2 (since Linux 5.14)
This operation is the same as **FUTEX_LOCK_PI**, except that the clock against which *timeout* is measured is selectable. By default, the (absolute) timeout specified in *timeout* is measured against the **CLOCK_MONOTONIC** clock, but if the **FUTEX_CLOCK_REALTIME** flag is specified in *futex_op*, then the timeout is measured against the **CLOCK_REALTIME** clock.

FUTEX_TRYLOCK_PI (since Linux 2.6.18)
This operation tries to acquire the lock at *uaddr*. It is invoked when a user-space atomic acquire did not succeed because the futex word was not 0.

Because the kernel has access to more state information than user space, acquisition of the lock might succeed if performed by the kernel in cases where the futex word (i.e., the state information accessible to use-space) contains stale state (**FUTEX_WAITERS** and/or **FUTEX_OWNER_DIED**). This can happen when the owner of the futex died. User space cannot handle this condition in a race-free manner, but the kernel can fix this up and acquire the futex.

The *uaddr2*, *val*, *timeout*, and *val3* arguments are ignored.

FUTEX_UNLOCK_PI (since Linux 2.6.18)
This operation wakes the top priority waiter that is waiting in **FUTEX_LOCK_PI** or **FUTEX_LOCK_PI2** on the futex address provided by the *uaddr* argument.

This is called when the user-space value at *uaddr* cannot be changed atomically from a TID (of the owner) to 0.

The *uaddr2*, *val*, *timeout*, and *val3* arguments are ignored.

FUTEX_CMP_REQUEUE_PI (since Linux 2.6.31)
This operation is a PI-aware variant of **FUTEX_CMP_REQUEUE**. It requeues waiters that are blocked via **FUTEX_WAIT_REQUEUE_PI** on *uaddr* from a non-PI source futex (*uaddr*) to a PI target futex (*uaddr2*).

As with **FUTEX_CMP_REQUEUE**, this operation wakes up a maximum of *val* waiters that are waiting on the futex at *uaddr*. However, for **FUTEX_CMP_REQUEUE_PI**, *val* is required to be 1 (since the main point is to avoid a thundering herd). The remaining waiters are removed from the wait queue of the source futex at *uaddr* and added to the wait queue of the target futex at *uaddr2*.

The *val2* and *val3* arguments serve the same purposes as for **FUTEX_CMP_REQUEUE**.

FUTEX_WAIT_REQUEUE_PI (since Linux 2.6.31)
Wait on a non-PI futex at *uaddr* and potentially be requeued (via a **FUTEX_CMP_REQUEUE_PI** operation in another task) onto a PI futex at *uaddr2*. The wait operation on *uaddr* is the same as for **FUTEX_WAIT**.

The waiter can be removed from the wait on *uaddr* without requeueing on *uaddr2* via a **FUTEX_WAKE** operation in another task. In this case, the **FUTEX_WAIT_REQUEUE_PI** operation fails with the error **EAGAIN**.

If *timeout* is not NULL, the structure it points to specifies an absolute timeout for the wait operation. If *timeout* is NULL, the operation can block indefinitely.

The *val3* argument is ignored.

The **FUTEX_WAIT_REQUEUE_PI** and **FUTEX_CMP_REQUEUE_PI** were added to support a fairly specific use case: support for priority-inheritance-aware POSIX threads condition variables. The idea is that these operations should always be paired, in order to ensure that user space and the kernel remain in sync. Thus, in the **FUTEX_WAIT_REQUEUE_PI** operation, the user-space application pre-specifies the target of the requeue that takes place in the **FUTEX_CMP_REQUEUE_PI** operation.

RETURN VALUE

In the event of an error (and assuming that **futex**() was invoked via *syscall*(2)), all operations return −1 and set *errno* to indicate the error.

The return value on success depends on the operation, as described in the following list:

FUTEX_WAIT
Returns 0 if the caller was woken up. Note that a wake-up can also be caused by common futex usage patterns in unrelated code that happened to have previously used the futex word's memory location (e.g., typical futex-based implementations of Pthreads mutexes can cause this under some conditions). Therefore, callers should always conservatively assume that a return value of 0 can mean a spurious wake-up, and use the futex word's value (i.e., the user-space synchronization scheme) to decide whether to continue to block or not.

FUTEX_WAKE
Returns the number of waiters that were woken up.

FUTEX_FD
Returns the new file descriptor associated with the futex.

FUTEX_REQUEUE
Returns the number of waiters that were woken up.

FUTEX_CMP_REQUEUE
Returns the total number of waiters that were woken up or requeued to the futex for the futex word at *uaddr2*. If this value is greater than *val*, then the difference is the number of waiters requeued to the futex for the futex word at *uaddr2*.

FUTEX_WAKE_OP
Returns the total number of waiters that were woken up. This is the sum of the woken waiters on the two futexes for the futex words at *uaddr* and *uaddr2*.

FUTEX_WAIT_BITSET
Returns 0 if the caller was woken up. See **FUTEX_WAIT** for how to interpret this correctly in practice.

FUTEX_WAKE_BITSET
Returns the number of waiters that were woken up.

FUTEX_LOCK_PI
Returns 0 if the futex was successfully locked.

FUTEX_LOCK_PI2
Returns 0 if the futex was successfully locked.

FUTEX_TRYLOCK_PI
Returns 0 if the futex was successfully locked.

FUTEX_UNLOCK_PI
Returns 0 if the futex was successfully unlocked.

FUTEX_CMP_REQUEUE_PI
Returns the total number of waiters that were woken up or requeued to the futex for the futex word at *uaddr2*. If this value is greater than *val*, then difference is the number of waiters requeued to the futex for the futex word at *uaddr2*.

FUTEX_WAIT_REQUEUE_PI
Returns 0 if the caller was successfully requeued to the futex for the futex word at *uaddr2*.

ERRORS

EACCES
No read access to the memory of a futex word.

EAGAIN
(**FUTEX_WAIT**, **FUTEX_WAIT_BITSET**, **FUTEX_WAIT_REQUEUE_PI**) The value pointed to by *uaddr* was not equal to the expected value *val* at the time of the call.

Note: on Linux, the symbolic names **EAGAIN** and **EWOULDBLOCK** (both of which appear in different parts of the kernel futex code) have the same value.

EAGAIN
(**FUTEX_CMP_REQUEUE**, **FUTEX_CMP_REQUEUE_PI**) The value pointed to by *uaddr* is not equal to the expected value *val3*.

EAGAIN
(**FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, **FUTEX_TRYLOCK_PI**, **FUTEX_CMP_REQUEUE_PI**) The futex owner thread ID of *uaddr* (for **FUTEX_CMP_REQUEUE_PI**: *uaddr2*) is about to exit, but has not yet handled the internal state cleanup. Try again.

EDEADLK
(**FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, **FUTEX_TRYLOCK_PI**, **FUTEX_CMP_REQUEUE_PI**) The futex word at *uaddr* is already locked by the caller.

EDEADLK
(**FUTEX_CMP_REQUEUE_PI**) While requeueing a waiter to the PI futex for the futex word at *uaddr2*, the kernel detected a deadlock.

EFAULT
A required pointer argument (i.e., *uaddr*, *uaddr2*, or *timeout*) did not point to a valid user-space address.

EINTR
A **FUTEX_WAIT** or **FUTEX_WAIT_BITSET** operation was interrupted by a signal (see *signal*(7)). Before Linux 2.6.22, this error could also be returned for a spurious wakeup; since Linux 2.6.22, this no longer happens.

EINVAL
The operation in *futex_op* is one of those that employs a timeout, but the supplied *timeout* argument was invalid (*tv_sec* was less than zero, or *tv_nsec* was not less than 1,000,000,000).

EINVAL
The operation specified in *futex_op* employs one or both of the pointers *uaddr* and *uaddr2*, but one of these does not point to a valid object—that is, the address is not four-byte-aligned.

EINVAL
(**FUTEX_WAIT_BITSET**, **FUTEX_WAKE_BITSET**) The bit mask supplied in *val3* is zero.

EINVAL
(**FUTEX_CMP_REQUEUE_PI**) *uaddr* equals *uaddr2* (i.e., an attempt was made to requeue to the same futex).

EINVAL
(**FUTEX_FD**) The signal number supplied in *val* is invalid.

EINVAL
(**FUTEX_WAKE**, **FUTEX_WAKE_OP**, **FUTEX_WAKE_BITSET**, **FUTEX_REQUEUE**, **FUTEX_CMP_REQUEUE**) The kernel detected an inconsistency between the user-space state at *uaddr* and the kernel state—that is, it detected a waiter which waits in **FUTEX_LOCK_PI** or **FUTEX_LOCK_PI2** on *uaddr*.

EINVAL
(**FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, **FUTEX_TRYLOCK_PI**, **FUTEX_UNLOCK_PI**) The kernel detected an inconsistency between the user-space state at *uaddr* and the kernel state. This indicates either state corruption or that the kernel found a waiter on *uaddr* which is waiting via **FUTEX_WAIT** or **FUTEX_WAIT_BITSET**.

EINVAL
(**FUTEX_CMP_REQUEUE_PI**) The kernel detected an inconsistency between the user-space state at *uaddr2* and the kernel state; that is, the kernel detected a waiter which waits via **FUTEX_WAIT** or **FUTEX_WAIT_BITSET** on *uaddr2*.

EINVAL
(**FUTEX_CMP_REQUEUE_PI**) The kernel detected an inconsistency between the user-space state at *uaddr* and the kernel state; that is, the kernel detected a waiter which waits via **FUTEX_WAIT** or **FUTEX_WAIT_BITSET** on *uaddr*.

EINVAL
(**FUTEX_CMP_REQUEUE_PI**) The kernel detected an inconsistency between the user-space state at *uaddr* and the kernel state; that is, the kernel detected a waiter which waits on *uaddr* via **FUTEX_LOCK_PI** or **FUTEX_LOCK_PI2** (instead of **FUTEX_WAIT_REQUEUE_PI**).

EINVAL
(**FUTEX_CMP_REQUEUE_PI**) An attempt was made to requeue a waiter to a futex other than that specified by the matching **FUTEX_WAIT_REQUEUE_PI** call for that waiter.

EINVAL
(**FUTEX_CMP_REQUEUE_PI**) The *val* argument is not 1.

EINVAL
Invalid argument.

ENFILE
(**FUTEX_FD**) The system-wide limit on the total number of open files has been reached.

ENOMEM
(**FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, **FUTEX_TRYLOCK_PI**, **FUTEX_CMP_REQUEUE_PI**) The kernel could not allocate memory to hold state information.

ENOSYS
Invalid operation specified in *futex_op*.

ENOSYS
The **FUTEX_CLOCK_REALTIME** option was specified in *futex_op*, but the accompanying operation was neither **FUTEX_WAIT**, **FUTEX_WAIT_BITSET**, **FUTEX_WAIT_REQUEUE_PI**, nor **FUTEX_LOCK_PI2**.

ENOSYS
(**FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, **FUTEX_TRYLOCK_PI**, **FUTEX_UNLOCK_PI**, **FUTEX_CMP_REQUEUE_PI**, **FUTEX_WAIT_REQUEUE_PI**) A run-time check determined that the operation is not available. The PI-futex operations are not implemented on all architectures and are not supported on some CPU variants.

EPERM
(**FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, **FUTEX_TRYLOCK_PI**, **FUTEX_CMP_REQUEUE_PI**) The caller is not allowed to attach itself to the futex at *uaddr* (for **FUTEX_CMP_REQUEUE_PI**: the futex at *uaddr2*). (This may be caused by a state corruption in user space.)

EPERM
(**FUTEX_UNLOCK_PI**) The caller does not own the lock represented by the futex word.

ESRCH
(**FUTEX_LOCK_PI**, **FUTEX_LOCK_PI2**, **FUTEX_TRYLOCK_PI**, **FUTEX_CMP_REQUEUE_PI**) The thread ID in the futex word at *uaddr* does not exist.

ESRCH
(**FUTEX_CMP_REQUEUE_PI**) The thread ID in the futex word at *uaddr2* does not exist.

ETIMEDOUT
The operation in *futex_op* employed the timeout specified in *timeout*, and the timeout expired before the operation completed.

STANDARDS
Linux.

HISTORY
Linux 2.6.0.

Initial futex support was merged in Linux 2.5.7 but with different semantics from what was described above. A four-argument system call with the semantics described in this page was introduced in Linux 2.5.40. A fifth argument was added in Linux 2.5.70, and a sixth argument was added in Linux 2.6.7.

EXAMPLES
The program below demonstrates use of futexes in a program where a parent process and a child process use a pair of futexes located inside a shared anonymous mapping to synchronize access to a shared resource: the terminal. The two processes each write *nloops* (a command-line argument that defaults to 5 if omitted) messages to the terminal and employ a synchronization protocol that ensures that they alternate in writing messages. Upon running this program we see output such as the following:

```
$ ./futex_demo
Parent (18534) 0
Child  (18535) 0
Parent (18534) 1
Child  (18535) 1
Parent (18534) 2
Child  (18535) 2
Parent (18534) 3
Child  (18535) 3
Parent (18534) 4
Child  (18535) 4
```

Program source

```
/* futex_demo.c

   Usage: futex_demo [nloops]
                     (Default: 5)

   Demonstrate the use of futexes in a program where parent and child
   use a pair of futexes located inside a shared anonymous mapping to
   synchronize access to a shared resource: the terminal. The two
   processes each write 'num-loops' messages to the terminal and employ
   a synchronization protocol that ensures that they alternate in
   writing messages.

NAME

futimesat − change timestamps of a file relative to a directory file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <fcntl.h>          /* Definition of AT_* constants */
#include <sys/time.h>

[[deprecated]] int futimesat(int dirfd, const char *pathname,
                             const struct timeval times[2]);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

futimesat():
_GNU_SOURCE

DESCRIPTION

This system call is obsolete. Use *utimensat*(2) instead.

The **futimesat**() system call operates in exactly the same way as *utimes*(2), except for the differences described in this manual page.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by *utimes*(2) for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *utimes*(2)).

If *pathname* is absolute, then *dirfd* is ignored. (See *openat*(2) for an explanation of why the *dirfd* argument is useful.)

RETURN VALUE

On success, **futimesat**() returns a 0. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

The same errors that occur for *utimes*(2) can also occur for **futimesat**(). The following additional errors can occur for **futimesat**():

EBADF
pathname is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

ENOTDIR
pathname is relative and *dirfd* is a file descriptor referring to a file other than a directory.

VERSIONS

glibc

If *pathname* is NULL, then the glibc **futimesat**() wrapper function updates the times for the file referred to by *dirfd*.

STANDARDS

None.

HISTORY

Linux 2.6.16, glibc 2.4.

It was implemented from a specification that was proposed for POSIX.1, but that specification was replaced by the one for *utimensat*(2).

A similar system call exists on Solaris.

NAME

get_kernel_syms − retrieve exported kernel and module symbols

SYNOPSIS

#include <linux/module.h>

[[deprecated]] int get_kernel_syms(struct kernel_sym ****table*);**

DESCRIPTION

Note: This system call is present only before Linux 2.6.

If *table* is NULL, **get_kernel_syms**() returns the number of symbols available for query. Otherwise, it fills in a table of structures:

```
struct kernel_sym {
    unsigned long value;
    char          name[60];
};
```

The symbols are interspersed with magic symbols of the form #*module-name* with the kernel having an empty name. The value associated with a symbol of this form is the address at which the module is loaded.

The symbols exported from each module follow their magic module tag and the modules are returned in the reverse of the order in which they were loaded.

RETURN VALUE

On success, returns the number of symbols copied to *table*. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

There is only one possible error return:

ENOSYS
get_kernel_syms() is not supported in this version of the kernel.

STANDARDS

Linux.

HISTORY

Removed in Linux 2.6.

This obsolete system call is not supported by glibc. No declaration is provided in glibc headers, but, through a quirk of history, glibc versions before glibc 2.23 did export an ABI for this system call. Therefore, in order to employ this system call, it was sufficient to manually declare the interface in your code; alternatively, you could invoke the system call using *syscall*(2).

BUGS

There is no way to indicate the size of the buffer allocated for *table*. If symbols have been added to the kernel since the program queried for the symbol table size, memory will be corrupted.

The length of exported symbol names is limited to 59 characters.

Because of these limitations, this system call is deprecated in favor of *query_module*(2) (which is itself nowadays deprecated in favor of other interfaces described on its manual page).

NAME

get_mempolicy − retrieve NUMA memory policy for a thread

LIBRARY

NUMA (Non-Uniform Memory Access) policy library (*libnuma*, −*lnuma*)

SYNOPSIS

```
#include <numaif.h>

long get_mempolicy(int *mode,
                   unsigned long nodemask[(.maxnode + ULONG_WIDTH - 1)
                                          / ULONG_WIDTH],
                   unsigned long maxnode, void *addr,
                   unsigned long  flags);
```

DESCRIPTION

get_mempolicy() retrieves the NUMA policy of the calling thread or of a memory address, depending on the setting of *flags*.

A NUMA machine has different memory controllers with different distances to specific CPUs. The memory policy defines from which node memory is allocated for the thread.

If *flags* is specified as 0, then information about the calling thread's default policy (as set by *set_mempolicy*(2)) is returned, in the buffers pointed to by *mode* and *nodemask*. The value returned in these arguments may be used to restore the thread's policy to its state at the time of the call to **get_mempolicy**() using *set_mempolicy*(2). When *flags* is 0, *addr* must be specified as NULL.

If *flags* specifies **MPOL_F_MEMS_ALLOWED** (available since Linux 2.6.24), the *mode* argument is ignored and the set of nodes (memories) that the thread is allowed to specify in subsequent calls to *mbind*(2) or *set_mempolicy*(2) (in the absence of any *mode flags*) is returned in *nodemask*. It is not permitted to combine **MPOL_F_MEMS_ALLOWED** with either **MPOL_F_ADDR** or **MPOL_F_NODE**.

If *flags* specifies **MPOL_F_ADDR**, then information is returned about the policy governing the memory address given in *addr*. This policy may be different from the thread's default policy if *mbind*(2) or one of the helper functions described in *numa*(3) has been used to establish a policy for the memory range containing *addr*.

If the *mode* argument is not NULL, then **get_mempolicy**() will store the policy mode and any optional *mode flags* of the requested NUMA policy in the location pointed to by this argument. If *nodemask* is not NULL, then the nodemask associated with the policy will be stored in the location pointed to by this argument. *maxnode* specifies the number of node IDs that can be stored into *nodemask*—that is, the maximum node ID plus one. The value specified by *maxnode* is always rounded to a multiple of *sizeof(unsigned long)*8*.

If *flags* specifies both **MPOL_F_NODE** and **MPOL_F_ADDR**, **get_mempolicy**() will return the node ID of the node on which the address *addr* is allocated into the location pointed to by *mode*. If no page has yet been allocated for the specified address, **get_mempolicy**() will allocate a page as if the thread had performed a read (load) access to that address, and return the ID of the node where that page was allocated.

If *flags* specifies **MPOL_F_NODE**, but not **MPOL_F_ADDR**, and the thread's current policy is **MPOL_INTERLEAVE**, then **get_mempolicy**() will return in the location pointed to by a non-NULL *mode* argument, the node ID of the next node that will be used for interleaving of internal kernel pages allocated on behalf of the thread. These allocations include pages for memory-mapped files in process memory ranges mapped using the *mmap*(2) call with the **MAP_PRIVATE** flag for read accesses, and in memory ranges mapped with the **MAP_SHARED** flag for all accesses.

Other flag values are reserved.

For an overview of the possible policies see *set_mempolicy*(2).

RETURN VALUE

On success, **get_mempolicy**() returns 0; on error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
Part of all of the memory range specified by *nodemask* and *maxnode* points outside your accessible address space.

EINVAL
The value specified by *maxnode* is less than the number of node IDs supported by the system. Or *flags* specified values other than **MPOL_F_NODE** or **MPOL_F_ADDR**; or *flags* specified **MPOL_F_ADDR** and *addr* is NULL, or *flags* did not specify **MPOL_F_ADDR** and *addr* is not NULL. Or, *flags* specified **MPOL_F_NODE** but not **MPOL_F_ADDR** and the current thread policy is not **MPOL_INTERLEAVE**. Or, *flags* specified **MPOL_F_MEMS_ALLOWED** with either **MPOL_F_ADDR** or **MPOL_F_NODE**. (And there are other **EINVAL** cases.)

STANDARDS
Linux.

NAME

get_robust_list, set_robust_list − get/set list of robust futexes

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/futex.h>   /* Definition of struct robust_list_head */
#include <sys/syscall.h>   /* Definition of SYS_* constants */
#include <unistd.h>

long syscall(SYS_get_robust_list, int pid,
             struct robust_list_head **head_ptr, size_t *len_ptr);
long syscall(SYS_set_robust_list,
             struct robust_list_head *head, size_t len);
```

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

These system calls deal with per-thread robust futex lists. These lists are managed in user space: the kernel knows only about the location of the head of the list. A thread can inform the kernel of the location of its robust futex list using **set_robust_list**(). The address of a thread's robust futex list can be obtained using **get_robust_list**().

The purpose of the robust futex list is to ensure that if a thread accidentally fails to unlock a futex before terminating or calling *execve*(2), another thread that is waiting on that futex is notified that the former owner of the futex has died. This notification consists of two pieces: the **FUTEX_OWNER_DIED** bit is set in the futex word, and the kernel performs a *futex*(2) **FUTEX_WAKE** operation on one of the threads waiting on the futex.

The **get_robust_list**() system call returns the head of the robust futex list of the thread whose thread ID is specified in *pid*. If *pid* is 0, the head of the list for the calling thread is returned. The list head is stored in the location pointed to by *head_ptr*. The size of the object pointed to by **head_ptr* is stored in *len_ptr*.

Permission to employ **get_robust_list**() is governed by a ptrace access mode **PTRACE_MODE_READ_REALCREDS** check; see *ptrace*(2).

The **set_robust_list**() system call requests the kernel to record the head of the list of robust futexes owned by the calling thread. The *head* argument is the list head to record. The *len* argument should be *sizeof(*head)*.

RETURN VALUE

The **set_robust_list**() and **get_robust_list**() system calls return zero when the operation is successful, an error code otherwise.

ERRORS

The **set_robust_list**() system call can fail with the following error:

EINVAL
: *len* does not equal *sizeof(struct robust_list_head)*.

The **get_robust_list**() system call can fail with the following errors:

EFAULT
: The head of the robust futex list can't be stored at the location *head*.

EPERM
: The calling process does not have permission to see the robust futex list of the thread with the thread ID *pid*, and does not have the **CAP_SYS_PTRACE** capability.

ESRCH
: No thread with the thread ID *pid* could be found.

VERSIONS

These system calls were added in Linux 2.6.17.

NOTES

These system calls are not needed by normal applications.

A thread can have only one robust futex list; therefore applications that wish to use this functionality should use the robust mutexes provided by glibc.

In the initial implementation, a thread waiting on a futex was notified that the owner had died only if the owner terminated. Starting with Linux 2.6.28, notification was extended to include the case where the owner performs an *execve*(2).

The thread IDs mentioned in the main text are *kernel* thread IDs of the kind returned by *clone*(2) and *gettid*(2).

NAME

getcpu − determine CPU and NUMA node on which the calling thread is running

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sched.h>

int getcpu(unsigned int *_Nullable cpu, unsigned int *_Nullable node);
```

DESCRIPTION

The **getcpu**() system call identifies the processor and node on which the calling thread or process is currently running and writes them into the integers pointed to by the *cpu* and *node* arguments. The processor is a unique small integer identifying a CPU. The node is a unique small identifier identifying a NUMA node. When either *cpu* or *node* is NULL nothing is written to the respective pointer.

The information placed in *cpu* is guaranteed to be current only at the time of the call: unless the CPU affinity has been fixed using *sched_setaffinity*(2), the kernel might change the CPU at any time. (Normally this does not happen because the scheduler tries to minimize movements between CPUs to keep caches hot, but it is possible.) The caller must allow for the possibility that the information returned in *cpu* and *node* is no longer current by the time the call returns.

RETURN VALUE

On success, 0 is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
: Arguments point outside the calling process's address space.

STANDARDS

Linux.

HISTORY

Linux 2.6.19 (x86-64 and i386), glibc 2.29.

C library/kernel differences

The kernel system call has a third argument:

```
int getcpu(unsigned int *cpu, unsigned int *node,
           struct getcpu_cache *tcache);
```

The *tcache* argument is unused since Linux 2.6.24, and (when invoking the system call directly) should be specified as NULL, unless portability to Linux 2.6.23 or earlier is required.

In Linux 2.6.23 and earlier, if the *tcache* argument was non-NULL, then it specified a pointer to a caller-allocated buffer in thread-local storage that was used to provide a caching mechanism for **getcpu**(). Use of the cache could speed **getcpu**() calls, at the cost that there was a very small chance that the returned information would be out of date. The caching mechanism was considered to cause problems when migrating threads between CPUs, and so the argument is now ignored.

NOTES

Linux makes a best effort to make this call as fast as possible. (On some architectures, this is done via an implementation in the *vdso*(7).) The intention of **getcpu**() is to allow programs to make optimizations with per-CPU data or for NUMA optimization.

mbind(2), *sched_setaffinity*(2), *set_mempolicy*(2), *sched_getcpu*(3), *cpuset*(7), *vdso*(7)

NAME

getdents, getdents64 − get directory entries

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

long syscall(SYS_getdents, unsigned int  fd, struct linux_dirent *dirp,
        unsigned int count);

#define _GNU_SOURCE           /* See feature_test_macros(7) */
#include <dirent.h>

ssize_t getdents64(int  fd, void dirp[.count], size_t count);
```

Note: glibc provides no wrapper for **getdents**(), necessitating the use of *syscall*(2).

Note: There is no definition of *struct linux_dirent* in glibc; see NOTES.

DESCRIPTION

These are not the interfaces you are interested in. Look at *readdir*(3) for the POSIX-conforming C library interface. This page documents the bare kernel system call interfaces.

getdents()

The system call **getdents**() reads several *linux_dirent* structures from the directory referred to by the open file descriptor *fd* into the buffer pointed to by *dirp*. The argument *count* specifies the size of that buffer.

The *linux_dirent* structure is declared as follows:

```
struct linux_dirent {
    unsigned long  d_ino;     /* Inode number */
    unsigned long  d_off;     /* Not an offset; see below */
    unsigned short d_reclen;  /* Length of this linux_dirent */
    char           d_name[];  /* Filename (null-terminated) */
                       /* length is actually (d_reclen - 2 -
                          offsetof(struct linux_dirent, d_name)) */
    /*
    char           pad;       // Zero padding byte
    char           d_type;    // File type (only since Linux
                              // 2.6.4); offset is (d_reclen - 1)
    */
}
```

d_ino is an inode number. *d_off* is a filesystem-specific value with no specific meaning to user space, though on older filesystems it used to be the distance from the start of the directory to the start of the next *linux_dirent*; see *readdir*(3). *d_reclen* is the size of this entire *linux_dirent*. *d_name* is a null-terminated filename.

d_type is a byte at the end of the structure that indicates the file type. It contains one of the following values (defined in <*dirent.h*>):

DT_BLK This is a block device.

DT_CHR This is a character device.

DT_DIR This is a directory.

DT_FIFO This is a named pipe (FIFO).

DT_LNK This is a symbolic link.

DT_REG This is a regular file.

DT_SOCK This is a UNIX domain socket.

DT_UNKNOWN
The file type is unknown.

The *d_type* field is implemented since Linux 2.6.4. It occupies a space that was previously a zero-filled padding byte in the *linux_dirent* structure. Thus, on kernels up to and including Linux 2.6.3, attempting to access this field always provides the value 0 (**DT_UNKNOWN**).

Currently, only some filesystems (among them: Btrfs, ext2, ext3, and ext4) have full support for returning the file type in *d_type*. All applications must properly handle a return of **DT_UNKNOWN**.

getdents64()
The original Linux **getdents**() system call did not handle large filesystems and large file offsets. Consequently, Linux 2.4 added **getdents64**(), with wider types for the *d_ino* and *d_off* fields. In addition, **getdents64**() supports an explicit *d_type* field.

The **getdents64**() system call is like **getdents**(), except that its second argument is a pointer to a buffer containing structures of the following type:

```
struct linux_dirent64 {
    ino64_t        d_ino;    /* 64-bit inode number */
    off64_t        d_off;    /* Not an offset; see getdents() */
    unsigned short d_reclen; /* Size of this dirent */
    unsigned char  d_type;   /* File type */
    char           d_name[]; /* Filename (null-terminated) */
};
```

RETURN VALUE
On success, the number of bytes read is returned. On end of directory, 0 is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS
EBADF
Invalid file descriptor *fd*.

EFAULT
Argument points outside the calling process's address space.

EINVAL
Result buffer is too small.

ENOENT
No such directory.

ENOTDIR
File descriptor does not refer to a directory.

STANDARDS
None.

HISTORY
SVr4.

getdents64()
glibc 2.30.

NOTES
glibc does not provide a wrapper for **getdents**(); call **getdents**() using *syscall*(2). In that case you will need to define the *linux_dirent* or *linux_dirent64* structure yourself.

Probably, you want to use *readdir*(3) instead of these system calls.

These calls supersede *readdir*(2).

EXAMPLES
The program below demonstrates the use of **getdents**(). The following output shows an example of what we see when running this program on an ext2 directory:

```
$ ./a.out /testfs/
-------------- nread=120 ---------------
inode#    file type  d_reclen  d_off   d_name
```

```
             2  directory    16         12  .
             2  directory    16         24  ..
            11  directory    24         44  lost+found
            12  regular      16         56  a
        228929  directory    16         68  sub
         16353  directory    16         80  sub2
        130817  directory    16       4096  sub3
```

Program source

```
#define _GNU_SOURCE
#include <dirent.h>     /* Defines DT_* constants */
#include <err.h>
#include <fcntl.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/syscall.h>
#include <unistd.h>

struct linux_dirent {
    unsigned long  d_ino;
    off_t          d_off;
    unsigned short d_reclen;
    char           d_name[];
};

#define BUF_SIZE 1024

int
main(int argc, char *argv[])
{
    int                 fd;
    char                d_type;
    char                buf[BUF_SIZE];
    long                nread;
    struct linux_dirent  *d;

    fd = open(argc > 1 ? argv[1] : ".", O_RDONLY | O_DIRECTORY);
    if (fd == -1)
        err(EXIT_FAILURE, "open");

    for (;;) {
        nread = syscall(SYS_getdents, fd, buf, BUF_SIZE);
        if (nread == -1)
            err(EXIT_FAILURE, "getdents");

        if (nread == 0)
            break;

        printf("--------------- nread=%ld ---------------\n", nread);
        printf("inode#    file type  d_reclen  d_off   d_name\n");
        for (size_t bpos = 0; bpos < nread;) {
            d = (struct linux_dirent *) (buf + bpos);
            printf("%8lu  ", d->d_ino);
            d_type = *(buf + bpos + d->d_reclen - 1);
            printf("%-10s ", (d_type == DT_REG) ?  "regular" :
                             (d_type == DT_DIR) ?  "directory" :
                             (d_type == DT_FIFO) ? "FIFO" :
```

```
                                (d_type == DT_SOCK) ? "socket" :
                                (d_type == DT_LNK) ?  "symlink" :
                                (d_type == DT_BLK) ?  "block dev" :
                                (d_type == DT_CHR) ?  "char dev" : "???");
                    printf("%4d %10jd  %s\n", d->d_reclen,
                           (intmax_t) d->d_off, d->d_name);
                    bpos += d->d_reclen;
                }
            }

            exit(EXIT_SUCCESS);
        }
```

readdir(2), *readdir*(3), *inode*(7)

NAME

getdomainname, setdomainname − get/set NIS domain name

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int getdomainname(char *name, size_t len);
int setdomainname(const char *name, size_t len);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

getdomainname(), **setdomainname**():
Since glibc 2.21:
_DEFAULT_SOURCE
In glibc 2.19 and 2.20:
_DEFAULT_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)
Up to and including glibc 2.19:
_BSD_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)

DESCRIPTION

These functions are used to access or to change the NIS domain name of the host system. More precisely, they operate on the NIS domain name associated with the calling process's UTS namespace.

setdomainname() sets the domain name to the value given in the character array *name*. The *len* argument specifies the number of bytes in *name*. (Thus, *name* does not require a terminating null byte.)

getdomainname() returns the null-terminated domain name in the character array *name*, which has a length of *len* bytes. If the null-terminated domain name requires more than *len* bytes, **getdomainname**() returns the first *len* bytes (glibc) or gives an error (libc).

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

setdomainname() can fail with the following errors:

EFAULT
name pointed outside of user address space.

EINVAL
len was negative or too large.

EPERM
The caller did not have the **CAP_SYS_ADMIN** capability in the user namespace associated with its UTS namespace (see *namespaces*(7)).

getdomainname() can fail with the following errors:

EINVAL
For **getdomainname**() under libc: *name* is NULL or *name* is longer than *len* bytes.

VERSIONS

On most Linux architectures (including x86), there is no **getdomainname**() system call; instead, glibc implements **getdomainname**() as a library function that returns a copy of the *domainname* field returned from a call to *uname*(2).

STANDARDS

None.

HISTORY

Since Linux 1.0, the limit on the length of a domain name, including the terminating null byte, is 64 bytes. In older kernels, it was 8 bytes.

SEE ALSO

gethostname(2), *sethostname*(2), *uname*(2), *uts_namespaces*(7)

NAME

getgid, getegid − get group identity

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

gid_t getgid(void);
gid_t getegid(void);
```

DESCRIPTION

getgid() returns the real group ID of the calling process.

getegid() returns the effective group ID of the calling process.

ERRORS

These functions are always successful and never modify *errno*.

VERSIONS

On Alpha, instead of a pair of **getgid**() and **getegid**() system calls, a single **getxgid**() system call is provided, which returns a pair of real and effective GIDs. The glibc **getgid**() and **getegid**() wrapper functions transparently deal with this. See *syscall*(2) for details regarding register mapping.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.3BSD.

The original Linux **getgid**() and **getegid**() system calls supported only 16-bit group IDs. Subsequently, Linux 2.4 added **getgid32**() and **getegid32**(), supporting 32-bit IDs. The glibc **getgid**() and **getegid**() wrapper functions transparently deal with the variations across kernel versions.

SEE ALSO

getresgid(2), *setgid*(2), *setregid*(2), *credentials*(7)

NAME

getgroups, setgroups − get/set list of supplementary group IDs

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int getgroups(int *size***, gid_t** *list***[]);**

#include <grp.h>

int setgroups(size_t *size***, const gid_t *_Nullable** *list***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

setgroups():
Since glibc 2.19:
_DEFAULT_SOURCE
glibc 2.19 and earlier:
_BSD_SOURCE

DESCRIPTION

getgroups() returns the supplementary group IDs of the calling process in *list*. The argument *size* should be set to the maximum number of items that can be stored in the buffer pointed to by *list*. If the calling process is a member of more than *size* supplementary groups, then an error results.

It is unspecified whether the effective group ID of the calling process is included in the returned list. (Thus, an application should also call *getegid*(2) and add or remove the resulting value.)

If *size* is zero, *list* is not modified, but the total number of supplementary group IDs for the process is returned. This allows the caller to determine the size of a dynamically allocated *list* to be used in a further call to **getgroups**().

setgroups() sets the supplementary group IDs for the calling process. Appropriate privileges are required (see the description of the **EPERM** error, below). The *size* argument specifies the number of supplementary group IDs in the buffer pointed to by *list*. A process can drop all of its supplementary groups with the call:

```
setgroups(0, NULL);
```

RETURN VALUE

On success, **getgroups**() returns the number of supplementary group IDs. On error, −1 is returned, and *errno* is set to indicate the error.

On success, **setgroups**() returns 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
list has an invalid address.

getgroups() can additionally fail with the following error:

EINVAL
size is less than the number of supplementary group IDs, but is not zero.

setgroups() can additionally fail with the following errors:

EINVAL
size is greater than **NGROUPS_MAX** (32 before Linux 2.6.4; 65536 since Linux 2.6.4).

ENOMEM
Out of memory.

EPERM
The calling process has insufficient privilege (the caller does not have the **CAP_SETGID** capability in the user namespace in which it resides).

EPERM (since Linux 3.19)
The use of **setgroups**() is denied in this user namespace. See the description of */proc/*pid*/setgroups* in *user_namespaces*(7).

VERSIONS

C library/kernel differences

At the kernel level, user IDs and group IDs are a per-thread attribute. However, POSIX requires that all threads in a process share the same credentials. The NPTL threading implementation handles the POSIX requirements by providing wrapper functions for the various system calls that change process UIDs and GIDs. These wrapper functions (including the one for *setgroups*()) employ a signal-based technique to ensure that when one thread changes credentials, all of the other threads in the process also change their credentials. For details, see *nptl*(7).

STANDARDS

getgroups()
: POSIX.1-2008.

setgroups()
: None.

HISTORY

getgroups()
: SVr4, 4.3BSD, POSIX.1-2001.

setgroups()
: SVr4, 4.3BSD. Since **setgroups**() requires privilege, it is not covered by POSIX.1.

The original Linux **getgroups**() system call supported only 16-bit group IDs. Subsequently, Linux 2.4 added **getgroups32**(), supporting 32-bit IDs. The glibc **getgroups**() wrapper function transparently deals with the variation across kernel versions.

NOTES

A process can have up to **NGROUPS_MAX** supplementary group IDs in addition to the effective group ID. The constant **NGROUPS_MAX** is defined in <*limits.h*>. The set of supplementary group IDs is inherited from the parent process, and preserved across an *execve*(2).

The maximum number of supplementary group IDs can be found at run time using *sysconf*(3):

```
long ngroups_max;
ngroups_max = sysconf(_SC_NGROUPS_MAX);
```

The maximum return value of **getgroups**() cannot be larger than one more than this value. Since Linux 2.6.4, the maximum number of supplementary group IDs is also exposed via the Linux-specific read-only file, */proc/sys/kernel/ngroups_max*.

SEE ALSO

getgid(2), *setgid*(2), *getgrouplist*(3), *group_member*(3), *initgroups*(3), *capabilities*(7), *credentials*(7)

NAME

gethostname, sethostname − get/set hostname

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int gethostname(char *name, size_t len);
int sethostname(const char *name, size_t len);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

gethostname():
_XOPEN_SOURCE >= 500 || _POSIX_C_SOURCE >= 200112L
|| /* glibc 2.19 and earlier */ _BSD_SOURCE

sethostname():
Since glibc 2.21:
_DEFAULT_SOURCE
In glibc 2.19 and 2.20:
_DEFAULT_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)
Up to and including glibc 2.19:
_BSD_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)

DESCRIPTION

These system calls are used to access or to change the system hostname. More precisely, they operate on the hostname associated with the calling process's UTS namespace.

sethostname() sets the hostname to the value given in the character array *name*. The *len* argument specifies the number of bytes in *name*. (Thus, *name* does not require a terminating null byte.)

gethostname() returns the null-terminated hostname in the character array *name*, which has a length of *len* bytes. If the null-terminated hostname is too large to fit, then the name is truncated, and no error is returned (but see NOTES below). POSIX.1 says that if such truncation occurs, then it is unspecified whether the returned buffer includes a terminating null byte.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
name is an invalid address.

EINVAL
len is negative or, for **sethostname**(), *len* is larger than the maximum allowed size.

ENAMETOOLONG
(glibc **gethostname**()) *len* is smaller than the actual size. (Before glibc 2.1, glibc uses **EINVAL** for this case.)

EPERM
For **sethostname**(), the caller did not have the **CAP_SYS_ADMIN** capability in the user namespace associated with its UTS namespace (see *namespaces*(7)).

VERSIONS

SUSv2 guarantees that "Host names are limited to 255 bytes". POSIX.1 guarantees that "Host names (not including the terminating null byte) are limited to **HOST_NAME_MAX** bytes". On Linux, **HOST_NAME_MAX** is defined with the value 64, which has been the limit since Linux 1.0 (earlier kernels imposed a limit of 8 bytes).

C library/kernel differences

The GNU C library does not employ the **gethostname**() system call; instead, it implements **gethostname**() as a library function that calls *uname*(2) and copies up to *len* bytes from the returned *nodename* field into *name*. Having performed the copy, the function then checks if the length of the *nodename* was greater than or equal to *len*, and if it is, then the function returns −1 with *errno* set to **ENAMETOOLONG**; in this case, a terminating null byte is not included in the returned *name*.

STANDARDS

gethostname()
POSIX.1-2008.

sethostname()
None.

HISTORY

SVr4, 4.4BSD (these interfaces first appeared in 4.2BSD). POSIX.1-2001 and POSIX.1-2008 specify **gethostname**() but not **sethostname**().

Versions of glibc before glibc 2.2 handle the case where the length of the *nodename* was greater than or equal to *len* differently: nothing is copied into *name* and the function returns −1 with *errno* set to **ENAMETOOLONG**.

SEE ALSO

hostname(1), *getdomainname*(2), *setdomainname*(2), *uname*(2), *uts_namespaces*(7)

NAME

getitimer, setitimer − get or set value of an interval timer

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/time.h>

int getitimer(int which, struct itimerval *curr_value);
int setitimer(int which, const struct itimerval *restrict new_value,
              struct itimerval *_Nullable restrict old_value);
```

DESCRIPTION

These system calls provide access to interval timers, that is, timers that initially expire at some point in the future, and (optionally) at regular intervals after that. When a timer expires, a signal is generated for the calling process, and the timer is reset to the specified interval (if the interval is nonzero).

Three types of timers—specified via the *which* argument—are provided, each of which counts against a different clock and generates a different signal on timer expiration:

ITIMER_REAL
: This timer counts down in real (i.e., wall clock) time. At each expiration, a **SIGALRM** signal is generated.

ITIMER_VIRTUAL
: This timer counts down against the user-mode CPU time consumed by the process. (The measurement includes CPU time consumed by all threads in the process.) At each expiration, a **SIGVTALRM** signal is generated.

ITIMER_PROF
: This timer counts down against the total (i.e., both user and system) CPU time consumed by the process. (The measurement includes CPU time consumed by all threads in the process.) At each expiration, a **SIGPROF** signal is generated.

  In conjunction with **ITIMER_VIRTUAL**, this timer can be used to profile user and system CPU time consumed by the process.

A process has only one of each of the three types of timers.

Timer values are defined by the following structures:

```
struct itimerval {
    struct timeval it_interval; /* Interval for periodic timer */
    struct timeval it_value;    /* Time until next expiration */
};

struct timeval {
    time_t      tv_sec;         /* seconds */
    suseconds_t tv_usec;        /* microseconds */
};
```

getitimer()

The function **getitimer**() places the current value of the timer specified by *which* in the buffer pointed to by *curr_value*.

The *it_value* substructure is populated with the amount of time remaining until the next expiration of the specified timer. This value changes as the timer counts down, and will be reset to *it_interval* when the timer expires. If both fields of *it_value* are zero, then this timer is currently disarmed (inactive).

The *it_interval* substructure is populated with the timer interval. If both fields of *it_interval* are zero, then this is a single-shot timer (i.e., it expires just once).

setitimer()

The function **setitimer**() arms or disarms the timer specified by *which*, by setting the timer to the value specified by *new_value*. If *old_value* is non-NULL, the buffer it points to is used to return the previous value of the timer (i.e., the same information that is returned by *getitimer*())

If either field in *new_value.it_value* is nonzero, then the timer is armed to initially expire at the

specified time. If both fields in *new_value.it_value* are zero, then the timer is disarmed.

The *new_value.it_interval* field specifies the new interval for the timer; if both of its subfields are zero, the timer is single-shot.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT

new_value, *old_value*, or *curr_value* is not valid a pointer.

EINVAL

which is not one of **ITIMER_REAL**, **ITIMER_VIRTUAL**, or **ITIMER_PROF**; or (since Linux 2.6.22) one of the *tv_usec* fields in the structure pointed to by *new_value* contains a value outside the range [0, 999999].

VERSIONS

The standards are silent on the meaning of the call:

```
setitimer(which, NULL, &old_value);
```

Many systems (Solaris, the BSDs, and perhaps others) treat this as equivalent to:

```
getitimer(which, &old_value);
```

In Linux, this is treated as being equivalent to a call in which the *new_value* fields are zero; that is, the timer is disabled. *Don't use this Linux misfeature*: it is nonportable and unnecessary.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.4BSD (this call first appeared in 4.2BSD). POSIX.1-2008 marks **getitimer**() and **setitimer**() obsolete, recommending the use of the POSIX timers API (**timer_gettime**(2), *timer_settime*(2), etc.) instead.

NOTES

Timers will never expire before the requested time, but may expire some (short) time afterward, which depends on the system timer resolution and on the system load; see *time*(7). (But see BUGS below.) If the timer expires while the process is active (always true for **ITIMER_VIRTUAL**), the signal will be delivered immediately when generated.

A child created via *fork*(2) does not inherit its parent's interval timers. Interval timers are preserved across an *execve*(2).

POSIX.1 leaves the interaction between **setitimer**() and the three interfaces *alarm*(2), *sleep*(3), and *usleep*(3) unspecified.

BUGS

The generation and delivery of a signal are distinct, and only one instance of each of the signals listed above may be pending for a process. Under very heavy loading, an **ITIMER_REAL** timer may expire before the signal from a previous expiration has been delivered. The second signal in such an event will be lost.

Before Linux 2.6.16, timer values are represented in jiffies. If a request is made set a timer with a value whose jiffies representation exceeds **MAX_SEC_IN_JIFFIES** (defined in *include/linux/jiffies.h*), then the timer is silently truncated to this ceiling value. On Linux/i386 (where, since Linux 2.6.13, the default jiffy is 0.004 seconds), this means that the ceiling value for a timer is approximately 99.42 days. Since Linux 2.6.16, the kernel uses a different internal representation for times, and this ceiling is removed.

On certain systems (including i386), Linux kernels before Linux 2.6.12 have a bug which will produce premature timer expirations of up to one jiffy under some circumstances. This bug is fixed in Linux 2.6.12.

POSIX.1-2001 says that **setitimer**() should fail if a *tv_usec* value is specified that is outside of the range [0, 999999]. However, up to and including Linux 2.6.21, Linux does not give an error, but instead silently adjusts the corresponding seconds value for the timer. From Linux 2.6.22 onward, this

nonconformance has been repaired: an improper *tv_usec* value results in an **EINVAL** error.

gettimeofday(2), *sigaction*(2), *signal*(2), *timer_create*(2), *timerfd_create*(2), *time*(7)

NAME

getpagesize − get memory page size

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int getpagesize(void);

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

getpagesize():
Since glibc 2.20:
_DEFAULT_SOURCE || ! (_POSIX_C_SOURCE >= 200112L)
glibc 2.12 to glibc 2.19:
_BSD_SOURCE || ! (_POSIX_C_SOURCE >= 200112L)
Before glibc 2.12:
_BSD_SOURCE || _XOPEN_SOURCE >= 500

DESCRIPTION

The function **getpagesize**() returns the number of bytes in a memory page, where "page" is a fixed-length block, the unit for memory allocation and file mapping performed by *mmap*(2).

STANDARDS

None.

HISTORY

This call first appeared in 4.2BSD. SVr4, 4.4BSD, SUSv2. In SUSv2 the **getpagesize**() call is labeled LEGACY, and in POSIX.1-2001 it has been dropped; HP-UX does not have this call.

NOTES

Portable applications should employ *sysconf(_SC_PAGESIZE)* instead of **getpagesize**():

```
#include <unistd.h>
long sz = sysconf(_SC_PAGESIZE);
```

(Most systems allow the synonym **_SC_PAGE_SIZE** for **_SC_PAGESIZE**.)

Whether **getpagesize**() is present as a Linux system call depends on the architecture. If it is, it returns the kernel symbol **PAGE_SIZE**, whose value depends on the architecture and machine model. Generally, one uses binaries that are dependent on the architecture but not on the machine model, in order to have a single binary distribution per architecture. This means that a user program should not find **PAGE_SIZE** at compile time from a header file, but use an actual system call, at least for those architectures (like sun4) where this dependency exists. Here glibc 2.0 fails because its **getpagesize**() returns a statically derived value, and does not use a system call. Things are OK in glibc 2.1.

SEE ALSO

mmap(2), *sysconf*(3)

NAME

getpeername − get name of connected peer socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/socket.h>

int getpeername(int sockfd, struct sockaddr *restrict addr,
                socklen_t *restrict addrlen);
```

DESCRIPTION

getpeername() returns the address of the peer connected to the socket *sockfd*, in the buffer pointed to by *addr*. The *addrlen* argument should be initialized to indicate the amount of space pointed to by *addr*. On return it contains the actual size of the name returned (in bytes). The name is truncated if the buffer provided is too small.

The returned address is truncated if the buffer provided is too small; in this case, *addrlen* will return a value greater than was supplied to the call.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
The argument *sockfd* is not a valid file descriptor.

EFAULT
The *addr* argument points to memory not in a valid part of the process address space.

EINVAL
addrlen is invalid (e.g., is negative).

ENOBUFS
Insufficient resources were available in the system to perform the operation.

ENOTCONN
The socket is not connected.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.4BSD (first appeared in 4.2BSD).

NOTES

For stream sockets, once a *connect*(2) has been performed, either socket can call **getpeername**() to obtain the address of the peer socket. On the other hand, datagram sockets are connectionless. Calling *connect*(2) on a datagram socket merely sets the peer address for outgoing datagrams sent with *write*(2) or *recv*(2). The caller of *connect*(2) can use **getpeername**() to obtain the peer address that it earlier set for the socket. However, the peer socket is unaware of this information, and calling **getpeername**() on the peer socket will return no useful information (unless a *connect*(2) call was also executed on the peer). Note also that the receiver of a datagram can obtain the address of the sender when using *recvfrom*(2).

SEE ALSO

accept(2), *bind*(2), *getsockname*(2), *ip*(7), *socket*(7), *unix*(7)

NAME

getpid, getppid − get process identification

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

pid_t getpid(void);
pid_t getppid(void);
```

DESCRIPTION

getpid() returns the process ID (PID) of the calling process. (This is often used by routines that generate unique temporary filenames.)

getppid() returns the process ID of the parent of the calling process. This will be either the ID of the process that created this process using **fork**(), or, if that process has already terminated, the ID of the process to which this process has been reparented (either *init*(1) or a "subreaper" process defined via the *prctl*(2) **PR_SET_CHILD_SUBREAPER** operation).

ERRORS

These functions are always successful.

VERSIONS

On Alpha, instead of a pair of **getpid**() and **getppid**() system calls, a single **getxpid**() system call is provided, which returns a pair of PID and parent PID. The glibc **getpid**() and **getppid**() wrapper functions transparently deal with this. See *syscall*(2) for details regarding register mapping.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.3BSD, SVr4.

C library/kernel differences

From glibc 2.3.4 up to and including glibc 2.24, the glibc wrapper function for **getpid**() cached PIDs, with the goal of avoiding additional system calls when a process calls **getpid**() repeatedly. Normally this caching was invisible, but its correct operation relied on support in the wrapper functions for *fork*(2), *vfork*(2), and *clone*(2): if an application bypassed the glibc wrappers for these system calls by using *syscall*(2), then a call to **getpid**() in the child would return the wrong value (to be precise: it would return the PID of the parent process). In addition, there were cases where **getpid**() could return the wrong value even when invoking *clone*(2) via the glibc wrapper function. (For a discussion of one such case, see BUGS in *clone*(2).) Furthermore, the complexity of the caching code had been the source of a few bugs within glibc over the years.

Because of the aforementioned problems, since glibc 2.25, the PID cache is removed: calls to **getpid**() always invoke the actual system call, rather than returning a cached value.

NOTES

If the caller's parent is in a different PID namespace (see *pid_namespaces*(7)), **getppid**() returns 0.

From a kernel perspective, the PID (which is shared by all of the threads in a multithreaded process) is sometimes also known as the thread group ID (TGID). This contrasts with the kernel thread ID (TID), which is unique for each thread. For further details, see *gettid*(2) and the discussion of the **CLONE_THREAD** flag in *clone*(2).

SEE ALSO

NAME

getpriority, setpriority − get/set program scheduling priority

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/resource.h>

int getpriority(int which, id_t who);
int setpriority(int which, id_t who, int prio);
```

DESCRIPTION

The scheduling priority of the process, process group, or user, as indicated by *which* and *who* is obtained with the **getpriority**() call and set with the **setpriority**() call. The process attribute dealt with by these system calls is the same attribute (also known as the "nice" value) that is dealt with by *nice*(2).

The value *which* is one of **PRIO_PROCESS**, **PRIO_PGRP**, or **PRIO_USER**, and *who* is interpreted relative to *which* (a process identifier for **PRIO_PROCESS**, process group identifier for **PRIO_PGRP**, and a user ID for **PRIO_USER**). A zero value for *who* denotes (respectively) the calling process, the process group of the calling process, or the real user ID of the calling process.

The *prio* argument is a value in the range −20 to 19 (but see NOTES below), with −20 being the highest priority and 19 being the lowest priority. Attempts to set a priority outside this range are silently clamped to the range. The default priority is 0; lower values give a process a higher scheduling priority.

The **getpriority**() call returns the highest priority (lowest numerical value) enjoyed by any of the specified processes. The **setpriority**() call sets the priorities of all of the specified processes to the specified value.

Traditionally, only a privileged process could lower the nice value (i.e., set a higher priority). However, since Linux 2.6.12, an unprivileged process can decrease the nice value of a target process that has a suitable **RLIMIT_NICE** soft limit; see *getrlimit*(2) for details.

RETURN VALUE

On success, **getpriority**() returns the calling thread's nice value, which may be a negative number. On error, it returns −1 and sets *errno* to indicate the error.

Since a successful call to **getpriority**() can legitimately return the value −1, it is necessary to clear *errno* prior to the call, then check *errno* afterward to determine if −1 is an error or a legitimate value.

setpriority() returns 0 on success. On failure, it returns −1 and sets *errno* to indicate the error.

ERRORS

EACCES
: The caller attempted to set a lower nice value (i.e., a higher process priority), but did not have the required privilege (on Linux: did not have the **CAP_SYS_NICE** capability).

EINVAL
: *which* was not one of **PRIO_PROCESS**, **PRIO_PGRP**, or **PRIO_USER**.

EPERM
: A process was located, but its effective user ID did not match either the effective or the real user ID of the caller, and was not privileged (on Linux: did not have the **CAP_SYS_NICE** capability). But see NOTES below.

ESRCH
: No process was located using the *which* and *who* values specified.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.4BSD (these interfaces first appeared in 4.2BSD).

NOTES

For further details on the nice value, see *sched*(7).

Note: the addition of the "autogroup" feature in Linux 2.6.38 means that the nice value no longer has

its traditional effect in many circumstances. For details, see *sched*(7).

A child created by *fork*(2) inherits its parent's nice value. The nice value is preserved across *execve*(2).

The details on the condition for **EPERM** depend on the system. The above description is what POSIX.1-2001 says, and seems to be followed on all System V-like systems. Linux kernels before Linux 2.6.12 required the real or effective user ID of the caller to match the real user of the process *who* (instead of its effective user ID). Linux 2.6.12 and later require the effective user ID of the caller to match the real or effective user ID of the process *who*. All BSD-like systems (SunOS 4.1.3, Ultrix 4.2, 4.3BSD, FreeBSD 4.3, OpenBSD-2.5, ...) behave in the same manner as Linux 2.6.12 and later.

C library/kernel differences

The getpriority system call returns nice values translated to the range 40..1, since a negative return value would be interpreted as an error. The glibc wrapper function for **getpriority**() translates the value back according to the formula *unice = 20 − knice* (thus, the 40..1 range returned by the kernel corresponds to the range −20..19 as seen by user space).

BUGS

According to POSIX, the nice value is a per-process setting. However, under the current Linux/NPTL implementation of POSIX threads, the nice value is a per-thread attribute: different threads in the same process can have different nice values. Portable applications should avoid relying on the Linux behavior, which may be made standards conformant in the future.

NAME

getrandom − obtain a series of random bytes

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/random.h>

ssize_t getrandom(void *buf* **[.***buflen***], size_t** *buflen***, unsigned int** *flags***);**

DESCRIPTION

The **getrandom**() system call fills the buffer pointed to by *buf* with up to *buflen* random bytes. These bytes can be used to seed user-space random number generators or for cryptographic purposes.

By default, **getrandom**() draws entropy from the *urandom* source (i.e., the same source as the */dev/urandom* device). This behavior can be changed via the *flags* argument.

If the *urandom* source has been initialized, reads of up to 256 bytes will always return as many bytes as requested and will not be interrupted by signals. No such guarantees apply for larger buffer sizes. For example, if the call is interrupted by a signal handler, it may return a partially filled buffer, or fail with the error **EINTR**.

If the *urandom* source has not yet been initialized, then **getrandom**() will block, unless **GRND_NONBLOCK** is specified in *flags*.

The *flags* argument is a bit mask that can contain zero or more of the following values ORed together:

GRND_RANDOM
: If this bit is set, then random bytes are drawn from the *random* source (i.e., the same source as the */dev/random* device) instead of the *urandom* source. The *random* source is limited based on the entropy that can be obtained from environmental noise. If the number of available bytes in the *random* source is less than requested in *buflen*, the call returns just the available random bytes. If no random bytes are available, the behavior depends on the presence of **GRND_NONBLOCK** in the *flags* argument.

GRND_NONBLOCK
: By default, when reading from the *random* source, **getrandom**() blocks if no random bytes are available, and when reading from the *urandom* source, it blocks if the entropy pool has not yet been initialized. If the **GRND_NONBLOCK** flag is set, then **getrandom**() does not block in these cases, but instead immediately returns −1 with *errno* set to **EAGAIN**.

RETURN VALUE

On success, **getrandom**() returns the number of bytes that were copied to the buffer *buf*. This may be less than the number of bytes requested via *buflen* if either **GRND_RANDOM** was specified in *flags* and insufficient entropy was present in the *random* source or the system call was interrupted by a signal.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EAGAIN
: The requested entropy was not available, and **getrandom**() would have blocked if the **GRND_NONBLOCK** flag was not set.

EFAULT
: The address referred to by *buf* is outside the accessible address space.

EINTR
: The call was interrupted by a signal handler; see the description of how interrupted *read*(2) calls on "slow" devices are handled with and without the **SA_RESTART** flag in the *signal*(7) man page.

EINVAL
: An invalid flag was specified in *flags*.

ENOSYS
: The glibc wrapper function for **getrandom**() determined that the underlying kernel does not implement this system call.

STANDARDS

Linux.

HISTORY

Linux 3.17, glibc 2.25.

NOTES

For an overview and comparison of the various interfaces that can be used to obtain randomness, see *random*(7).

Unlike */dev/random* and */dev/urandom*, **getrandom**() does not involve the use of pathnames or file descriptors. Thus, **getrandom**() can be useful in cases where *chroot*(2) makes */dev* pathnames invisible, and where an application (e.g., a daemon during start-up) closes a file descriptor for one of these files that was opened by a library.

Maximum number of bytes returned

As of Linux 3.19 the following limits apply:

- When reading from the *urandom* source, a maximum of 32Mi-1 bytes is returned by a single call to **getrandom**() on systems where *int* has a size of 32 bits.
- When reading from the *random* source, a maximum of 512 bytes is returned.

Interruption by a signal handler

When reading from the *urandom* source (**GRND_RANDOM** is not set), **getrandom**() will block until the entropy pool has been initialized (unless the **GRND_NONBLOCK** flag was specified). If a request is made to read a large number of bytes (more than 256), **getrandom**() will block until those bytes have been generated and transferred from kernel memory to *buf*. When reading from the *random* source (**GRND_RANDOM** is set), **getrandom**() will block until some random bytes become available (unless the **GRND_NONBLOCK** flag was specified).

The behavior when a call to **getrandom**() that is blocked while reading from the *urandom* source is interrupted by a signal handler depends on the initialization state of the entropy buffer and on the request size, *buflen*. If the entropy is not yet initialized, then the call fails with the **EINTR** error. If the entropy pool has been initialized and the request size is large (*buflen* > 256), the call either succeeds, returning a partially filled buffer, or fails with the error **EINTR**. If the entropy pool has been initialized and the request size is small (*buflen* <= 256), then **getrandom**() will not fail with **EINTR**. Instead, it will return all of the bytes that have been requested.

When reading from the *random* source, blocking requests of any size can be interrupted by a signal handler (the call fails with the error **EINTR**).

Using **getrandom**() to read small buffers (<= 256 bytes) from the *urandom* source is the preferred mode of usage.

The special treatment of small values of *buflen* was designed for compatibility with OpenBSD's *getentropy*(3), which is nowadays supported by glibc.

The user of **getrandom**() *must* always check the return value, to determine whether either an error occurred or fewer bytes than requested were returned. In the case where **GRND_RANDOM** is not specified and *buflen* is less than or equal to 256, a return of fewer bytes than requested should never happen, but the careful programmer will check for this anyway!

BUGS

As of Linux 3.19, the following bug exists:

- Depending on CPU load, **getrandom**() does not react to interrupts before reading all bytes requested.

SEE ALSO

getentropy(3), *random*(4), *urandom*(4), *random*(7), *signal*(7)

NAME

getresuid, getresgid − get real, effective, and saved user/group IDs

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <unistd.h>

int getresuid(uid_t *ruid, uid_t *euid, uid_t *suid);
int getresgid(gid_t *rgid, gid_t *egid, gid_t *sgid);
```

DESCRIPTION

getresuid() returns the real UID, the effective UID, and the saved set-user-ID of the calling process, in the arguments *ruid*, *euid*, and *suid*, respectively. **getresgid**() performs the analogous task for the process's group IDs.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
: One of the arguments specified an address outside the calling program's address space.

STANDARDS

None. These calls also appear on HP-UX and some of the BSDs.

HISTORY

Linux 2.1.44, glibc 2.3.2.

The original Linux **getresuid**() and **getresgid**() system calls supported only 16-bit user and group IDs. Subsequently, Linux 2.4 added **getresuid32**() and **getresgid32**(), supporting 32-bit IDs. The glibc **getresuid**() and **getresgid**() wrapper functions transparently deal with the variations across kernel versions.

SEE ALSO

getuid(2), *setresuid*(2), *setreuid*(2), *setuid*(2), *credentials*(7)

NAME

getrlimit, setrlimit, prlimit − get/set resource limits

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/resource.h>

int getrlimit(int resource, struct rlimit *rlim);
int setrlimit(int resource, const struct rlimit *rlim);

int prlimit(pid_t pid, int resource,
        const struct rlimit *_Nullable new_limit,
        struct rlimit *_Nullable old_limit);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

prlimit():
_GNU_SOURCE

DESCRIPTION

The **getrlimit**() and **setrlimit**() system calls get and set resource limits. Each resource has an associated soft and hard limit, as defined by the *rlimit* structure:

```
struct rlimit {
    rlim_t rlim_cur;  /* Soft limit */
    rlim_t rlim_max;  /* Hard limit (ceiling for rlim_cur) */
};
```

The soft limit is the value that the kernel enforces for the corresponding resource. The hard limit acts as a ceiling for the soft limit: an unprivileged process may set only its soft limit to a value in the range from 0 up to the hard limit, and (irreversibly) lower its hard limit. A privileged process (under Linux: one with the **CAP_SYS_RESOURCE** capability in the initial user namespace) may make arbitrary changes to either limit value.

The value **RLIM_INFINITY** denotes no limit on a resource (both in the structure returned by **getrlimit**() and in the structure passed to *setrlimit*())

The *resource* argument must be one of:

RLIMIT_AS
: This is the maximum size of the process's virtual memory (address space). The limit is specified in bytes, and is rounded down to the system page size. This limit affects calls to *brk*(2), *mmap*(2), and *mremap*(2), which fail with the error **ENOMEM** upon exceeding this limit. In addition, automatic stack expansion fails (and generates a **SIGSEGV** that kills the process if no alternate stack has been made available via *sigaltstack*(2)). Since the value is a *long*, on machines with a 32-bit *long* either this limit is at most 2 GiB, or this resource is unlimited.

RLIMIT_CORE
: This is the maximum size of a *core* file (see *core*(5)) in bytes that the process may dump. When 0 no core dump files are created. When nonzero, larger dumps are truncated to this size.

RLIMIT_CPU
: This is a limit, in seconds, on the amount of CPU time that the process can consume. When the process reaches the soft limit, it is sent a **SIGXCPU** signal. The default action for this signal is to terminate the process. However, the signal can be caught, and the handler can return control to the main program. If the process continues to consume CPU time, it will be sent **SIGXCPU** once per second until the hard limit is reached, at which time it is sent **SIGKILL**. (This latter point describes Linux behavior. Implementations vary in how they treat processes which continue to consume CPU time after reaching the soft limit. Portable applications that need to catch this signal should perform an orderly termination upon first receipt of **SIGXCPU**.)

RLIMIT_DATA
: This is the maximum size of the process's data segment (initialized data, uninitialized data, and heap). The limit is specified in bytes, and is rounded down to the system page size. This

limit affects calls to *brk*(2), *sbrk*(2), and (since Linux 4.7) *mmap*(2), which fail with the error **ENOMEM** upon encountering the soft limit of this resource.

RLIMIT_FSIZE
This is the maximum size in bytes of files that the process may create. Attempts to extend a file beyond this limit result in delivery of a **SIGXFSZ** signal. By default, this signal terminates a process, but a process can catch this signal instead, in which case the relevant system call (e.g., *write*(2), *truncate*(2)) fails with the error **EFBIG**.

RLIMIT_LOCKS (Linux 2.4.0 to Linux 2.4.24)
This is a limit on the combined number of *flock*(2) locks and *fcntl*(2) leases that this process may establish.

RLIMIT_MEMLOCK
This is the maximum number of bytes of memory that may be locked into RAM. This limit is in effect rounded down to the nearest multiple of the system page size. This limit affects *mlock*(2), *mlockall*(2), and the *mmap*(2) **MAP_LOCKED** operation. Since Linux 2.6.9, it also affects the *shmctl*(2) **SHM_LOCK** operation, where it sets a maximum on the total bytes in shared memory segments (see *shmget*(2)) that may be locked by the real user ID of the calling process. The *shmctl*(2) **SHM_LOCK** locks are accounted for separately from the per-process memory locks established by *mlock*(2), *mlockall*(2), and *mmap*(2) **MAP_LOCKED**; a process can lock bytes up to this limit in each of these two categories.

Before Linux 2.6.9, this limit controlled the amount of memory that could be locked by a privileged process. Since Linux 2.6.9, no limits are placed on the amount of memory that a privileged process may lock, and this limit instead governs the amount of memory that an unprivileged process may lock.

RLIMIT_MSGQUEUE (since Linux 2.6.8)
This is a limit on the number of bytes that can be allocated for POSIX message queues for the real user ID of the calling process. This limit is enforced for *mq_open*(3). Each message queue that the user creates counts (until it is removed) against this limit according to the formula:

Since Linux 3.5:

```
bytes = attr.mq_maxmsg * sizeof(struct msg_msg) +
        MIN(attr.mq_maxmsg, MQ_PRIO_MAX) *
              sizeof(struct posix_msg_tree_node)+
                        /* For overhead */
        attr.mq_maxmsg * attr.mq_msgsize;
                        /* For message data */
```

Linux 3.4 and earlier:

```
bytes = attr.mq_maxmsg * sizeof(struct msg_msg *) +
                        /* For overhead */
        attr.mq_maxmsg * attr.mq_msgsize;
                        /* For message data */
```

where *attr* is the *mq_attr* structure specified as the fourth argument to *mq_open*(3), and the *msg_msg* and *posix_msg_tree_node* structures are kernel-internal structures.

The "overhead" addend in the formula accounts for overhead bytes required by the implementation and ensures that the user cannot create an unlimited number of zero-length messages (such messages nevertheless each consume some system memory for bookkeeping overhead).

RLIMIT_NICE (since Linux 2.6.12, but see BUGS below)
This specifies a ceiling to which the process's nice value can be raised using *setpriority*(2) or *nice*(2). The actual ceiling for the nice value is calculated as *20 − rlim_cur*. The useful range for this limit is thus from 1 (corresponding to a nice value of 19) to 40 (corresponding to a nice value of −20). This unusual choice of range was necessary because negative numbers cannot be specified as resource limit values, since they typically have special meanings. For example, **RLIM_INFINITY** typically is the same as −1. For more detail on the nice value, see *sched*(7).

RLIMIT_NOFILE
This specifies a value one greater than the maximum file descriptor number that can be opened by this process. Attempts (**open**(2), *pipe*(2), *dup*(2), etc.) to exceed this limit yield the error **EMFILE**. (Historically, this limit was named **RLIMIT_OFILE** on BSD.)

Since Linux 4.5, this limit also defines the maximum number of file descriptors that an unprivileged process (one without the **CAP_SYS_RESOURCE** capability) may have "in flight" to other processes, by being passed across UNIX domain sockets. This limit applies to the *sendmsg*(2) system call. For further details, see *unix*(7).

RLIMIT_NPROC
This is a limit on the number of extant process (or, more precisely on Linux, threads) for the real user ID of the calling process. So long as the current number of processes belonging to this process's real user ID is greater than or equal to this limit, *fork*(2) fails with the error **EAGAIN**.

The **RLIMIT_NPROC** limit is not enforced for processes that have either the **CAP_SYS_ADMIN** or the **CAP_SYS_RESOURCE** capability, or run with real user ID 0.

RLIMIT_RSS
This is a limit (in bytes) on the process's resident set (the number of virtual pages resident in RAM). This limit has effect only in Linux 2.4.x, x < 30, and there affects only calls to *madvise*(2) specifying **MADV_WILLNEED**.

RLIMIT_RTPRIO (since Linux 2.6.12, but see BUGS)
This specifies a ceiling on the real-time priority that may be set for this process using *sched_setscheduler*(2) and *sched_setparam*(2).

For further details on real-time scheduling policies, see *sched*(7)

RLIMIT_RTTIME (since Linux 2.6.25)
This is a limit (in microseconds) on the amount of CPU time that a process scheduled under a real-time scheduling policy may consume without making a blocking system call. For the purpose of this limit, each time a process makes a blocking system call, the count of its consumed CPU time is reset to zero. The CPU time count is not reset if the process continues trying to use the CPU but is preempted, its time slice expires, or it calls *sched_yield*(2).

Upon reaching the soft limit, the process is sent a **SIGXCPU** signal. If the process catches or ignores this signal and continues consuming CPU time, then **SIGXCPU** will be generated once each second until the hard limit is reached, at which point the process is sent a **SIGKILL** signal.

The intended use of this limit is to stop a runaway real-time process from locking up the system.

For further details on real-time scheduling policies, see *sched*(7)

RLIMIT_SIGPENDING (since Linux 2.6.8)
This is a limit on the number of signals that may be queued for the real user ID of the calling process. Both standard and real-time signals are counted for the purpose of checking this limit. However, the limit is enforced only for *sigqueue*(3); it is always possible to use *kill*(2) to queue one instance of any of the signals that are not already queued to the process.

RLIMIT_STACK
This is the maximum size of the process stack, in bytes. Upon reaching this limit, a **SIGSEGV** signal is generated. To handle this signal, a process must employ an alternate signal stack (**sigaltstack**(2)).

Since Linux 2.6.23, this limit also determines the amount of space used for the process's command-line arguments and environment variables; for details, see *execve*(2).

prlimit()
The Linux-specific **prlimit**() system call combines and extends the functionality of **setrlimit**() and **getrlimit**(). It can be used to both set and get the resource limits of an arbitrary process.

The *resource* argument has the same meaning as for **setrlimit**() and **getrlimit**().

If the *new_limit* argument is not NULL, then the *rlimit* structure to which it points is used to set new

values for the soft and hard limits for *resource*. If the *old_limit* argument is not NULL, then a successful call to **prlimit**() places the previous soft and hard limits for *resource* in the *rlimit* structure pointed to by *old_limit*.

The *pid* argument specifies the ID of the process on which the call is to operate. If *pid* is 0, then the call applies to the calling process. To set or get the resources of a process other than itself, the caller must have the **CAP_SYS_RESOURCE** capability in the user namespace of the process whose resource limits are being changed, or the real, effective, and saved set user IDs of the target process must match the real user ID of the caller *and* the real, effective, and saved set group IDs of the target process must match the real group ID of the caller.

RETURN VALUE

On success, these system calls return 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
A pointer argument points to a location outside the accessible address space.

EINVAL
The value specified in *resource* is not valid; or, for **setrlimit**() or **prlimit**(): *rlim->rlim_cur* was greater than *rlim->rlim_max*.

EPERM
An unprivileged process tried to raise the hard limit; the **CAP_SYS_RESOURCE** capability is required to do this.

EPERM
The caller tried to increase the hard **RLIMIT_NOFILE** limit above the maximum defined by */proc/sys/fs/nr_open* (see *proc*(5))

EPERM
(**prlimit**()) The calling process did not have permission to set limits for the process specified by *pid*.

ESRCH
Could not find a process with the ID specified in *pid*.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
getrlimit(), **setrlimit**(), **prlimit**()	Thread safety	MT-Safe

STANDARDS

getrlimit()
setrlimit()
POSIX.1-2008.

prlimit()
Linux.

RLIMIT_MEMLOCK and **RLIMIT_NPROC** derive from BSD and are not specified in POSIX.1; they are present on the BSDs and Linux, but on few other implementations. **RLIMIT_RSS** derives from BSD and is not specified in POSIX.1; it is nevertheless present on most implementations. **RLIMIT_MSGQUEUE**, **RLIMIT_NICE**, **RLIMIT_RTPRIO**, **RLIMIT_RTTIME**, and **RLIMIT_SIGPENDING** are Linux-specific.

HISTORY

getrlimit()
setrlimit()
POSIX.1-2001, SVr4, 4.3BSD.

prlimit()
Linux 2.6.36, glibc 2.13.

NOTES

A child process created via *fork*(2) inherits its parent's resource limits. Resource limits are preserved across *execve*(2).

Resource limits are per-process attributes that are shared by all of the threads in a process.

Lowering the soft limit for a resource below the process's current consumption of that resource will succeed (but will prevent the process from further increasing its consumption of the resource).

One can set the resource limits of the shell using the built-in *ulimit* command (*limit* in *csh*(1)). The shell's resource limits are inherited by the processes that it creates to execute commands.

Since Linux 2.6.24, the resource limits of any process can be inspected via */proc/*pid*/limits*; see *proc*(5).

Ancient systems provided a **vlimit**() function with a similar purpose to **setrlimit**(). For backward compatibility, glibc also provides **vlimit**(). All new applications should be written using **setrlimit**().

C library/kernel ABI differences

Since glibc 2.13, the glibc **getrlimit**() and **setrlimit**() wrapper functions no longer invoke the corresponding system calls, but instead employ **prlimit**(), for the reasons described in BUGS.

The name of the glibc wrapper function is **prlimit**(); the underlying system call is **prlimit64**().

BUGS

In older Linux kernels, the **SIGXCPU** and **SIGKILL** signals delivered when a process encountered the soft and hard **RLIMIT_CPU** limits were delivered one (CPU) second later than they should have been. This was fixed in Linux 2.6.8.

In Linux 2.6.x kernels before Linux 2.6.17, a **RLIMIT_CPU** limit of 0 is wrongly treated as "no limit" (like **RLIM_INFINITY**). Since Linux 2.6.17, setting a limit of 0 does have an effect, but is actually treated as a limit of 1 second.

A kernel bug means that **RLIMIT_RTPRIO** does not work in Linux 2.6.12; the problem is fixed in Linux 2.6.13.

In Linux 2.6.12, there was an off-by-one mismatch between the priority ranges returned by *getpriority*(2) and **RLIMIT_NICE**. This had the effect that the actual ceiling for the nice value was calculated as *19 − rlim_cur*. This was fixed in Linux 2.6.13.

Since Linux 2.6.12, if a process reaches its soft **RLIMIT_CPU** limit and has a handler installed for **SIGXCPU**, then, in addition to invoking the signal handler, the kernel increases the soft limit by one second. This behavior repeats if the process continues to consume CPU time, until the hard limit is reached, at which point the process is killed. Other implementations do not change the **RLIMIT_CPU** soft limit in this manner, and the Linux behavior is probably not standards conformant; portable applications should avoid relying on this Linux-specific behavior. The Linux-specific **RLIMIT_RTTIME** limit exhibits the same behavior when the soft limit is encountered.

Kernels before Linux 2.4.22 did not diagnose the error **EINVAL** for **setrlimit**() when *rlim->rlim_cur* was greater than *rlim->rlim_max*.

Linux doesn't return an error when an attempt to set **RLIMIT_CPU** has failed, for compatibility reasons.

Representation of "large" resource limit values on 32-bit platforms

The glibc **getrlimit**() and **setrlimit**() wrapper functions use a 64-bit *rlim_t* data type, even on 32-bit platforms. However, the *rlim_t* data type used in the **getrlimit**() and **setrlimit**() system calls is a (32-bit) *unsigned long*. Furthermore, in Linux, the kernel represents resource limits on 32-bit platforms as *unsigned long*. However, a 32-bit data type is not wide enough. The most pertinent limit here is **RLIMIT_FSIZE**, which specifies the maximum size to which a file can grow: to be useful, this limit must be represented using a type that is as wide as the type used to represent file offsets—that is, as wide as a 64-bit **off_t** (assuming a program compiled with *_FILE_OFFSET_BITS=64*).

To work around this kernel limitation, if a program tried to set a resource limit to a value larger than can be represented in a 32-bit *unsigned long*, then the glibc **setrlimit**() wrapper function silently converted the limit value to **RLIM_INFINITY**. In other words, the requested resource limit setting was silently ignored.

Since glibc 2.13, glibc works around the limitations of the **getrlimit**() and **setrlimit**() system calls by implementing **setrlimit**() and **getrlimit**() as wrapper functions that call **prlimit**().

EXAMPLES

The program below demonstrates the use of **prlimit**().

```
#define _GNU_SOURCE
#define _FILE_OFFSET_BITS 64
#include <err.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/resource.h>
#include <time.h>

int
main(int argc, char *argv[])
{
    pid_t          pid;
    struct rlimit  old, new;
    struct rlimit  *newp;

    if (!(argc == 2 || argc == 4)) {
        fprintf(stderr, "Usage: %s <pid> [<new-soft-limit> "
                "<new-hard-limit>]\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    pid = atoi(argv[1]);        /* PID of target process */

    newp = NULL;
    if (argc == 4) {
        new.rlim_cur = atoi(argv[2]);
        new.rlim_max = atoi(argv[3]);
        newp = &new;
    }

    /* Set CPU time limit of target process; retrieve and display
       previous limit */

    if (prlimit(pid, RLIMIT_CPU, newp, &old) == -1)
        err(EXIT_FAILURE, "prlimit-1");
    printf("Previous limits: soft=%jd; hard=%jd\n",
           (intmax_t) old.rlim_cur, (intmax_t) old.rlim_max);

    /* Retrieve and display new CPU time limit */

    if (prlimit(pid, RLIMIT_CPU, NULL, &old) == -1)
        err(EXIT_FAILURE, "prlimit-2");
    printf("New limits: soft=%jd; hard=%jd\n",
           (intmax_t) old.rlim_cur, (intmax_t) old.rlim_max);

    exit(EXIT_SUCCESS);
}
```

NAME

getrusage − get resource usage

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/resource.h>

int getrusage(int *who***, struct rusage *****usage***);**

DESCRIPTION

getrusage() returns resource usage measures for *who*, which can be one of the following:

RUSAGE_SELF
: Return resource usage statistics for the calling process, which is the sum of resources used by all threads in the process.

RUSAGE_CHILDREN
: Return resource usage statistics for all children of the calling process that have terminated and been waited for. These statistics will include the resources used by grandchildren, and further removed descendants, if all of the intervening descendants waited on their terminated children.

RUSAGE_THREAD (since Linux 2.6.26)
: Return resource usage statistics for the calling thread. The **_GNU_SOURCE** feature test macro must be defined (before including *any* header file) in order to obtain the definition of this constant from <*sys/resource.h*>.

The resource usages are returned in the structure pointed to by *usage*, which has the following form:

```
struct rusage {
    struct timeval ru_utime; /* user CPU time used */
    struct timeval ru_stime; /* system CPU time used */
    long   ru_maxrss;        /* maximum resident set size */
    long   ru_ixrss;         /* integral shared memory size */
    long   ru_idrss;         /* integral unshared data size */
    long   ru_isrss;         /* integral unshared stack size */
    long   ru_minflt;        /* page reclaims (soft page faults) */
    long   ru_majflt;        /* page faults (hard page faults) */
    long   ru_nswap;         /* swaps */
    long   ru_inblock;       /* block input operations */
    long   ru_oublock;       /* block output operations */
    long   ru_msgsnd;        /* IPC messages sent */
    long   ru_msgrcv;        /* IPC messages received */
    long   ru_nsignals;      /* signals received */
    long   ru_nvcsw;         /* voluntary context switches */
    long   ru_nivcsw;        /* involuntary context switches */
};
```

Not all fields are completed; unmaintained fields are set to zero by the kernel. (The unmaintained fields are provided for compatibility with other systems, and because they may one day be supported on Linux.) The fields are interpreted as follows:

ru_utime
: This is the total amount of time spent executing in user mode, expressed in a *timeval* structure (seconds plus microseconds).

ru_stime
: This is the total amount of time spent executing in kernel mode, expressed in a *timeval* structure (seconds plus microseconds).

ru_maxrss (since Linux 2.6.32)
: This is the maximum resident set size used (in kilobytes). For **RUSAGE_CHILDREN**, this is the resident set size of the largest child, not the maximum resident set size of the process tree.

ru_ixrss (unmaintained)
This field is currently unused on Linux.

ru_idrss (unmaintained)
This field is currently unused on Linux.

ru_isrss (unmaintained)
This field is currently unused on Linux.

ru_minflt
The number of page faults serviced without any I/O activity; here I/O activity is avoided by "reclaiming" a page frame from the list of pages awaiting reallocation.

ru_majflt
The number of page faults serviced that required I/O activity.

ru_nswap (unmaintained)
This field is currently unused on Linux.

ru_inblock (since Linux 2.6.22)
The number of times the filesystem had to perform input.

ru_oublock (since Linux 2.6.22)
The number of times the filesystem had to perform output.

ru_msgsnd (unmaintained)
This field is currently unused on Linux.

ru_msgrcv (unmaintained)
This field is currently unused on Linux.

ru_nsignals (unmaintained)
This field is currently unused on Linux.

ru_nvcsw (since Linux 2.6)
The number of times a context switch resulted due to a process voluntarily giving up the processor before its time slice was completed (usually to await availability of a resource).

ru_nivcsw (since Linux 2.6)
The number of times a context switch resulted due to a higher priority process becoming runnable or because the current process exceeded its time slice.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
usage points outside the accessible address space.

EINVAL
who is invalid.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
getrusage()	Thread safety	MT-Safe

STANDARDS

POSIX.1-2008.

POSIX.1 specifies **getrusage**(), but specifies only the fields *ru_utime* and *ru_stime*.

RUSAGE_THREAD is Linux-specific.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

Before Linux 2.6.9, if the disposition of **SIGCHLD** is set to **SIG_IGN** then the resource usages of child processes are automatically included in the value returned by **RUSAGE_CHILDREN**, although POSIX.1-2001 explicitly prohibits this. This nonconformance is rectified in Linux 2.6.9 and later.

The structure definition shown at the start of this page was taken from 4.3BSD Reno.

Ancient systems provided a **vtimes**() function with a similar purpose to **getrusage**(). For backward compatibility, glibc (up until Linux 2.32) also provides **vtimes**(). All new applications should be written using **getrusage**(). (Since Linux 2.33, glibc no longer provides an **vtimes**() implementation.)

NOTES

Resource usage metrics are preserved across an *execve*(2).

NAME

getsid − get session ID

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

pid_t getsid(pid_t *pid***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

getsid():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L

DESCRIPTION

getsid() returns the session ID of the process with process ID *pid*. If *pid* is 0, **getsid**() returns the session ID of the calling process.

RETURN VALUE

On success, a session ID is returned. On error, *(pid_t) −1* is returned, and *errno* is set to indicate the error.

ERRORS

EPERM
A process with process ID *pid* exists, but it is not in the same session as the calling process, and the implementation considers this an error.

ESRCH
No process with process ID *pid* was found.

VERSIONS

Linux does not return **EPERM**.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4. Linux 2.0.

NOTES

See *credentials*(7) for a description of sessions and session IDs.

SEE ALSO

getpgid(2), *setsid*(2), *credentials*(7)

NAME

getsockname − get socket name

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/socket.h>

int getsockname(int sockfd, struct sockaddr *restrict addr,
                socklen_t *restrict addrlen);
```

DESCRIPTION

getsockname() returns the current address to which the socket *sockfd* is bound, in the buffer pointed to by *addr*. The *addrlen* argument should be initialized to indicate the amount of space (in bytes) pointed to by *addr*. On return it contains the actual size of the socket address.

The returned address is truncated if the buffer provided is too small; in this case, *addrlen* will return a value greater than was supplied to the call.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
The argument *sockfd* is not a valid file descriptor.

EFAULT
The *addr* argument points to memory not in a valid part of the process address space.

EINVAL
addrlen is invalid (e.g., is negative).

ENOBUFS
Insufficient resources were available in the system to perform the operation.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.4BSD (first appeared in 4.2BSD).

SEE ALSO

bind(2), *socket*(2), *getifaddrs*(3), *ip*(7), *socket*(7), *unix*(7)

NAME

getsockopt, setsockopt − get and set options on sockets

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/socket.h>

int getsockopt(int sockfd, int level, int optname,
               void optval[restrict *.optlen],
               socklen_t *restrict optlen);
int setsockopt(int sockfd, int level, int optname,
               const void optval[.optlen],
               socklen_t optlen);
```

DESCRIPTION

getsockopt() and **setsockopt**() manipulate options for the socket referred to by the file descriptor *sockfd*. Options may exist at multiple protocol levels; they are always present at the uppermost socket level.

When manipulating socket options, the level at which the option resides and the name of the option must be specified. To manipulate options at the sockets API level, *level* is specified as **SOL_SOCKET**. To manipulate options at any other level the protocol number of the appropriate protocol controlling the option is supplied. For example, to indicate that an option is to be interpreted by the **TCP** protocol, *level* should be set to the protocol number of **TCP**; see *getprotoent*(3).

The arguments *optval* and *optlen* are used to access option values for **setsockopt**(). For **getsockopt**() they identify a buffer in which the value for the requested option(s) are to be returned. For **getsockopt**(), *optlen* is a value-result argument, initially containing the size of the buffer pointed to by *optval*, and modified on return to indicate the actual size of the value returned. If no option value is to be supplied or returned, *optval* may be NULL.

Optname and any specified options are passed uninterpreted to the appropriate protocol module for interpretation. The include file <*sys/socket.h*> contains definitions for socket level options, described below. Options at other protocol levels vary in format and name; consult the appropriate entries in section 4 of the manual.

Most socket-level options utilize an *int* argument for *optval*. For **setsockopt**(), the argument should be nonzero to enable a boolean option, or zero if the option is to be disabled.

For a description of the available socket options see *socket*(7) and the appropriate protocol man pages.

RETURN VALUE

On success, zero is returned for the standard options. On error, −1 is returned, and *errno* is set to indicate the error.

Netfilter allows the programmer to define custom socket options with associated handlers; for such options, the return value on success is the value returned by the handler.

ERRORS

EBADF
: The argument *sockfd* is not a valid file descriptor.

EFAULT
: The address pointed to by *optval* is not in a valid part of the process address space. For **getsockopt**(), this error may also be returned if *optlen* is not in a valid part of the process address space.

EINVAL
: *optlen* invalid in **setsockopt**(). In some cases this error can also occur for an invalid value in *optval* (e.g., for the **IP_ADD_MEMBERSHIP** option described in *ip*(7)).

ENOPROTOOPT
: The option is unknown at the level indicated.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

STANDARDS
POSIX.1-2008.

HISTORY
POSIX.1-2001, SVr4, 4.4BSD (first appeared in 4.2BSD).

BUGS
Several of the socket options should be handled at lower levels of the system.

SEE ALSO
ioctl(2), *socket*(2), *getprotoent*(3), *protocols*(5), *ip*(7), *packet*(7), *socket*(7), *tcp*(7), *udp*(7), *unix*(7)

NAME

gettid − get thread identification

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE
#include <unistd.h>

pid_t gettid(void);
```

DESCRIPTION

gettid() returns the caller's thread ID (TID). In a single-threaded process, the thread ID is equal to the process ID (PID, as returned by *getpid*(2)). In a multithreaded process, all threads have the same PID, but each one has a unique TID. For further details, see the discussion of **CLONE_THREAD** in *clone*(2).

RETURN VALUE

On success, returns the thread ID of the calling thread.

ERRORS

This call is always successful.

STANDARDS

Linux.

HISTORY

Linux 2.4.11, glibc 2.30.

NOTES

The thread ID returned by this call is not the same thing as a POSIX thread ID (i.e., the opaque value returned by *pthread_self*(3)).

In a new thread group created by a *clone*(2) call that does not specify the **CLONE_THREAD** flag (or, equivalently, a new process created by *fork*(2)), the new process is a thread group leader, and its thread group ID (the value returned by *getpid*(2)) is the same as its thread ID (the value returned by *gettid*())

SEE ALSO

capget(2), *clone*(2), *fcntl*(2), *fork*(2), *get_robust_list*(2), *getpid*(2), *ioprio_set*(2), *perf_event_open*(2), *sched_setaffinity*(2), *sched_setparam*(2), *sched_setscheduler*(2), *tgkill*(2), *timer_create*(2)

NAME

gettimeofday, settimeofday − get / set time

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/time.h>

int gettimeofday(struct timeval *restrict tv,
                 struct timezone *_Nullable restrict tz);
int settimeofday(const struct timeval *tv,
                 const struct timezone *_Nullable tz);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

settimeofday():
Since glibc 2.19:
_DEFAULT_SOURCE
glibc 2.19 and earlier:
_BSD_SOURCE

DESCRIPTION

The functions **gettimeofday**() and **settimeofday**() can get and set the time as well as a timezone.

The *tv* argument is a *struct timeval* (as specified in <*sys/time.h*>):

```
struct timeval {
    time_t      tv_sec;     /* seconds */
    suseconds_t tv_usec;    /* microseconds */
};
```

and gives the number of seconds and microseconds since the Epoch (see *time*(2)).

The *tz* argument is a *struct timezone*:

```
struct timezone {
    int tz_minuteswest;     /* minutes west of Greenwich */
    int tz_dsttime;         /* type of DST correction */
};
```

If either *tv* or *tz* is NULL, the corresponding structure is not set or returned. (However, compilation warnings will result if *tv* is NULL.)

The use of the *timezone* structure is obsolete; the *tz* argument should normally be specified as NULL. (See NOTES below.)

Under Linux, there are some peculiar "warp clock" semantics associated with the **settimeofday**() system call if on the very first call (after booting) that has a non-NULL *tz* argument, the *tv* argument is NULL and the *tz_minuteswest* field is nonzero. (The *tz_dsttime* field should be zero for this case.) In such a case it is assumed that the CMOS clock is on local time, and that it has to be incremented by this amount to get UTC system time. No doubt it is a bad idea to use this feature.

RETURN VALUE

gettimeofday() and **settimeofday**() return 0 for success. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
One of *tv* or *tz* pointed outside the accessible address space.

EINVAL
(**settimeofday**()): *timezone* is invalid.

EINVAL
(**settimeofday**()): *tv.tv_sec* is negative or *tv.tv_usec* is outside the range [0, 999,999].

EINVAL (since Linux 4.3)
(**settimeofday**()): An attempt was made to set the time to a value less than the current value of the **CLOCK_MONOTONIC** clock (see *clock_gettime*(2)).

EPERM
The calling process has insufficient privilege to call **settimeofday**(); under Linux the **CAP_SYS_TIME** capability is required.

VERSIONS

C library/kernel differences

On some architectures, an implementation of **gettimeofday**() is provided in the *vdso*(7).

The kernel accepts NULL for both *tv* and *tz*. The timezone argument is ignored by glibc and musl, and not passed to/from the kernel. Android's bionic passes the timezone argument to/from the kernel, but Android does not update the kernel timezone based on the device timezone in Settings, so the kernel's timezone is typically UTC.

STANDARDS

gettimeofday()
POSIX.1-2008 (obsolete).

settimeofday()
None.

HISTORY

SVr4, 4.3BSD. POSIX.1-2001 describes **gettimeofday**() but not **settimeofday**(). POSIX.1-2008 marks **gettimeofday**() as obsolete, recommending the use of *clock_gettime*(2) instead.

Traditionally, the fields of *struct timeval* were of type *long*.

The tz_dsttime field

On a non-Linux kernel, with glibc, the *tz_dsttime* field of *struct timezone* will be set to a nonzero value by **gettimeofday**() if the current timezone has ever had or will have a daylight saving rule applied. In this sense it exactly mirrors the meaning of *daylight*(3) for the current zone. On Linux, with glibc, the setting of the *tz_dsttime* field of *struct timezone* has never been used by **settimeofday**() or **gettimeofday**(). Thus, the following is purely of historical interest.

On old systems, the field *tz_dsttime* contains a symbolic constant (values are given below) that indicates in which part of the year Daylight Saving Time is in force. (Note: this value is constant throughout the year: it does not indicate that DST is in force, it just selects an algorithm.) The daylight saving time algorithms defined are as follows:

```
DST_NONE     /* not on DST */
DST_USA      /* USA style DST */
DST_AUST     /* Australian style DST */
DST_WET      /* Western European DST */
DST_MET      /* Middle European DST */
DST_EET      /* Eastern European DST */
DST_CAN      /* Canada */
DST_GB       /* Great Britain and Eire */
DST_RUM      /* Romania */
DST_TUR      /* Turkey */
DST_AUSTALT  /* Australian style with shift in 1986 */
```

Of course it turned out that the period in which Daylight Saving Time is in force cannot be given by a simple algorithm, one per country; indeed, this period is determined by unpredictable political decisions. So this method of representing timezones has been abandoned.

NOTES

The time returned by **gettimeofday**() *is* affected by discontinuous jumps in the system time (e.g., if the system administrator manually changes the system time). If you need a monotonically increasing clock, see *clock_gettime*(2).

Macros for operating on *timeval* structures are described in *timeradd*(3).

SEE ALSO

NAME

getuid, geteuid − get user identity

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

uid_t getuid(void);
uid_t geteuid(void);
```

DESCRIPTION

getuid() returns the real user ID of the calling process.

geteuid() returns the effective user ID of the calling process.

ERRORS

These functions are always successful and never modify *errno*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.3BSD.

In UNIX V6 the **getuid**() call returned *(euid << 8) + uid*. UNIX V7 introduced separate calls **getuid**() and **geteuid**().

The original Linux **getuid**() and **geteuid**() system calls supported only 16-bit user IDs. Subsequently, Linux 2.4 added **getuid32**() and **geteuid32**(), supporting 32-bit IDs. The glibc **getuid**() and **geteuid**() wrapper functions transparently deal with the variations across kernel versions.

On Alpha, instead of a pair of **getuid**() and **geteuid**() system calls, a single **getxuid**() system call is provided, which returns a pair of real and effective UIDs. The glibc **getuid**() and **geteuid**() wrapper functions transparently deal with this. See *syscall*(2) for details regarding register mapping.

SEE ALSO

getresuid(2), *setreuid*(2), *setuid*(2), *credentials*(7)

NAME

getunwind − copy the unwind data to caller's buffer

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/unwind.h>
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

[[deprecated]] long syscall(SYS_getunwind, void *buf***[.***buf_size***],**
size_t *buf_size***);**

DESCRIPTION

Note: this system call is obsolete.

The IA-64-specific **getunwind**() system call copies the kernel's call frame unwind data into the buffer pointed to by *buf* and returns the size of the unwind data; this data describes the gate page (kernel code that is mapped into user space).

The size of the buffer *buf* is specified in *buf_size*. The data is copied only if *buf_size* is greater than or equal to the size of the unwind data and *buf* is not NULL; otherwise, no data is copied, and the call succeeds, returning the size that would be needed to store the unwind data.

The first part of the unwind data contains an unwind table. The rest contains the associated unwind information, in no particular order. The unwind table contains entries of the following form:

```
u64 start;      (64−bit address of start of function)
u64 end;        (64−bit address of end of function)
u64 info;       (BUF−relative offset to unwind info)
```

An entry whose *start* value is zero indicates the end of the table. For more information about the format, see the *IA-64 Software Conventions and Runtime Architecture* manual.

RETURN VALUE

On success, **getunwind**() returns the size of the unwind data. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

getunwind() fails with the error **EFAULT** if the unwind info can't be stored in the space specified by *buf*.

STANDARDS

Linux on IA-64.

HISTORY

Linux 2.4.

This system call has been deprecated. The modern way to obtain the kernel's unwind data is via the *vdso*(7).

SEE ALSO

getauxval(3)

NAME

getxattr, lgetxattr, fgetxattr − retrieve an extended attribute value

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/xattr.h>

ssize_t getxattr(const char *path, const char *name,
                 void value[.size], size_t size);
ssize_t lgetxattr(const char *path, const char *name,
                 void value[.size], size_t size);
ssize_t fgetxattr(int fd, const char *name,
                 void value[.size], size_t size);
```

DESCRIPTION

Extended attributes are *name*:*value* pairs associated with inodes (files, directories, symbolic links, etc.). They are extensions to the normal attributes which are associated with all inodes in the system (i.e., the *stat*(2) data). A complete overview of extended attributes concepts can be found in *xattr*(7).

getxattr() retrieves the value of the extended attribute identified by *name* and associated with the given *path* in the filesystem. The attribute value is placed in the buffer pointed to by *value*; *size* specifies the size of that buffer. The return value of the call is the number of bytes placed in *value*.

lgetxattr() is identical to **getxattr**(), except in the case of a symbolic link, where the link itself is interrogated, not the file that it refers to.

fgetxattr() is identical to **getxattr**(), only the open file referred to by *fd* (as returned by *open*(2)) is interrogated in place of *path*.

An extended attribute *name* is a null-terminated string. The name includes a namespace prefix; there may be several, disjoint namespaces associated with an individual inode. The value of an extended attribute is a chunk of arbitrary textual or binary data that was assigned using *setxattr*(2).

If *size* is specified as zero, these calls return the current size of the named extended attribute (and leave *value* unchanged). This can be used to determine the size of the buffer that should be supplied in a subsequent call. (But, bear in mind that there is a possibility that the attribute value may change between the two calls, so that it is still necessary to check the return status from the second call.)

RETURN VALUE

On success, these calls return a nonnegative value which is the size (in bytes) of the extended attribute value. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

E2BIG The size of the attribute value is larger than the maximum size allowed; the attribute cannot be retrieved. This can happen on filesystems that support very large attribute values such as NFSv4, for example.

ENODATA
The named attribute does not exist, or the process has no access to this attribute.

ENOTSUP
Extended attributes are not supported by the filesystem, or are disabled.

ERANGE
The *size* of the *value* buffer is too small to hold the result.

In addition, the errors documented in *stat*(2) can also occur.

STANDARDS

Linux.

HISTORY

Linux 2.4, glibc 2.3.

EXAMPLES

See *listxattr*(2).

SEE ALSO

NAME

idle − make process 0 idle

SYNOPSIS

#include <unistd.h>

[[deprecated]] int idle(void);

DESCRIPTION

idle() is an internal system call used during bootstrap. It marks the process's pages as swappable, lowers its priority, and enters the main scheduling loop. **idle**() never returns.

Only process 0 may call **idle**(). Any user process, even a process with superuser permission, will receive **EPERM**.

RETURN VALUE

idle() never returns for process 0, and always returns −1 for a user process.

ERRORS

EPERM

Always, for a user process.

STANDARDS

Linux.

HISTORY

Removed in Linux 2.3.13.

NAME

init_module, finit_module − load a kernel module

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/module.h>    /* Definition of MODULE_* constants */
#include <sys/syscall.h>     /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_init_module, void module_image[.len], unsigned long len,
        const char *param_values);
int syscall(SYS_finit_module, int fd,
        const char *param_values, int flags);
```

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

init_module() loads an ELF image into kernel space, performs any necessary symbol relocations, initializes module parameters to values provided by the caller, and then runs the module's *init* function. This system call requires privilege.

The *module_image* argument points to a buffer containing the binary image to be loaded; *len* specifies the size of that buffer. The module image should be a valid ELF image, built for the running kernel.

The *param_values* argument is a string containing space-delimited specifications of the values for module parameters (defined inside the module using **module_param**() and *module_param_array*())The kernel parses this string and initializes the specified parameters. Each of the parameter specifications has the form:

name[=*value*[,*value*...]]

The parameter *name* is one of those defined within the module using *module_param*() (see the Linux kernel source file *include/linux/moduleparam.h*). The parameter *value* is optional in the case of *bool* and *invbool* parameters. Values for array parameters are specified as a comma-separated list.

finit_module()

The **finit_module**() system call is like **init_module**(), but reads the module to be loaded from the file descriptor *fd*. It is useful when the authenticity of a kernel module can be determined from its location in the filesystem; in cases where that is possible, the overhead of using cryptographically signed modules to determine the authenticity of a module can be avoided. The *param_values* argument is as for **init_module**().

The *flags* argument modifies the operation of **finit_module**(). It is a bit mask value created by ORing together zero or more of the following flags:

MODULE_INIT_IGNORE_MODVERSIONS
: Ignore symbol version hashes.

MODULE_INIT_IGNORE_VERMAGIC
: Ignore kernel version magic.

There are some safety checks built into a module to ensure that it matches the kernel against which it is loaded. These checks are recorded when the module is built and verified when the module is loaded. First, the module records a "vermagic" string containing the kernel version number and prominent features (such as the CPU type). Second, if the module was built with the **CONFIG_MODVERSIONS** configuration option enabled, a version hash is recorded for each symbol the module uses. This hash is based on the types of the arguments and return value for the function named by the symbol. In this case, the kernel version number within the "vermagic" string is ignored, as the symbol version hashes are assumed to be sufficiently reliable.

Using the **MODULE_INIT_IGNORE_VERMAGIC** flag indicates that the "vermagic" string is to be ignored, and the **MODULE_INIT_IGNORE_MODVERSIONS** flag indicates that the symbol version hashes are to be ignored. If the kernel is built to permit forced loading (i.e., configured with **CONFIG_MODULE_FORCE_LOAD**), then loading continues, otherwise it fails with the error **ENOEXEC** as expected for malformed modules.

RETURN VALUE

On success, these system calls return 0. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADMSG (since Linux 3.7)
Module signature is misformatted.

EBUSY
Timeout while trying to resolve a symbol reference by this module.

EFAULT
An address argument referred to a location that is outside the process's accessible address space.

ENOKEY (since Linux 3.7)
Module signature is invalid or the kernel does not have a key for this module. This error is returned only if the kernel was configured with **CONFIG_MODULE_SIG_FORCE**; if the kernel was not configured with this option, then an invalid or unsigned module simply taints the kernel.

ENOMEM
Out of memory.

EPERM
The caller was not privileged (did not have the **CAP_SYS_MODULE** capability), or module loading is disabled (see */proc/sys/kernel/modules_disabled* in *proc*(5)).

The following errors may additionally occur for **init_module**():

EEXIST
A module with this name is already loaded.

EINVAL
param_values is invalid, or some part of the ELF image in *module_image* contains inconsistencies.

ENOEXEC
The binary image supplied in *module_image* is not an ELF image, or is an ELF image that is invalid or for a different architecture.

The following errors may additionally occur for **finit_module**():

EBADF
The file referred to by *fd* is not opened for reading.

EFBIG
The file referred to by *fd* is too large.

EINVAL
flags is invalid.

ENOEXEC
fd does not refer to an open file.

ETXTBSY (since Linux 4.7)
The file referred to by *fd* is opened for read-write.

In addition to the above errors, if the module's *init* function is executed and returns an error, then **init_module**() or **finit_module**() fails and *errno* is set to the value returned by the *init* function.

STANDARDS

Linux.

HISTORY

finit_module()
Linux 3.8.

The **init_module**() system call is not supported by glibc. No declaration is provided in glibc headers, but, through a quirk of history, glibc versions before glibc 2.23 did export an ABI for this system call. Therefore, in order to employ this system call, it is (before glibc 2.23) sufficient to manually declare the interface in your code; alternatively, you can invoke the system call using *syscall*(2).

Linux 2.4 and earlier

In Linux 2.4 and earlier, the **init_module**() system call was rather different:

#include <linux/module.h>

int init_module(const char ****name*, struct module ****image***);**

(User-space applications can detect which version of **init_module**() is available by calling **query_module**(); the latter call fails with the error **ENOSYS** on Linux 2.6 and later.)

The older version of the system call loads the relocated module image pointed to by *image* into kernel space and runs the module's *init* function. The caller is responsible for providing the relocated image (since Linux 2.6, the **init_module**() system call does the relocation).

The module image begins with a module structure and is followed by code and data as appropriate. Since Linux 2.2, the module structure is defined as follows:

```
struct module {
    unsigned long         size_of_struct;
    struct module        *next;
    const char           *name;
    unsigned long         size;
    long                  usecount;
    unsigned long         flags;
    unsigned int          nsyms;
    unsigned int          ndeps;
    struct module_symbol *syms;
    struct module_ref    *deps;
    struct module_ref    *refs;
    int                 (*init)(void);
    void                (*cleanup)(void);
    const struct exception_table_entry *ex_table_start;
    const struct exception_table_entry *ex_table_end;
#ifdef __alpha__
    unsigned long gp;
#endif
};
```

All of the pointer fields, with the exception of *next* and *refs*, are expected to point within the module body and be initialized as appropriate for kernel space, that is, relocated with the rest of the module.

NOTES

Information about currently loaded modules can be found in */proc/modules* and in the file trees under the per-module subdirectories under */sys/module*.

See the Linux kernel source file *include/linux/module.h* for some useful background information.

NAME

inotify_add_watch − add a watch to an initialized inotify instance

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/inotify.h>

int inotify_add_watch(int *fd***, const char *** *pathname***, uint32_t** *mask***);**

DESCRIPTION

inotify_add_watch() adds a new watch, or modifies an existing watch, for the file whose location is specified in *pathname*; the caller must have read permission for this file. The *fd* argument is a file descriptor referring to the inotify instance whose watch list is to be modified. The events to be monitored for *pathname* are specified in the *mask* bit-mask argument. See *inotify*(7) for a description of the bits that can be set in *mask*.

A successful call to **inotify_add_watch**() returns a unique watch descriptor for this inotify instance, for the filesystem object (inode) that corresponds to *pathname*. If the filesystem object was not previously being watched by this inotify instance, then the watch descriptor is newly allocated. If the filesystem object was already being watched (perhaps via a different link to the same object), then the descriptor for the existing watch is returned.

The watch descriptor is returned by later *read*(2)s from the inotify file descriptor. These reads fetch *inotify_event* structures (see *inotify*(7)) indicating filesystem events; the watch descriptor inside this structure identifies the object for which the event occurred.

RETURN VALUE

On success, **inotify_add_watch**() returns a watch descriptor (a nonnegative integer). On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
Read access to the given file is not permitted.

EBADF
The given file descriptor is not valid.

EEXIST
mask contains **IN_MASK_CREATE** and *pathname* refers to a file already being watched by the same *fd*.

EFAULT
pathname points outside of the process's accessible address space.

EINVAL
The given event mask contains no valid events; or *mask* contains both **IN_MASK_ADD** and **IN_MASK_CREATE**; or *fd* is not an inotify file descriptor.

ENAMETOOLONG
pathname is too long.

ENOENT
A directory component in *pathname* does not exist or is a dangling symbolic link.

ENOMEM
Insufficient kernel memory was available.

ENOSPC
The user limit on the total number of inotify watches was reached or the kernel failed to allocate a needed resource.

ENOTDIR
mask contains **IN_ONLYDIR** and *pathname* is not a directory.

STANDARDS

Linux.

HISTORY

Linux 2.6.13.

EXAMPLES

See *inotify*(7).

SEE ALSO

inotify_init(2), *inotify_rm_watch*(2), *inotify*(7)

NAME

inotify_init, inotify_init1 − initialize an inotify instance

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/inotify.h>

int inotify_init(void);
int inotify_init1(int *flags***);**

DESCRIPTION

For an overview of the inotify API, see *inotify*(7).

inotify_init() initializes a new inotify instance and returns a file descriptor associated with a new inotify event queue.

If *flags* is 0, then **inotify_init1**() is the same as **inotify_init**(). The following values can be bitwise ORed in *flags* to obtain different behavior:

IN_NONBLOCK
: Set the **O_NONBLOCK** file status flag on the open file description (see *open*(2)) referred to by the new file descriptor. Using this flag saves extra calls to *fcntl*(2) to achieve the same result.

IN_CLOEXEC
: Set the close-on-exec (**FD_CLOEXEC**) flag on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

RETURN VALUE

On success, these system calls return a new file descriptor. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
: (**inotify_init1**()) An invalid value was specified in *flags*.

EMFILE
: The user limit on the total number of inotify instances has been reached.

EMFILE
: The per-process limit on the number of open file descriptors has been reached.

ENFILE
: The system-wide limit on the total number of open files has been reached.

ENOMEM
: Insufficient kernel memory is available.

NAME

inotify_rm_watch − remove an existing watch from an inotify instance

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/inotify.h>

int inotify_rm_watch(int *fd***, int** *wd***);**

DESCRIPTION

inotify_rm_watch() removes the watch associated with the watch descriptor *wd* from the inotify instance associated with the file descriptor *fd*.

Removing a watch causes an **IN_IGNORED** event to be generated for this watch descriptor. (See *inotify*(7).)

RETURN VALUE

On success, **inotify_rm_watch**() returns zero. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF
fd is not a valid file descriptor.

EINVAL
The watch descriptor *wd* is not valid; or *fd* is not an inotify file descriptor.

NAME

io_cancel − cancel an outstanding asynchronous I/O operation

LIBRARY

Standard C library (*libc*, *−lc*)

Alternatively, Asynchronous I/O library (*libaio*, *−laio*); see VERSIONS.

SYNOPSIS

```
#include <linux/aio_abi.h>    /* Definition of needed types */
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_io_cancel, aio_context_t ctx_id, struct iocb *iocb,
            struct io_event *result);
```

DESCRIPTION

Note: this page describes the raw Linux system call interface. The wrapper function provided by *libaio* uses a different type for the *ctx_id* argument. See VERSIONS.

The **io_cancel**() system call attempts to cancel an asynchronous I/O operation previously submitted with *io_submit*(2). The *iocb* argument describes the operation to be canceled and the *ctx_id* argument is the AIO context to which the operation was submitted. If the operation is successfully canceled, the event will be copied into the memory pointed to by *result* without being placed into the completion queue.

RETURN VALUE

On success, **io_cancel**() returns 0. For the failure return, see VERSIONS.

ERRORS

EAGAIN
: The *iocb* specified was not canceled.

EFAULT
: One of the data structures points to invalid data.

EINVAL
: The AIO context specified by *ctx_id* is invalid.

ENOSYS
: **io_cancel**() is not implemented on this architecture.

VERSIONS

You probably want to use the **io_cancel**() wrapper function provided by *libaio*.

Note that the *libaio* wrapper function uses a different type (*io_context_t*) for the *ctx_id* argument. Note also that the *libaio* wrapper does not follow the usual C library conventions for indicating errors: on error it returns a negated error number (the negative of one of the values listed in ERRORS). If the system call is invoked via *syscall*(2), then the return value follows the usual conventions for indicating an error: −1, with *errno* set to a (positive) value that indicates the error.

STANDARDS

Linux.

HISTORY

Linux 2.5.

SEE ALSO

io_destroy(2), *io_getevents*(2), *io_setup*(2), *io_submit*(2), *aio*(7)

NAME

io_destroy − destroy an asynchronous I/O context

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/aio_abi.h>    /* Definition of aio_context_t */
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_io_destroy, aio_context_t ctx_id);
```

Note: glibc provides no wrapper for **io_destroy**(), necessitating the use of *syscall*(2).

DESCRIPTION

Note: this page describes the raw Linux system call interface. The wrapper function provided by *libaio* uses a different type for the *ctx_id* argument. See VERSIONS.

The **io_destroy**() system call will attempt to cancel all outstanding asynchronous I/O operations against *ctx_id*, will block on the completion of all operations that could not be canceled, and will destroy the *ctx_id*.

RETURN VALUE

On success, **io_destroy**() returns 0. For the failure return, see VERSIONS.

ERRORS

EFAULT
: The context pointed to is invalid.

EINVAL
: The AIO context specified by *ctx_id* is invalid.

ENOSYS
: **io_destroy**() is not implemented on this architecture.

VERSIONS

You probably want to use the **io_destroy**() wrapper function provided by *libaio*.

Note that the *libaio* wrapper function uses a different type (*io_context_t*) for the *ctx_id* argument. Note also that the *libaio* wrapper does not follow the usual C library conventions for indicating errors: on error it returns a negated error number (the negative of one of the values listed in ERRORS). If the system call is invoked via *syscall*(2), then the return value follows the usual conventions for indicating an error: −1, with *errno* set to a (positive) value that indicates the error.

NAME

io_getevents − read asynchronous I/O events from the completion queue

LIBRARY

Standard C library (*libc*, *−lc*)

Alternatively, Asynchronous I/O library (*libaio*, *−laio*); see VERSIONS.

SYNOPSIS

```
#include <linux/aio_abi.h>    /* Definition of *io_* types */
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_io_getevents, aio_context_t ctx_id,
            long min_nr, long nr, struct io_event *events,
            struct timespec *timeout);
```

Note: glibc provides no wrapper for **io_getevents**(), necessitating the use of *syscall*(2).

DESCRIPTION

Note: this page describes the raw Linux system call interface. The wrapper function provided by *libaio* uses a different type for the *ctx_id* argument. See VERSIONS.

The **io_getevents**() system call attempts to read at least *min_nr* events and up to *nr* events from the completion queue of the AIO context specified by *ctx_id*.

The *timeout* argument specifies the amount of time to wait for events, and is specified as a relative timeout in a *timespec*(3) structure.

The specified time will be rounded up to the system clock granularity and is guaranteed not to expire early.

Specifying *timeout* as NULL means block indefinitely until at least *min_nr* events have been obtained.

RETURN VALUE

On success, **io_getevents**() returns the number of events read. This may be 0, or a value less than *min_nr*, if the *timeout* expired. It may also be a nonzero value less than *min_nr*, if the call was interrupted by a signal handler.

For the failure return, see VERSIONS.

ERRORS

EFAULT
: Either *events* or *timeout* is an invalid pointer.

EINTR
: Interrupted by a signal handler; see *signal*(7).

EINVAL
: *ctx_id* is invalid. *min_nr* is out of range or *nr* is out of range.

ENOSYS
: **io_getevents**() is not implemented on this architecture.

VERSIONS

You probably want to use the **io_getevents**() wrapper function provided by *libaio*.

Note that the *libaio* wrapper function uses a different type (*io_context_t*) for the *ctx_id* argument. Note also that the *libaio* wrapper does not follow the usual C library conventions for indicating errors: on error it returns a negated error number (the negative of one of the values listed in ERRORS). If the system call is invoked via *syscall*(2), then the return value follows the usual conventions for indicating an error: −1, with *errno* set to a (positive) value that indicates the error.

NAME

io_setup − create an asynchronous I/O context

LIBRARY

Standard C library (*libc*, *−lc*)

Alternatively, Asynchronous I/O library (*libaio*, *−laio*); see VERSIONS.

SYNOPSIS

#include <linux/aio_abi.h> /* Defines needed types */

long io_setup(unsigned int *nr_events***, aio_context_t ***_ctx_idp_**);**

Note: There is no glibc wrapper for this system call; see VERSIONS.

DESCRIPTION

Note: this page describes the raw Linux system call interface. The wrapper function provided by *libaio* uses a different type for the *ctx_idp* argument. See VERSIONS.

The **io_setup**() system call creates an asynchronous I/O context suitable for concurrently processing *nr_events* operations. The *ctx_idp* argument must not point to an AIO context that already exists, and must be initialized to 0 prior to the call. On successful creation of the AIO context, **ctx_idp* is filled in with the resulting handle.

RETURN VALUE

On success, **io_setup**() returns 0. For the failure return, see VERSIONS.

ERRORS

EAGAIN
: The specified *nr_events* exceeds the limit of available events, as defined in */proc/sys/fs/aio−max−nr* (see *proc*(5)).

EFAULT
: An invalid pointer is passed for *ctx_idp*.

EINVAL
: *ctx_idp* is not initialized, or the specified *nr_events* exceeds internal limits. *nr_events* should be greater than 0.

ENOMEM
: Insufficient kernel resources are available.

ENOSYS
: **io_setup**() is not implemented on this architecture.

VERSIONS

glibc does not provide a wrapper for this system call. You could invoke it using *syscall*(2). But instead, you probably want to use the **io_setup**() wrapper function provided by *libaio*.

Note that the *libaio* wrapper function uses a different type (*io_context_t* *) for the *ctx_idp* argument. Note also that the *libaio* wrapper does not follow the usual C library conventions for indicating errors: on error it returns a negated error number (the negative of one of the values listed in ERRORS). If the system call is invoked via *syscall*(2), then the return value follows the usual conventions for indicating an error: −1, with *errno* set to a (positive) value that indicates the error.

io_cancel(2), *io_destroy*(2), *io_getevents*(2), *io_submit*(2), *aio*(7)

NAME

io_submit − submit asynchronous I/O blocks for processing

LIBRARY

Standard C library (*libc*, *−lc*)

Alternatively, Asynchronous I/O library (*libaio*, *−laio*); see VERSIONS.

SYNOPSIS

#include <linux/aio_abi.h> /* Defines needed types */

int io_submit(aio_context_t *ctx_id***, long** *nr***, struct iocb *****iocbpp***);**

Note: There is no glibc wrapper for this system call; see VERSIONS.

DESCRIPTION

Note: this page describes the raw Linux system call interface. The wrapper function provided by *libaio* uses a different type for the *ctx_id* argument. See VERSIONS.

The **io_submit**() system call queues *nr* I/O request blocks for processing in the AIO context *ctx_id*. The *iocbpp* argument should be an array of *nr* AIO control blocks, which will be submitted to context *ctx_id*.

The *iocb* (I/O control block) structure defined in *linux/aio_abi.h* defines the parameters that control the I/O operation.

```
#include <linux/aio_abi.h>

struct iocb {
    __u64   aio_data;
    __u32   PADDED(aio_key, aio_rw_flags);
    __u16   aio_lio_opcode;
    __s16   aio_reqprio;
    __u32   aio_fildes;
    __u64   aio_buf;
    __u64   aio_nbytes;
    __s64   aio_offset;
    __u64   aio_reserved2;
    __u32   aio_flags;
    __u32   aio_resfd;
};
```

The fields of this structure are as follows:

aio_data
: This data is copied into the *data* field of the *io_event* structure upon I/O completion (see *io_getevents*(2)).

aio_key
: This is an internal field used by the kernel. Do not modify this field after an **io_submit**() call.

aio_rw_flags
: This defines the R/W flags passed with structure. The valid values are:

  RWF_APPEND (since Linux 4.16)
  : Append data to the end of the file. See the description of the flag of the same name in *pwritev2*(2) as well as the description of **O_APPEND** in *open*(2). The *aio_offset* field is ignored. The file offset is not changed.

  RWF_DSYNC (since Linux 4.13)
  : Write operation complete according to requirement of synchronized I/O data integrity. See the description of the flag of the same name in *pwritev2*(2) as well the description of **O_DSYNC** in *open*(2).

  RWF_HIPRI (since Linux 4.13)
  : High priority request, poll if possible

RWF_NOWAIT (since Linux 4.14)
Don't wait if the I/O will block for operations such as file block allocations, dirty page flush, mutex locks, or a congested block device inside the kernel. If any of these conditions are met, the control block is returned immediately with a return value of **−EAGAIN** in the *res* field of the *io_event* structure (see *io_getevents*(2)).

RWF_SYNC (since Linux 4.13)
Write operation complete according to requirement of synchronized I/O file integrity. See the description of the flag of the same name in *pwritev2*(2) as well the description of **O_SYNC** in *open*(2).

aio_lio_opcode
This defines the type of I/O to be performed by the *iocb* structure. The valid values are defined by the enum defined in *linux/aio_abi.h*:

```
enum {
    IOCB_CMD_PREAD = 0,
    IOCB_CMD_PWRITE = 1,
    IOCB_CMD_FSYNC = 2,
    IOCB_CMD_FDSYNC = 3,
    IOCB_CMD_POLL = 5,
    IOCB_CMD_NOOP = 6,
    IOCB_CMD_PREADV = 7,
    IOCB_CMD_PWRITEV = 8,
};
```

aio_reqprio
This defines the requests priority.

aio_fildes
The file descriptor on which the I/O operation is to be performed.

aio_buf
This is the buffer used to transfer data for a read or write operation.

aio_nbytes
This is the size of the buffer pointed to by *aio_buf*.

aio_offset
This is the file offset at which the I/O operation is to be performed.

aio_flags
This is the set of flags associated with the *iocb* structure. The valid values are:

IOCB_FLAG_RESFD
Asynchronous I/O control must signal the file descriptor mentioned in *aio_resfd* upon completion.

IOCB_FLAG_IOPRIO (since Linux 4.18)
Interpret the *aio_reqprio* field as an **IOPRIO_VALUE** as defined by *linux/ioprio.h*.

aio_resfd
The file descriptor to signal in the event of asynchronous I/O completion.

RETURN VALUE

On success, **io_submit**() returns the number of *iocb*s submitted (which may be less than *nr*, or 0 if *nr* is zero). For the failure return, see VERSIONS.

ERRORS

EAGAIN
Insufficient resources are available to queue any *iocb*s.

EBADF
The file descriptor specified in the first *iocb* is invalid.

EFAULT
One of the data structures points to invalid data.

EINVAL
The AIO context specified by *ctx_id* is invalid. *nr* is less than 0. The *iocb* at **iocbpp[0]* is not properly initialized, the operation specified is invalid for the file descriptor in the *iocb*, or the value in the *aio_reqprio* field is invalid.

ENOSYS
io_submit() is not implemented on this architecture.

EPERM
The *aio_reqprio* field is set with the class **IOPRIO_CLASS_RT**, but the submitting context does not have the **CAP_SYS_ADMIN** capability.

VERSIONS

glibc does not provide a wrapper for this system call. You could invoke it using *syscall*(2). But instead, you probably want to use the **io_submit**() wrapper function provided by *libaio*.

Note that the *libaio* wrapper function uses a different type (*io_context_t*) for the *ctx_id* argument. Note also that the *libaio* wrapper does not follow the usual C library conventions for indicating errors: on error it returns a negated error number (the negative of one of the values listed in ERRORS). If the system call is invoked via *syscall*(2), then the return value follows the usual conventions for indicating an error: −1, with *errno* set to a (positive) value that indicates the error.

NAME

ioctl − control device

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/ioctl.h>

int ioctl(int fd, unsigned long op, ...);  /* glibc, BSD */
int ioctl(int fd, int op, ...);            /* musl, other UNIX */
```

DESCRIPTION

The **ioctl**() system call manipulates the underlying device parameters of special files. In particular, many operating characteristics of character special files (e.g., terminals) may be controlled with **ioctl**() operations. The argument *fd* must be an open file descriptor.

The second argument is a device-dependent operation code. The third argument is an untyped pointer to memory. It's traditionally **char ***argp* (from the days before **void *** was valid C), and will be so named for this discussion.

An **ioctl**() *op* has encoded in it whether the argument is an *in* parameter or *out* parameter, and the size of the argument *argp* in bytes. Macros and defines used in specifying an **ioctl**() *op* are located in the file *<sys/ioctl.h>*. See NOTES.

RETURN VALUE

Usually, on success zero is returned. A few **ioctl**() operations use the return value as an output parameter and return a nonnegative value on success. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
: *fd* is not a valid file descriptor.

EFAULT
: *argp* references an inaccessible memory area.

EINVAL
: *op* or *argp* is not valid.

ENOTTY
: *fd* is not associated with a character special device.

ENOTTY
: The specified operation does not apply to the kind of object that the file descriptor *fd* references.

VERSIONS

Arguments, returns, and semantics of **ioctl**() vary according to the device driver in question (the call is used as a catch-all for operations that don't cleanly fit the UNIX stream I/O model).

STANDARDS

None.

HISTORY

Version 7 AT&T UNIX has

```
ioctl(int fildes, int op, struct sgttyb *argp);
```

(where **struct sgttyb** has historically been used by *stty*(2) and *gtty*(2), and is polymorphic by operation type (like a **void *** would be, if it had been available)).

SysIII documents *arg* without a type at all.

4.3BSD has

```
ioctl(int d, unsigned long op, char *argp);
```

(with **char *** similarly in for **void ***).

SysVr4 has

```
int ioctl(int fildes, int op, ... /* arg */);
```

NOTES

In order to use this call, one needs an open file descriptor. Often the *open*(2) call has unwanted side effects, that can be avoided under Linux by giving it the **O_NONBLOCK** flag.

ioctl structure

Ioctl *op* values are 32-bit constants. In principle these constants are completely arbitrary, but people have tried to build some structure into them.

The old Linux situation was that of mostly 16-bit constants, where the last byte is a serial number, and the preceding byte(s) give a type indicating the driver. Sometimes the major number was used: 0x03 for the **HDIO_*** ioctls, 0x06 for the **LP*** ioctls. And sometimes one or more ASCII letters were used. For example, **TCGETS** has value 0x00005401, with 0x54 = 'T' indicating the terminal driver, and **CYGETTIMEOUT** has value 0x00435906, with 0x43 0x59 = 'C' 'Y' indicating the cyclades driver.

Later (0.98p5) some more information was built into the number. One has 2 direction bits (00: none, 01: write, 10: read, 11: read/write) followed by 14 size bits (giving the size of the argument), followed by an 8-bit type (collecting the ioctls in groups for a common purpose or a common driver), and an 8-bit serial number.

The macros describing this structure live in *<asm/ioctl.h>* and are **_IO(type,nr)** and **{_IOR,_IOW,_IOWR}(type,nr,size)**. They use *sizeof(size)* so that size is a misnomer here: this third argument is a data type.

Note that the size bits are very unreliable: in lots of cases they are wrong, either because of buggy macros using *sizeof(sizeof(struct))*, or because of legacy values.

Thus, it seems that the new structure only gave disadvantages: it does not help in checking, but it causes varying values for the various architectures.

NAME

ioctl_console − ioctls for console terminal and virtual consoles

DESCRIPTION

The following Linux-specific *ioctl*(2) operations are supported for console terminals and virtual consoles. Each operation requires a third argument, assumed here to be *argp*.

KDGETLED

Get state of LEDs. *argp* points to a *char*. The lower three bits of **argp* are set to the state of the LEDs, as follows:

LED_CAP	0x04	caps lock led
LED_NUM	0x02	num lock led
LED_SCR	0x01	scroll lock led

KDSETLED

Set the LEDs. The LEDs are set to correspond to the lower three bits of the unsigned long integer in *argp*. However, if a higher order bit is set, the LEDs revert to normal: displaying the state of the keyboard functions of caps lock, num lock, and scroll lock.

Before Linux 1.1.54, the LEDs just reflected the state of the corresponding keyboard flags, and KDGETLED/KDSETLED would also change the keyboard flags. Since Linux 1.1.54 the LEDs can be made to display arbitrary information, but by default they display the keyboard flags. The following two ioctls are used to access the keyboard flags.

KDGKBLED

Get keyboard flags CapsLock, NumLock, ScrollLock (not lights). *argp* points to a char which is set to the flag state. The low order three bits (mask 0x7) get the current flag state, and the low order bits of the next nibble (mask 0x70) get the default flag state. (Since Linux 1.1.54.)

KDSKBLED

Set keyboard flags CapsLock, NumLock, ScrollLock (not lights). *argp* is an unsigned long integer that has the desired flag state. The low order three bits (mask 0x7) have the flag state, and the low order bits of the next nibble (mask 0x70) have the default flag state. (Since Linux 1.1.54.)

KDGKBTYPE

Get keyboard type. This returns the value KB_101, defined as 0x02.

KDADDIO

Add I/O port as valid. Equivalent to *ioperm(arg,1,1)*.

KDDELIO

Delete I/O port as valid. Equivalent to *ioperm(arg,1,0)*.

KDENABIO

Enable I/O to video board. Equivalent to *ioperm(0x3b4, 0x3df−0x3b4+1, 1)*.

KDDISABIO

Disable I/O to video board. Equivalent to *ioperm(0x3b4, 0x3df−0x3b4+1, 0)*.

KDSETMODE

Set text/graphics mode. *argp* is an unsigned integer containing one of:

KD_TEXT	0x00
KD_GRAPHICS	0x01

KDGETMODE

Get text/graphics mode. *argp* points to an *int* which is set to one of the values shown above for **KDSETMODE**.

KDMKTONE

Generate tone of specified length. The lower 16 bits of the unsigned long integer in *argp* specify the period in clock cycles, and the upper 16 bits give the duration in msec. If the duration is zero, the sound is turned off. Control returns immediately. For example, *argp* = (125<<16) + 0x637 would specify the beep normally associated with a ctrl-G. (Thus since Linux 0.99pl1; broken in Linux 2.1.49-50.)

KIOCSOUND
Start or stop sound generation. The lower 16 bits of *argp* specify the period in clock cycles (that is, *argp* = 1193180/frequency). *argp* = 0 turns sound off. In either case, control returns immediately.

GIO_CMAP
Get the current default color map from kernel. *argp* points to a 48-byte array. (Since Linux 1.3.3.)

PIO_CMAP
Change the default text-mode color map. *argp* points to a 48-byte array which contains, in order, the Red, Green, and Blue values for the 16 available screen colors: 0 is off, and 255 is full intensity. The default colors are, in order: black, dark red, dark green, brown, dark blue, dark purple, dark cyan, light grey, dark grey, bright red, bright green, yellow, bright blue, bright purple, bright cyan, and white. (Since Linux 1.3.3.)

GIO_FONT
Gets 256-character screen font in expanded form. *argp* points to an 8192-byte array. Fails with error code **EINVAL** if the currently loaded font is a 512-character font, or if the console is not in text mode.

GIO_FONTX
Gets screen font and associated information. *argp* points to a *struct consolefontdesc* (see **PIO_FONTX**). On call, the *charcount* field should be set to the maximum number of characters that would fit in the buffer pointed to by *chardata*. On return, the *charcount* and *charheight* are filled with the respective data for the currently loaded font, and the *chardata* array contains the font data if the initial value of *charcount* indicated enough space was available; otherwise the buffer is untouched and *errno* is set to **ENOMEM**. (Since Linux 1.3.1.)

PIO_FONT
Sets 256-character screen font. Load font into the EGA/VGA character generator. *argp* points to an 8192-byte map, with 32 bytes per character. Only the first *N* of them are used for an 8x*N* font (0 < *N* <= 32). This call also invalidates the Unicode mapping.

PIO_FONTX
Sets screen font and associated rendering information. *argp* points to a

```
struct consolefontdesc {
    unsigned short charcount;  /* characters in font
                                  (256 or 512) */
    unsigned short charheight; /* scan lines per
                                  character (1−32) */
    char          *chardata;   /* font data in
                                  expanded form */
};
```

If necessary, the screen will be appropriately resized, and **SIGWINCH** sent to the appropriate processes. This call also invalidates the Unicode mapping. (Since Linux 1.3.1.)

PIO_FONTRESET
Resets the screen font, size, and Unicode mapping to the bootup defaults. *argp* is unused, but should be set to NULL to ensure compatibility with future versions of Linux. (Since Linux 1.3.28.)

GIO_SCRNMAP
Get screen mapping from kernel. *argp* points to an area of size E_TABSZ, which is loaded with the font positions used to display each character. This call is likely to return useless information if the currently loaded font is more than 256 characters.

GIO_UNISCRNMAP
Get full Unicode screen mapping from kernel. *argp* points to an area of size *E_TABSZ*sizeof(unsigned short)*, which is loaded with the Unicodes each character represent. A special set of Unicodes, starting at U+F000, are used to represent "direct to font" mappings. (Since Linux 1.3.1.)

PIO_SCRNMAP
Loads the "user definable" (fourth) table in the kernel which maps bytes into console screen symbols. *argp* points to an area of size E_TABSZ.

PIO_UNISCRNMAP
Loads the "user definable" (fourth) table in the kernel which maps bytes into Unicodes, which are then translated into screen symbols according to the currently loaded Unicode-to-font map. Special Unicodes starting at U+F000 can be used to map directly to the font symbols. (Since Linux 1.3.1.)

GIO_UNIMAP
Get Unicode-to-font mapping from kernel. *argp* points to a

```
struct unimapdesc {
    unsigned short  entry_ct;
    struct unipair *entries;
};
```

where *entries* points to an array of

```
struct unipair {
    unsigned short unicode;
    unsigned short fontpos;
};
```

(Since Linux 1.1.92.)

PIO_UNIMAP
Put unicode-to-font mapping in kernel. *argp* points to a *struct unimapdesc*. (Since Linux 1.1.92)

PIO_UNIMAPCLR
Clear table, possibly advise hash algorithm. *argp* points to a

```
struct unimapinit {
    unsigned short advised_hashsize;  /* 0 if no opinion */
    unsigned short advised_hashstep;  /* 0 if no opinion */
    unsigned short advised_hashlevel; /* 0 if no opinion */
};
```

(Since Linux 1.1.92.)

KDGKBMODE
Gets current keyboard mode. *argp* points to a *long* which is set to one of these:

```
K_RAW        0x00  /* Raw (scancode) mode */
K_XLATE      0x01  /* Translate keycodes using keymap */
K_MEDIUMRAW  0x02  /* Medium raw (scancode) mode */
K_UNICODE    0x03  /* Unicode mode */
K_OFF        0x04  /* Disabled mode; since Linux 2.6.39 */
```

KDSKBMODE
Sets current keyboard mode. *argp* is a *long* equal to one of the values shown for **KDGKBMODE**.

KDGKBMETA
Gets meta key handling mode. *argp* points to a *long* which is set to one of these:

```
K_METABIT    0x03    set high order bit
K_ESCPREFIX  0x04    escape prefix
```

KDSKBMETA
Sets meta key handling mode. *argp* is a *long* equal to one of the values shown above for **KDGKBMETA**.

KDGKBENT
Gets one entry in key translation table (keycode to action code). *argp* points to a

```
struct kbentry {
    unsigned char  kb_table;
```

```
    unsigned char  kb_index;
    unsigned short kb_value;
};
```

with the first two members filled in: *kb_table* selects the key table (0 <= *kb_table* < MAX_NR_KEYMAPS), and *kb_index* is the keycode (0 <= *kb_index* < NR_KEYS). *kb_value* is set to the corresponding action code, or K_HOLE if there is no such key, or K_NOSUCHMAP if *kb_table* is invalid.

KDSKBENT
Sets one entry in translation table. *argp* points to a *struct kbentry*.

KDGKBSENT
Gets one function key string. *argp* points to a

```
struct kbsentry {
    unsigned char kb_func;
    unsigned char kb_string[512];
};
```

kb_string is set to the (null-terminated) string corresponding to the *kb_func*th function key action code.

KDSKBSENT
Sets one function key string entry. *argp* points to a *struct kbsentry*.

KDGKBDIACR
Read kernel accent table. *argp* points to a

```
struct kbdiacrs {
    unsigned int   kb_cnt;
    struct kbdiacr kbdiacr[256];
};
```

where *kb_cnt* is the number of entries in the array, each of which is a

```
struct kbdiacr {
    unsigned char diacr;
    unsigned char base;
    unsigned char result;
};
```

KDGETKEYCODE
Read kernel keycode table entry (scan code to keycode). *argp* points to a

```
struct kbkeycode {
    unsigned int scancode;
    unsigned int keycode;
};
```

keycode is set to correspond to the given *scancode*. (89 <= *scancode* <= 255 only. For 1 <= *scancode* <= 88, *keycode*==*scancode*.) (Since Linux 1.1.63.)

KDSETKEYCODE
Write kernel keycode table entry. *argp* points to a *struct kbkeycode*. (Since Linux 1.1.63.)

KDSIGACCEPT
The calling process indicates its willingness to accept the signal *argp* when it is generated by pressing an appropriate key combination. (1 <= *argp* <= NSIG). (See *spawn_console*() in *linux/drivers/char/keyboard.c*.)

VT_OPENQRY
Returns the first available (non-opened) console. *argp* points to an *int* which is set to the number of the vt (1 <= **argp* <= MAX_NR_CONSOLES).

VT_GETMODE
Get mode of active vt. *argp* points to a

```
struct vt_mode {
    char  mode;    /* vt mode */
    char  waitv;   /* if set, hang on writes if not active */
    short relsig;  /* signal to raise on release op */
    short acqsig;  /* signal to raise on acquisition */
    short frsig;   /* unused (set to 0) */
};
```

which is set to the mode of the active vt. *mode* is set to one of these values:

VT_AUTO	auto vt switching
VT_PROCESS	process controls switching
VT_ACKACQ	acknowledge switch

VT_SETMODE
Set mode of active vt. *argp* points to a *struct vt_mode*.

VT_GETSTATE
Get global vt state info. *argp* points to a

```
struct vt_stat {
    unsigned short v_active;  /* active vt */
    unsigned short v_signal;  /* signal to send */
    unsigned short v_state;   /* vt bit mask */
};
```

For each vt in use, the corresponding bit in the *v_state* member is set. (Linux 1.0 through Linux 1.1.92.)

VT_RELDISP
Release a display.

VT_ACTIVATE
Switch to vt *argp* (1 <= *argp* <= MAX_NR_CONSOLES).

VT_WAITACTIVE
Wait until vt *argp* has been activated.

VT_DISALLOCATE
Deallocate the memory associated with vt *argp*. (Since Linux 1.1.54.)

VT_RESIZE
Set the kernel's idea of screensize. *argp* points to a

```
struct vt_sizes {
    unsigned short v_rows;       /* # rows */
    unsigned short v_cols;       /* # columns */
    unsigned short v_scrollsize; /* no longer used */
};
```

Note that this does not change the videomode. See *resizecons*(8)(Since Linux 1.1.54.)

VT_RESIZEX
Set the kernel's idea of various screen parameters. *argp* points to a

```
struct vt_consize {
    unsigned short v_rows;  /* number of rows */
    unsigned short v_cols;  /* number of columns */
    unsigned short v_vlin;  /* number of pixel rows
                               on screen */
    unsigned short v_clin;  /* number of pixel rows
                               per character */
    unsigned short v_vcol;  /* number of pixel columns
                               on screen */
    unsigned short v_ccol;  /* number of pixel columns
                               per character */
};
```

Any parameter may be set to zero, indicating "no change", but if multiple parameters are set, they must be self-consistent. Note that this does not change the videomode. See *resizecons*(8)(Since Linux 1.3.3.)

The action of the following ioctls depends on the first byte in the struct pointed to by *argp*, referred to here as the *subcode*. These are legal only for the superuser or the owner of the current terminal. Symbolic *subcode*s are available in <*linux/tiocl.h*> since Linux 2.5.71.

TIOCLINUX, **subcode**=**0**
Dump the screen. Disappeared in Linux 1.1.92. (With Linux 1.1.92 or later, read from */dev/vcsN* or */dev/vcsaN* instead.)

TIOCLINUX, **subcode**=**1**
Get task information. Disappeared in Linux 1.1.92.

TIOCLINUX, **subcode**=**TIOCL_SETSEL**
Set selection. *argp* points to a

```
struct {
    char  subcode;
    short xs, ys, xe, ye;
    short sel_mode;
};
```

xs and *ys* are the starting column and row. *xe* and *ye* are the ending column and row. (Upper left corner is row=column=1.) *sel_mode* is 0 for character-by-character selection, 1 for word-by-word selection, or 2 for line-by-line selection. The indicated screen characters are highlighted and saved in a kernel buffer.

Since Linux 6.7, using this subcode requires the **CAP_SYS_ADMIN** capability.

TIOCLINUX, **subcode**=**TIOCL_PASTESEL**
Paste selection. The characters in the selection buffer are written to *fd*.

Since Linux 6.7, using this subcode requires the **CAP_SYS_ADMIN** capability.

TIOCLINUX, **subcode**=**TIOCL_UNBLANKSCREEN**
Unblank the screen.

TIOCLINUX, **subcode**=**TIOCL_SELLOADLUT**
Sets contents of a 256-bit look up table defining characters in a "word", for word-by-word selection. (Since Linux 1.1.32.)

Since Linux 6.7, using this subcode requires the **CAP_SYS_ADMIN** capability.

TIOCLINUX, **subcode**=**TIOCL_GETSHIFTSTATE**
argp points to a char which is set to the value of the kernel variable *shift_state*. (Since Linux 1.1.32.)

TIOCLINUX, **subcode**=**TIOCL_GETMOUSEREPORTING**
argp points to a char which is set to the value of the kernel variable *report_mouse*. (Since Linux 1.1.33.)

TIOCLINUX, **subcode**=**8**
Dump screen width and height, cursor position, and all the character-attribute pairs. (Linux 1.1.67 through Linux 1.1.91 only. With Linux 1.1.92 or later, read from */dev/vcsa** instead.)

TIOCLINUX, **subcode**=**9**
Restore screen width and height, cursor position, and all the character-attribute pairs. (Linux 1.1.67 through Linux 1.1.91 only. With Linux 1.1.92 or later, write to */dev/vcsa** instead.)

TIOCLINUX, **subcode**=**TIOCL_SETVESABLANK**
Handles the Power Saving feature of the new generation of monitors. VESA screen blanking mode is set to *argp[1]*, which governs what screen blanking does:

0 Screen blanking is disabled.

1 The current video adapter register settings are saved, then the controller is programmed to turn off the vertical synchronization pulses. This puts the monitor into "standby" mode. If your monitor has an Off_Mode timer, then it will eventually

power down by itself.

2 The current settings are saved, then both the vertical and horizontal synchronization pulses are turned off. This puts the monitor into "off" mode. If your monitor has no Off_Mode timer, or if you want your monitor to power down immediately when the blank_timer times out, then you choose this option. (*Caution:* Powering down frequently will damage the monitor.) (Since Linux 1.1.76.)

TIOCLINUX, **subcode**=**TIOCL_SETKMSGREDIRECT**
Change target of kernel messages ("console"): by default, and if this is set to **0**, messages are written to the currently active VT. The VT to write to is a single byte following **subcode**. (Since Linux 2.5.36.)

TIOCLINUX, **subcode**=**TIOCL_GETFGCONSOLE**
Returns the number of VT currently in foreground. (Since Linux 2.5.36.)

TIOCLINUX, **subcode**=**TIOCL_SCROLLCONSOLE**
Scroll the foreground VT by the specified amount of *lines* down, or half the screen if **0**. *lines* is *(((int32_t *)&subcode) + 1). (Since Linux 2.5.67.)

TIOCLINUX, **subcode**=**TIOCL_BLANKSCREEN**
Blank the foreground VT, ignoring "pokes" (typing): can only be unblanked explicitly (by switching VTs, to text mode, etc.). (Since Linux 2.5.71.)

TIOCLINUX, **subcode**=**TIOCL_BLANKEDSCREEN**
Returns the number of VT currently blanked, **0** if none. (Since Linux 2.5.71.)

TIOCLINUX, **subcode**=**16**
Never used.

TIOCLINUX, **subcode**=**TIOCL_GETKMSGREDIRECT**
Returns target of kernel messages. (Since Linux 2.6.17.)

RETURN VALUE

On success, 0 is returned (except where indicated). On failure, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
The file descriptor is invalid.

EINVAL
The file descriptor or *argp* is invalid.

ENOTTY
The file descriptor is not associated with a character special device, or the specified operation does not apply to it.

EPERM
Insufficient permission.

NOTES

Warning: Do not regard this man page as documentation of the Linux console ioctls. This is provided for the curious only, as an alternative to reading the source. Ioctl's are undocumented Linux internals, liable to be changed without warning. (And indeed, this page more or less describes the situation as of kernel version 1.1.94; there are many minor and not-so-minor differences with earlier versions.)

Very often, ioctls are introduced for communication between the kernel and one particular well-known program (fdisk, hdparm, setserial, tunelp, loadkeys, selection, setfont, etc.), and their behavior will be changed when required by this particular program.

Programs using these ioctls will not be portable to other versions of UNIX, will not work on older versions of Linux, and will not work on future versions of Linux.

Use POSIX functions.

NAME

ioctl_fat − manipulating the FAT filesystem

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/msdos_fs.h>     /* Definition of [V]FAT_* and
                                   ATTR_* constants*/"
#include <sys/ioctl.h>

int ioctl(int fd, FAT_IOCTL_GET_ATTRIBUTES, uint32_t *attr);
int ioctl(int fd, FAT_IOCTL_SET_ATTRIBUTES, uint32_t *attr);
int ioctl(int fd, FAT_IOCTL_GET_VOLUME_ID, uint32_t *id);
int ioctl(int fd, VFAT_IOCTL_READDIR_BOTH,
        struct __fat_dirent entry[2]);
int ioctl(int fd, VFAT_IOCTL_READDIR_SHORT,
        struct __fat_dirent entry[2]);
```

DESCRIPTION

The *ioctl*(2) system call can be used to read and write metadata of FAT filesystems that are not accessible using other system calls.

Reading and setting file attributes

Files and directories in the FAT filesystem possess an attribute bit mask that can be read with **FAT_IOCTL_GET_ATTRIBUTES** and written with **FAT_IOCTL_SET_ATTRIBUTES**.

The *fd* argument contains a file descriptor for a file or directory. It is sufficient to create the file descriptor by calling *open*(2) with the **O_RDONLY** flag.

The *attr* argument contains a pointer to a bit mask. The bits of the bit mask are:

ATTR_RO
: This bit specifies that the file or directory is read-only.

ATTR_HIDDEN
: This bit specifies that the file or directory is hidden.

ATTR_SYS
: This bit specifies that the file is a system file.

ATTR_VOLUME
: This bit specifies that the file is a volume label. This attribute is read-only.

ATTR_DIR
: This bit specifies that this is a directory. This attribute is read-only.

ATTR_ARCH
: This bit indicates that this file or directory should be archived. It is set when a file is created or modified. It is reset by an archiving system.

The zero value **ATTR_NONE** can be used to indicate that no attribute bit is set.

Reading the volume ID

FAT filesystems are identified by a volume ID. The volume ID can be read with **FAT_IOCTL_GET_VOLUME_ID**.

The *fd* argument can be a file descriptor for any file or directory of the filesystem. It is sufficient to create the file descriptor by calling *open*(2) with the **O_RDONLY** flag.

The *id* argument is a pointer to the field that will be filled with the volume ID. Typically the volume ID is displayed to the user as a group of two 16-bit fields:

```
printf("Volume ID %04x-%04x\n", id >> 16, id & 0xFFFF);
```

Reading short filenames of a directory

A file or directory on a FAT filesystem always has a short filename consisting of up to 8 capital letters, optionally followed by a period and up to 3 capital letters for the file extension. If the actual filename does not fit into this scheme, it is stored as a long filename of up to 255 UTF-16 characters.

The short filenames in a directory can be read with **VFAT_IOCTL_READDIR_SHORT**.

VFAT_IOCTL_READDIR_BOTH reads both the short and the long filenames.

The *fd* argument must be a file descriptor for a directory. It is sufficient to create the file descriptor by calling *open*(2) with the **O_RDONLY** flag. The file descriptor can be used only once to iterate over the directory entries by calling *ioctl*(2) repeatedly.

The *entry* argument is a two-element array of the following structures:

```
struct __fat_dirent {
    long            d_ino;
    __kernel_off_t  d_off;
    uint32_t short  d_reclen;
    char            d_name[256];
};
```

The first entry in the array is for the short filename. The second entry is for the long filename.

The *d_ino* and *d_off* fields are filled only for long filenames. The *d_ino* field holds the inode number of the directory. The *d_off* field holds the offset of the file entry in the directory. As these values are not available for short filenames, the user code should simply ignore them.

The field *d_reclen* contains the length of the filename in the field *d_name*. To keep backward compatibility, a length of 0 for the short filename signals that the end of the directory has been reached. However, the preferred method for detecting the end of the directory is to test the *ioctl*(2) return value. If no long filename exists, field *d_reclen* is set to 0 and *d_name* is a character string of length 0 for the long filename.

RETURN VALUE

On error, −1 is returned, and *errno* is set to indicate the error.

For **VFAT_IOCTL_READDIR_BOTH** and **VFAT_IOCTL_READDIR_SHORT** a return value of 1 signals that a new directory entry has been read and a return value of 0 signals that the end of the directory has been reached.

ERRORS

ENOENT
: This error is returned by **VFAT_IOCTL_READDIR_BOTH** and **VFAT_IOCTL_READDIR_SHORT** if the file descriptor *fd* refers to a removed, but still open directory.

ENOTDIR
: This error is returned by **VFAT_IOCTL_READDIR_BOTH** and **VFAT_IOCTL_READDIR_SHORT** if the file descriptor *fd* does not refer to a directory.

ENOTTY
: The file descriptor *fd* does not refer to an object in a FAT filesystem.

For further error values, see *ioctl*(2).

STANDARDS

Linux.

HISTORY

VFAT_IOCTL_READDIR_BOTH
VFAT_IOCTL_READDIR_SHORT
: Linux 2.0.

FAT_IOCTL_GET_ATTRIBUTES
FAT_IOCTL_SET_ATTRIBUTES
: Linux 2.6.12.

FAT_IOCTL_GET_VOLUME_ID
: Linux 3.11.

EXAMPLES

Toggling the archive flag

The following program demonstrates the usage of *ioctl*(2) to manipulate file attributes. The program reads and displays the archive attribute of a file. After inverting the value of the attribute, the program reads and displays the attribute again.

The following was recorded when applying the program for the file */mnt/user/foo*:

```
# ./toggle_fat_archive_flag /mnt/user/foo
Archive flag is set
Toggling archive flag
Archive flag is not set
```

Program source (toggle_fat_archive_flag.c)

```
#include <fcntl.h>
#include <linux/msdos_fs.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/ioctl.h>
#include <unistd.h>

/*
 * Read file attributes of a file on a FAT filesystem.
 * Output the state of the archive flag.
 */
static uint32_t
readattr(int fd)
{
    int       ret;
    uint32_t  attr;

    ret = ioctl(fd, FAT_IOCTL_GET_ATTRIBUTES, &attr);
    if (ret == -1) {
        perror("ioctl");
        exit(EXIT_FAILURE);
    }

    if (attr & ATTR_ARCH)
        printf("Archive flag is set\n");
    else
        printf("Archive flag is not set\n");

    return attr;
}

int
main(int argc, char *argv[])
{
    int       fd;
    int       ret;
    uint32_t  attr;

    if (argc != 2) {
        printf("Usage: %s FILENAME\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    fd = open(argv[1], O_RDONLY);
    if (fd == -1) {
        perror("open");
        exit(EXIT_FAILURE);
    }

    /*
```

```
         * Read and display the FAT file attributes.
         */
        attr = readattr(fd);

        /*
         * Invert archive attribute.
         */
        printf("Toggling archive flag\n");
        attr ^= ATTR_ARCH;

        /*
         * Write the changed FAT file attributes.
         */
        ret = ioctl(fd, FAT_IOCTL_SET_ATTRIBUTES, &attr);
        if (ret == -1) {
            perror("ioctl");
            exit(EXIT_FAILURE);
        }

        /*
         * Read and display the FAT file attributes.
         */
        readattr(fd);

        close(fd);

        exit(EXIT_SUCCESS);
    }
```

Reading the volume ID

The following program demonstrates the use of *ioctl*(2) to display the volume ID of a FAT filesystem.

The following output was recorded when applying the program for directory */mnt/user*:

```
$ ./display_fat_volume_id /mnt/user
Volume ID 6443-6241
```

Program source (display_fat_volume_id.c)

```
#include <fcntl.h>
#include <linux/msdos_fs.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/ioctl.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int       fd;
    int       ret;
    uint32_t  id;

    if (argc != 2) {
        printf("Usage: %s FILENAME\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    fd = open(argv[1], O_RDONLY);
    if (fd == -1) {
```

```
            perror("open");
            exit(EXIT_FAILURE);
        }

        /*
         * Read volume ID.
         */
        ret = ioctl(fd, FAT_IOCTL_GET_VOLUME_ID, &id);
        if (ret == -1) {
            perror("ioctl");
            exit(EXIT_FAILURE);
        }

        /*
         * Format the output as two groups of 16 bits each.
         */
        printf("Volume ID %04x-%04x\n", id >> 16, id & 0xFFFF);

        close(fd);

        exit(EXIT_SUCCESS);
    }
```

Listing a directory

The following program demonstrates the use of *ioctl*(2) to list a directory.

The following was recorded when applying the program to the directory */mnt/user*:

```
$ ./fat_dir /mnt/user
. -> ''
.. -> ''
ALONGF~1.TXT -> 'a long filename.txt'
UPPER.TXT -> ''
LOWER.TXT -> 'lower.txt'
```

Program source

```
#include <fcntl.h>
#include <linux/msdos_fs.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/ioctl.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int                 fd;
    int                 ret;
    struct __fat_dirent  entry[2];

    if (argc != 2) {
        printf("Usage: %s DIRECTORY\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    /*
     * Open file descriptor for the directory.
     */
    fd = open(argv[1], O_RDONLY | O_DIRECTORY);
    if (fd == -1) {
        perror("open");
```

```
            exit(EXIT_FAILURE);
        }

        for (;;) {

            /*
             * Read next directory entry.
             */
            ret = ioctl(fd, VFAT_IOCTL_READDIR_BOTH, entry);

            /*
             * If an error occurs, the return value is -1.
             * If the end of the directory list has been reached,
             * the return value is 0.
             * For backward compatibility the end of the directory
             * list is also signaled by d_reclen == 0.
             */
            if (ret < 1)
                break;

            /*
             * Write both the short name and the long name.
             */
            printf("%s -> '%s'\n", entry[0].d_name, entry[1].d_name);
        }

        if (ret == -1) {
            perror("VFAT_IOCTL_READDIR_BOTH");
            exit(EXIT_FAILURE);
        }

        /*
         * Close the file descriptor.
         */
        close(fd);

        exit(EXIT_SUCCESS);
    }
```

SEE ALSO

ioctl(2)

NAME

ioctl_ficlonerange, ioctl_ficlone − share some the data of one file with another file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/fs.h> /* Definition of **FICLONE*** constants */
#include <sys/ioctl.h>

int ioctl(int *dest_fd***, FICLONERANGE, struct file_clone_range ***arg***);**
int ioctl(int *dest_fd***, FICLONE, int** *src_fd***);**

DESCRIPTION

If a filesystem supports files sharing physical storage between multiple files ("reflink"), this *ioctl*(2) operation can be used to make some of the data in the *src_fd* file appear in the *dest_fd* file by sharing the underlying storage, which is faster than making a separate physical copy of the data. Both files must reside within the same filesystem. If a file write should occur to a shared region, the filesystem must ensure that the changes remain private to the file being written. This behavior is commonly referred to as "copy on write".

This ioctl reflinks up to *src_length* bytes from file descriptor *src_fd* at offset *src_offset* into the file *dest_fd* at offset *dest_offset*, provided that both are files. If *src_length* is zero, the ioctl reflinks to the end of the source file. This information is conveyed in a structure of the following form:

```
struct file_clone_range {
    __s64 src_fd;
    __u64 src_offset;
    __u64 src_length;
    __u64 dest_offset;
};
```

Clones are atomic with regards to concurrent writes, so no locks need to be taken to obtain a consistent cloned copy.

The **FICLONE** ioctl clones entire files.

RETURN VALUE

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Error codes can be one of, but are not limited to, the following:

EBADF
src_fd is not open for reading; *dest_fd* is not open for writing or is open for append-only writes; or the filesystem which *src_fd* resides on does not support reflink.

EINVAL
The filesystem does not support reflinking the ranges of the given files. This error can also appear if either file descriptor represents a device, FIFO, or socket. Disk filesystems generally require the offset and length arguments to be aligned to the fundamental block size. XFS and Btrfs do not support overlapping reflink ranges in the same file.

EISDIR
One of the files is a directory and the filesystem does not support shared regions in directories.

EOPNOTSUPP
This can appear if the filesystem does not support reflinking either file descriptor, or if either file descriptor refers to special inodes.

EPERM
dest_fd is immutable.

ETXTBSY
One of the files is a swap file. Swap files cannot share storage.

EXDEV
dest_fd and *src_fd* are not on the same mounted filesystem.

STANDARDS

Linux.

HISTORY

Linux 4.5.

They were previously known as **BTRFS_IOC_CLONE** and **BTRFS_IOC_CLONE_RANGE**, and were private to Btrfs.

NOTES

Because a copy-on-write operation requires the allocation of new storage, the *fallocate*(2) operation may unshare shared blocks to guarantee that subsequent writes will not fail because of lack of disk space.

SEE ALSO

ioctl(2)

NAME

ioctl_fideduperange − share some the data of one file with another file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/fs.h> /* Definition of **FIDEDUPERANGE** and
FILE_DEDUPE_* constants***/**
#include <sys/ioctl.h>

int ioctl(int *src_fd***, FIDEDUPERANGE, struct file_dedupe_range ****arg***);**

DESCRIPTION

If a filesystem supports files sharing physical storage between multiple files, this *ioctl*(2) operation can be used to make some of the data in the **src_fd** file appear in the **dest_fd** file by sharing the underlying storage if the file data is identical ("deduplication"). Both files must reside within the same filesystem. This reduces storage consumption by allowing the filesystem to store one shared copy of the data. If a file write should occur to a shared region, the filesystem must ensure that the changes remain private to the file being written. This behavior is commonly referred to as "copy on write".

This ioctl performs the "compare and share if identical" operation on up to *src_length* bytes from file descriptor *src_fd* at offset *src_offset*. This information is conveyed in a structure of the following form:

```
struct file_dedupe_range {
    __u64 src_offset;
    __u64 src_length;
    __u16 dest_count;
    __u16 reserved1;
    __u32 reserved2;
    struct file_dedupe_range_info info[0];
};
```

Deduplication is atomic with regards to concurrent writes, so no locks need to be taken to obtain a consistent deduplicated copy.

The fields *reserved1* and *reserved2* must be zero.

Destinations for the deduplication operation are conveyed in the array at the end of the structure. The number of destinations is given in *dest_count*, and the destination information is conveyed in the following form:

```
struct file_dedupe_range_info {
    __s64 dest_fd;
    __u64 dest_offset;
    __u64 bytes_deduped;
    __s32 status;
    __u32 reserved;
};
```

Each deduplication operation targets *src_length* bytes in file descriptor *dest_fd* at offset *dest_offset*. The field *reserved* must be zero. During the call, *src_fd* must be open for reading and *dest_fd* must be open for writing. The combined size of the struct *file_dedupe_range* and the struct *file_dedupe_range_info* array must not exceed the system page size. The maximum size of *src_length* is filesystem dependent and is typically 16 MiB. This limit will be enforced silently by the filesystem. By convention, the storage used by *src_fd* is mapped into *dest_fd* and the previous contents in *dest_fd* are freed.

Upon successful completion of this ioctl, the number of bytes successfully deduplicated is returned in *bytes_deduped* and a status code for the deduplication operation is returned in *status*. If even a single byte in the range does not match, the deduplication operation request will be ignored and *status* set to **FILE_DEDUPE_RANGE_DIFFERS**. The *status* code is set to **FILE_DEDUPE_RANGE_SAME** for success, a negative error code in case of error, or **FILE_DEDUPE_RANGE_DIFFERS** if the data did not match.

RETURN VALUE

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Possible errors include (but are not limited to) the following:

EBADF
src_fd is not open for reading; *dest_fd* is not open for writing or is open for append-only writes; or the filesystem which *src_fd* resides on does not support deduplication.

EINVAL
The filesystem does not support deduplicating the ranges of the given files. This error can also appear if either file descriptor represents a device, FIFO, or socket. Disk filesystems generally require the offset and length arguments to be aligned to the fundamental block size. Neither Btrfs nor XFS support overlapping deduplication ranges in the same file.

EISDIR
One of the files is a directory and the filesystem does not support shared regions in directories.

ENOMEM
The kernel was unable to allocate sufficient memory to perform the operation or *dest_count* is so large that the input argument description spans more than a single page of memory.

EOPNOTSUPP
This can appear if the filesystem does not support deduplicating either file descriptor, or if either file descriptor refers to special inodes.

EPERM
dest_fd is immutable.

ETXTBSY
One of the files is a swap file. Swap files cannot share storage.

EXDEV
dest_fd and *src_fd* are not on the same mounted filesystem.

VERSIONS

Some filesystems may limit the amount of data that can be deduplicated in a single call.

STANDARDS

Linux.

HISTORY

Linux 4.5.

It was previously known as **BTRFS_IOC_FILE_EXTENT_SAME** and was private to Btrfs.

NOTES

Because a copy-on-write operation requires the allocation of new storage, the *fallocate*(2) operation may unshare shared blocks to guarantee that subsequent writes will not fail because of lack of disk space.

SEE ALSO

ioctl(2)

NAME

ioctl_fslabel − get or set a filesystem label

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/fs.h> /* Definition of ***FSLABEL*** constants */
#include <sys/ioctl.h>

int ioctl(int *fd***, FS_IOC_GETFSLABEL, char** *label***[FSLABEL_MAX]);**
int ioctl(int *fd***, FS_IOC_SETFSLABEL, char** *label***[FSLABEL_MAX]);**

DESCRIPTION

If a filesystem supports online label manipulation, these *ioctl*(2) operations can be used to get or set the filesystem label for the filesystem on which *fd* resides. The **FS_IOC_SETFSLABEL** operation requires privilege (**CAP_SYS_ADMIN**).

RETURN VALUE

On success zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Possible errors include (but are not limited to) the following:

EFAULT
label references an inaccessible memory area.

EINVAL
The specified label exceeds the maximum label length for the filesystem.

ENOTTY
This can appear if the filesystem does not support online label manipulation.

EPERM
The calling process does not have sufficient permissions to set the label.

STANDARDS

Linux.

HISTORY

Linux 4.18.

They were previously known as **BTRFS_IOC_GET_FSLABEL** and **BTRFS_IOC_SET_FSLABEL** and were private to Btrfs.

NOTES

The maximum string length for this interface is **FSLABEL_MAX**, including the terminating null byte ('\0'). Filesystems have differing maximum label lengths, which may or may not include the terminating null. The string provided to **FS_IOC_SETFSLABEL** must always be null-terminated, and the string returned by **FS_IOC_GETFSLABEL** will always be null-terminated.

ioctl(2), *blkid*(8)

NAME

ioctl_getfsmap − retrieve the physical layout of the filesystem

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/fsmap.h> /* Definition of **FS_IOC_GETFSMAP**,
FM?_OF_*, and ***FMR_OWN_*** constants */
#include <sys/ioctl.h>

int ioctl(int *fd***, FS_IOC_GETFSMAP, struct fsmap_head *** *arg***);**

DESCRIPTION

This *ioctl*(2) operation retrieves physical extent mappings for a filesystem. This information can be used to discover which files are mapped to a physical block, examine free space, or find known bad blocks, among other things.

The sole argument to this operation should be a pointer to a single *struct fsmap_head*:

```
struct fsmap {
    __u32 fmr_device;      /* Device ID */
    __u32 fmr_flags;       /* Mapping flags */
    __u64 fmr_physical;    /* Device offset of segment */
    __u64 fmr_owner;       /* Owner ID */
    __u64 fmr_offset;      /* File offset of segment */
    __u64 fmr_length;      /* Length of segment */
    __u64 fmr_reserved[3]; /* Must be zero */
};

struct fsmap_head {
    __u32 fmh_iflags;       /* Control flags */
    __u32 fmh_oflags;       /* Output flags */
    __u32 fmh_count;        /* # of entries in array incl. input */
    __u32 fmh_entries;      /* # of entries filled in (output) */
    __u64 fmh_reserved[6];  /* Must be zero */

    struct fsmap fmh_keys[2];  /* Low and high keys for
                                  the mapping search */
    struct fsmap fmh_recs[];   /* Returned records */
};
```

The two *fmh_keys* array elements specify the lowest and highest reverse-mapping key for which the application would like physical mapping information. A reverse mapping key consists of the tuple (device, block, owner, offset). The owner and offset fields are part of the key because some filesystems support sharing physical blocks between multiple files and therefore may return multiple mappings for a given physical block.

Filesystem mappings are copied into the *fmh_recs* array, which immediately follows the header data.

Fields of struct fsmap_head

The *fmh_iflags* field is a bit mask passed to the kernel to alter the output. No flags are currently defined, so the caller must set this value to zero.

The *fmh_oflags* field is a bit mask of flags set by the kernel concerning the returned mappings. If **FMH_OF_DEV_T** is set, then the *fmr_device* field represents a *dev_t* structure containing the major and minor numbers of the block device.

The *fmh_count* field contains the number of elements in the array being passed to the kernel. If this value is 0, *fmh_entries* will be set to the number of records that would have been returned had the array been large enough; no mapping information will be returned.

The *fmh_entries* field contains the number of elements in the *fmh_recs* array that contain useful information.

The *fmh_reserved* fields must be set to zero.

Keys

The two key records in *fsmap_head.fmh_keys* specify the lowest and highest extent records in the key-space that the caller wants returned. A filesystem that can share blocks between files likely requires the tuple (*device*, *physical*, *owner*, *offset*, *flags*) to uniquely index any filesystem mapping record. Classic non-sharing filesystems might be able to identify any record with only (*device*, *physical*, *flags*). For example, if the low key is set to (8:0, 36864, 0, 0, 0), the filesystem will only return records for extents starting at or above 36 KiB on disk. If the high key is set to (8:0, 1048576, 0, 0, 0), only records below 1 MiB will be returned. The format of *fmr_device* in the keys must match the format of the same field in the output records, as defined below. By convention, the field *fsmap_head.fmh_keys[0]* must contain the low key and *fsmap_head.fmh_keys[1]* must contain the high key for the operation.

For convenience, if *fmr_length* is set in the low key, it will be added to *fmr_block* or *fmr_offset* as appropriate. The caller can take advantage of this subtlety to set up subsequent calls by copying *fsmap_head.fmh_recs[fsmap_head.fmh_entries − 1]* into the low key. The function *fsmap_advance* (defined in *linux/fsmap.h*) provides this functionality.

Fields of struct fsmap

The *fmr_device* field uniquely identifies the underlying storage device. If the **FMH_OF_DEV_T** flag is set in the header's *fmh_oflags* field, this field contains a *dev_t* from which major and minor numbers can be extracted. If the flag is not set, this field contains a value that must be unique for each unique storage device.

The *fmr_physical* field contains the disk address of the extent in bytes.

The *fmr_owner* field contains the owner of the extent. This is an inode number unless **FMR_OF_SPECIAL_OWNER** is set in the *fmr_flags* field, in which case the value is determined by the filesystem. See the section below about owner values for more details.

The *fmr_offset* field contains the logical address in the mapping record in bytes. This field has no meaning if the **FMR_OF_SPECIAL_OWNER** or **FMR_OF_EXTENT_MAP** flags are set in *fmr_flags*.

The *fmr_length* field contains the length of the extent in bytes.

The *fmr_flags* field is a bit mask of extent state flags. The bits are:

FMR_OF_PREALLOC
The extent is allocated but not yet written.

FMR_OF_ATTR_FORK
This extent contains extended attribute data.

FMR_OF_EXTENT_MAP
This extent contains extent map information for the owner.

FMR_OF_SHARED
Parts of this extent may be shared.

FMR_OF_SPECIAL_OWNER
The *fmr_owner* field contains a special value instead of an inode number.

FMR_OF_LAST
This is the last record in the data set.

The *fmr_reserved* field will be set to zero.

Owner values

Generally, the value of the *fmr_owner* field for non-metadata extents should be an inode number. However, filesystems are under no obligation to report inode numbers; they may instead report **FMR_OWN_UNKNOWN** if the inode number cannot easily be retrieved, if the caller lacks sufficient privilege, if the filesystem does not support stable inode numbers, or for any other reason. If a filesystem wishes to condition the reporting of inode numbers based on process capabilities, it is strongly urged that the **CAP_SYS_ADMIN** capability be used for this purpose.

The following special owner values are generic to all filesystems:

FMR_OWN_FREE
Free space.

FMR_OWN_UNKNOWN
This extent is in use but its owner is not known or not easily retrieved.

FMR_OWN_METADATA
This extent is filesystem metadata.

XFS can return the following special owner values:

XFS_FMR_OWN_FREE
Free space.

XFS_FMR_OWN_UNKNOWN
This extent is in use but its owner is not known or not easily retrieved.

XFS_FMR_OWN_FS
Static filesystem metadata which exists at a fixed address. These are the AG superblock, the AGF, the AGFL, and the AGI headers.

XFS_FMR_OWN_LOG
The filesystem journal.

XFS_FMR_OWN_AG
Allocation group metadata, such as the free space btrees and the reverse mapping btrees.

XFS_FMR_OWN_INOBT
The inode and free inode btrees.

XFS_FMR_OWN_INODES
Inode records.

XFS_FMR_OWN_REFC
Reference count information.

XFS_FMR_OWN_COW
This extent is being used to stage a copy-on-write.

XFS_FMR_OWN_DEFECTIVE:
This extent has been marked defective either by the filesystem or the underlying device.

ext4 can return the following special owner values:

EXT4_FMR_OWN_FREE
Free space.

EXT4_FMR_OWN_UNKNOWN
This extent is in use but its owner is not known or not easily retrieved.

EXT4_FMR_OWN_FS
Static filesystem metadata which exists at a fixed address. This is the superblock and the group descriptors.

EXT4_FMR_OWN_LOG
The filesystem journal.

EXT4_FMR_OWN_INODES
Inode records.

EXT4_FMR_OWN_BLKBM
Block bit map.

EXT4_FMR_OWN_INOBM
Inode bit map.

RETURN VALUE

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

The error placed in *errno* can be one of, but is not limited to, the following:

EBADF
fd is not open for reading.

EBADMSG
The filesystem has detected a checksum error in the metadata.

EFAULT
The pointer passed in was not mapped to a valid memory address.

EINVAL
The array is not long enough, the keys do not point to a valid part of the filesystem, the low key points to a higher point in the filesystem's physical storage address space than the high key, or a nonzero value was passed in one of the fields that must be zero.

ENOMEM
Insufficient memory to process the operation.

EOPNOTSUPP
The filesystem does not support this operation.

EUCLEAN
The filesystem metadata is corrupt and needs repair.

STANDARDS
Linux.

Not all filesystems support it.

HISTORY
Linux 4.12.

EXAMPLES
See *io/fsmap.c* in the *xfsprogs* distribution for a sample program.

ioctl(2)

NAME

ioctl_iflags − ioctl() operations for inode flags

DESCRIPTION

Various Linux filesystems support the notion of *inode flags*—attributes that modify the semantics of files and directories. These flags can be retrieved and modified using two *ioctl*(2) operations:

```
int attr;
fd = open("pathname", ...);

ioctl(fd, FS_IOC_GETFLAGS, &attr);  /* Place current flags
                                       in 'attr' */
attr |= FS_NOATIME_FL;              /* Tweak returned bit mask */
ioctl(fd, FS_IOC_SETFLAGS, &attr);  /* Update flags for inode
                                       referred to by 'fd' */
```

The *lsattr*(1) and *chattr*(1) shell commands provide interfaces to these two operations, allowing a user to view and modify the inode flags associated with a file.

The following flags are supported (shown along with the corresponding letter used to indicate the flag by *lsattr*(1) and *chattr*(1)):

FS_APPEND_FL 'a'
: The file can be opened only with the **O_APPEND** flag. (This restriction applies even to the superuser.) Only a privileged process (**CAP_LINUX_IMMUTABLE**) can set or clear this attribute.

FS_COMPR_FL 'c'
: Store the file in a compressed format on disk. This flag is *not* supported by most of the mainstream filesystem implementations; one exception is *btrfs*(5)

FS_DIRSYNC_FL 'D' (since Linux 2.6.0)
: Write directory changes synchronously to disk. This flag provides semantics equivalent to the *mount*(2) **MS_DIRSYNC** option, but on a per-directory basis. This flag can be applied only to directories.

FS_IMMUTABLE_FL 'i'
: The file is immutable: no changes are permitted to the file contents or metadata (permissions, timestamps, ownership, link count, and so on). (This restriction applies even to the superuser.) Only a privileged process (**CAP_LINUX_IMMUTABLE**) can set or clear this attribute.

FS_JOURNAL_DATA_FL 'j'
: Enable journaling of file data on *ext3*(5) and *ext4*(5) filesystems. On a filesystem that is journaling in *ordered* or *writeback* mode, a privileged (**CAP_SYS_RESOURCE**) process can set this flag to enable journaling of data updates on a per-file basis.

FS_NOATIME_FL 'A'
: Don’t update the file last access time when the file is accessed. This can provide I/O performance benefits for applications that do not care about the accuracy of this timestamp. This flag provides functionality similar to the *mount*(2) **MS_NOATIME** flag, but on a per-file basis.

FS_NOCOW_FL 'C' (since Linux 2.6.39)
: The file will not be subject to copy-on-write updates. This flag has an effect only on filesystems that support copy-on-write semantics, such as Btrfs. See *chattr*(1) and *btrfs*(5)

FS_NODUMP_FL 'd'
: Don’t include this file in backups made using *dump*(8)

FS_NOTAIL_FL 't'
: This flag is supported only on Reiserfs. It disables the Reiserfs tail-packing feature, which tries to pack small files (and the final fragment of larger files) into the same disk block as the file metadata.

FS_PROJINHERIT_FL 'P' (since Linux 4.5)
: Inherit the quota project ID. Files and subdirectories will inherit the project ID of the directory. This flag can be applied only to directories.

FS_SECRM_FL 's'
Mark the file for secure deletion. This feature is not implemented by any filesystem, since the task of securely erasing a file from a recording medium is surprisingly difficult.

FS_SYNC_FL 'S'
Make file updates synchronous. For files, this makes all writes synchronous (as though all opens of the file were with the **O_SYNC** flag). For directories, this has the same effect as the **FS_DIRSYNC_FL** flag.

FS_TOPDIR_FL 'T'
Mark a directory for special treatment under the Orlov block-allocation strategy. See *chattr*(1) for details. This flag can be applied only to directories and has an effect only for ext2, ext3, and ext4.

FS_UNRM_FL 'u'
Allow the file to be undeleted if it is deleted. This feature is not implemented by any filesystem, since it is possible to implement file-recovery mechanisms outside the kernel.

In most cases, when any of the above flags is set on a directory, the flag is inherited by files and subdirectories created inside that directory. Exceptions include **FS_TOPDIR_FL**, which is not inheritable, and **FS_DIRSYNC_FL**, which is inherited only by subdirectories.

STANDARDS
Linux.

NOTES
In order to change the inode flags of a file using the **FS_IOC_SETFLAGS** operation, the effective user ID of the caller must match the owner of the file, or the caller must have the **CAP_FOWNER** capability.

The type of the argument given to the **FS_IOC_GETFLAGS** and **FS_IOC_SETFLAGS** operations is *int **, notwithstanding the implication in the kernel source file *include/uapi/linux/fs.h* that the argument is *long **.

NAME

ioctl_ns − ioctl() operations for Linux namespaces

DESCRIPTION

Discovering namespace relationships

The following *ioctl*(2) operations are provided to allow discovery of namespace relationships (see *user_namespaces*(7) and *pid_namespaces*(7)). The form of the calls is:

```
new_fd = ioctl(fd, op);
```

In each case, *fd* refers to a */proc/*pid*/ns/** file. Both operations return a new file descriptor on success.

NS_GET_USERNS (since Linux 4.9)
: Returns a file descriptor that refers to the owning user namespace for the namespace referred to by *fd*.

NS_GET_PARENT (since Linux 4.9)
: Returns a file descriptor that refers to the parent namespace of the namespace referred to by *fd*. This operation is valid only for hierarchical namespaces (i.e., PID and user namespaces). For user namespaces, **NS_GET_PARENT** is synonymous with **NS_GET_USERNS**.

The new file descriptor returned by these operations is opened with the **O_RDONLY** and **O_CLOEXEC** (close-on-exec; see *fcntl*(2)) flags.

By applying *fstat*(2) to the returned file descriptor, one obtains a *stat* structure whose *st_dev* (resident device) and *st_ino* (inode number) fields together identify the owning/parent namespace. This inode number can be matched with the inode number of another */proc/*pid*/ns/*{*pid*,*user*} file to determine whether that is the owning/parent namespace.

Either of these *ioctl*(2) operations can fail with the following errors:

EPERM
: The requested namespace is outside of the caller's namespace scope. This error can occur if, for example, the owning user namespace is an ancestor of the caller's current user namespace. It can also occur on attempts to obtain the parent of the initial user or PID namespace.

ENOTTY
: The operation is not supported by this kernel version.

Additionally, the **NS_GET_PARENT** operation can fail with the following error:

EINVAL
: *fd* refers to a nonhierarchical namespace.

See the EXAMPLES section for an example of the use of these operations.

Discovering the namespace type

The **NS_GET_NSTYPE** operation (available since Linux 4.11) can be used to discover the type of namespace referred to by the file descriptor *fd*:

```
nstype = ioctl(fd, NS_GET_NSTYPE);
```

fd refers to a */proc/*pid*/ns/** file.

The return value is one of the **CLONE_NEW*** values that can be specified to *clone*(2) or *unshare*(2) in order to create a namespace.

Discovering the owner of a user namespace

The **NS_GET_OWNER_UID** operation (available since Linux 4.11) can be used to discover the owner user ID of a user namespace (i.e., the effective user ID of the process that created the user namespace). The form of the call is:

```
uid_t uid;
ioctl(fd, NS_GET_OWNER_UID, &uid);
```

fd refers to a */proc/*pid*/ns/user* file.

The owner user ID is returned in the *uid_t* pointed to by the third argument.

This operation can fail with the following error:

EINVAL
fd does not refer to a user namespace.

ERRORS

Any of the above **ioctl**() operations can return the following errors:

ENOTTY
fd does not refer to a */proc/*pid*/ns/** file.

STANDARDS

Linux.

EXAMPLES

The example shown below uses the *ioctl*(2) operations described above to perform simple discovery of namespace relationships. The following shell sessions show various examples of the use of this program.

Trying to get the parent of the initial user namespace fails, since it has no parent:

```
$ ./ns_show /proc/self/ns/user p
The parent namespace is outside your namespace scope
```

Create a process running *sleep*(1) that resides in new user and UTS namespaces, and show that the new UTS namespace is associated with the new user namespace:

```
$ unshare -Uu sleep 1000 &
[1] 23235
$ ./ns_show /proc/23235/ns/uts u
Device/Inode of owning user namespace is: [0,3] / 4026532448
$ readlink /proc/23235/ns/user
user:[4026532448]
```

Then show that the parent of the new user namespace in the preceding example is the initial user namespace:

```
$ readlink /proc/self/ns/user
user:[4026531837]
$ ./ns_show /proc/23235/ns/user p
Device/Inode of parent namespace is: [0,3] / 4026531837
```

Start a shell in a new user namespace, and show that from within this shell, the parent user namespace can't be discovered. Similarly, the UTS namespace (which is associated with the initial user namespace) can't be discovered.

```
$ PS1="sh2$ " unshare -U bash
sh2$ ./ns_show /proc/self/ns/user p
The parent namespace is outside your namespace scope
sh2$ ./ns_show /proc/self/ns/uts u
The owning user namespace is outside your namespace scope
```

```

```
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int          fd, userns_fd, parent_fd;
    struct stat  sb;

    if (argc < 2) {
        fprintf(stderr, "Usage: %s /proc/[pid]/ns/[file] [p|u]\n",
                argv[0]);
        fprintf(stderr, "\nDisplay the result of one or both "
                "of NS_GET_USERNS (u) or NS_GET_PARENT (p)\n"
                "for the specified /proc/[pid]/ns/[file]. If neither "
                "'p' nor 'u' is specified,\n"
                "NS_GET_USERNS is the default.\n");
        exit(EXIT_FAILURE);
    }

    /* Obtain a file descriptor for the 'ns' file specified
       in argv[1]. */

    fd = open(argv[1], O_RDONLY);
    if (fd == -1) {
        perror("open");
        exit(EXIT_FAILURE);
    }

    /* Obtain a file descriptor for the owning user namespace and
       then obtain and display the inode number of that namespace. */

    if (argc < 3 || strchr(argv[2], 'u')) {
        userns_fd = ioctl(fd, NS_GET_USERNS);

        if (userns_fd == -1) {
            if (errno == EPERM)
                printf("The owning user namespace is outside "
                       "your namespace scope\n");
            else
               perror("ioctl-NS_GET_USERNS");
            exit(EXIT_FAILURE);
         }

        if (fstat(userns_fd, &sb) == -1) {
            perror("fstat-userns");
            exit(EXIT_FAILURE);
        }
        printf("Device/Inode of owning user namespace is: "
               "[%x,%x] / %ju\n",
               major(sb.st_dev),
               minor(sb.st_dev),
               (uintmax_t) sb.st_ino);

        close(userns_fd);
    }

    /* Obtain a file descriptor for the parent namespace and
       then obtain and display the inode number of that namespace. */
```

```
        if (argc > 2 && strchr(argv[2], 'p')) {
            parent_fd = ioctl(fd, NS_GET_PARENT);

            if (parent_fd == -1) {
                if (errno == EINVAL)
                    printf("Can' get parent namespace of a "
                           "nonhierarchical namespace\n");
                else if (errno == EPERM)
                    printf("The parent namespace is outside "
                           "your namespace scope\n");
                else
                    perror("ioctl-NS_GET_PARENT");
                exit(EXIT_FAILURE);
            }

            if (fstat(parent_fd, &sb) == -1) {
                perror("fstat-parentns");
                exit(EXIT_FAILURE);
            }
            printf("Device/Inode of parent namespace is: [%x,%x] / %ju\n",
                   major(sb.st_dev),
                   minor(sb.st_dev),
                   (uintmax_t) sb.st_ino);

            close(parent_fd);
        }

        exit(EXIT_SUCCESS);
    }
```

NAME

ioctl_pagemap_scan − get and/or clear page flags

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/fs.h> /* Definition of **struct pm_scan_arg**,
struct page_region, and **PAGE_IS_*** constants */
#include <sys/ioctl.h>

int ioctl(int *pagemap_fd***, PAGEMAP_SCAN, struct pm_scan_arg *****arg***);**

DESCRIPTION

This *ioctl*(2) is used to get and optionally clear some specific flags from page table entries. The information is returned with **PAGE_SIZE** granularity.

To start tracking the written state (flag) of a page or range of memory, the **UFFD_FEATURE_WP_ASYNC** must be enabled by **UFFDIO_API** *ioctl*(2) on **userfaultfd** and memory range must be registered with **UFFDIO_REGISTER** *ioctl*(2) in **UFFDIO_REGISTER_MODE_WP** mode.

Supported page flags

The following page table entry flags are supported:

PAGE_IS_WPALLOWED
The page has asynchronous write-protection enabled.

PAGE_IS_WRITTEN
The page has been written to from the time it was write protected.

PAGE_IS_FILE
The page is file backed.

PAGE_IS_PRESENT
The page is present in the memory.

PAGE_IS_SWAPPED
The page is swapped.

PAGE_IS_PFNZERO
The page has zero PFN.

PAGE_IS_HUGE
The page is THP or Hugetlb backed.

Supported operations

The get operation is always performed if the output buffer is specified. The other operations are as following:

PM_SCAN_WP_MATCHING
Write protect the matched pages.

PM_SCAN_CHECK_WPASYNC
Abort the scan when a page is found which doesn't have the Userfaultfd Asynchronous Write protection enabled.

The *struct pm_scan_arg* argument

```
struct pm_scan_arg {
    __u64  size;
    __u64  flags;
    __u64  start;
    __u64  end;
    __u64  walk_end;
    __u64  vec;
    __u64  vec_len;
    __u64  max_pages
    __u64  category_inverted;
    __u64  category_mask;
    __u64  category_anyof_mask
```

```
    __u64  return_mask;
};
```

size This field should be set to the size of the structure in bytes, as in *sizeof(struct pm_scan_arg)*.

flags The operations to be performed are specified in it.

start The starting address of the scan is specified in it.

end The ending address of the scan is specified in it.

walk_end
The kernel returns the scan's ending address in it. The *walk_end* equal to *end* means that scan has completed on the entire range.

vec The address of *page_region* array for output.

```
struct page_region {
    __u64  start;
    __u64  end;
    __u64  categories;
};
```

vec_len
The length of the *page_region* struct array.

max_pages
It is the optional limit for the number of output pages required.

category_inverted
PAGE_IS_* categories which values match if 0 instead of 1.

category_mask
Skip pages for which any **PAGE_IS_*** category doesn't match.

category_anyof_mask
Skip pages for which no **PAGE_IS_*** category matches.

return_mask
PAGE_IS_* categories that are to be reported in *page_region*.

RETURN VALUE
On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS
Error codes can be one of, but are not limited to, the following:

EINVAL
Invalid arguments i.e., invalid *size* of the argument, invalid *flags*, invalid *categories*, the *start* address isn't aligned with **PAGE_SIZE**, or *vec_len* is specified when *vec* is NULL.

EFAULT
Invalid *arg* pointer, invalid *vec* pointer, or invalid address range specified by *start* and *end*.

ENOMEM
No memory is available.

EINTR
Fetal signal is pending.

STANDARDS
Linux.

HISTORY
Linux 6.7.

NAME

ioctl_pipe − ioctl() operations for General notification mechanism

SYNOPSIS

#include <linux/watch_queue.h> /* Definition of **IOC_WATCH_QUEUE_*** */
#include <sys/ioctl.h>

int ioctl(int *pipefd***[1], IOC_WATCH_QUEUE_SET_SIZE, int** *size***);**
int ioctl(int *pipefd***[1], IOC_WATCH_QUEUE_SET_FILTER,**
struct watch_notification_filter * *filter***);**

DESCRIPTION

The following *ioctl*(2) operations are provided to set up general notification queue parameters. The notification queue is built on the top of a *pipe*(2) opened with the **O_NOTIFICATION_PIPE** flag.

IOC_WATCH_QUEUE_SET_SIZE (since Linux 5.8)
Preallocates the pipe buffer memory so that it can fit *size* notification messages. Currently, *size* must be between 1 and 512.

IOC_WATCH_QUEUE_SET_FILTER (since Linux 5.8)
Watch queue filter can limit events that are received. Filters are passed in a *struct watch_notification_filter* and each filter is described by a *struct watch_notification_type_filter* structure.

```
struct watch_notification_filter {
        __u32   nr_filters;
        __u32   __reserved;
        struct watch_notification_type_filter filters[];
};

struct watch_notification_type_filter {
        __u32   type;
        __u32   info_filter;
        __u32   info_mask;
        __u32   subtype_filter[8];
};
```

NAME

ioctl_tty − ioctls for terminals and serial lines

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/ioctl.h>
#include <asm/termbits.h>  /* Definition of struct termios,
                              struct termios2, and
                              Bnnn, BOTHER, CBAUD, CLOCAL,
                              TC*{FLUSH,ON,OFF} and other constants */

int ioctl(int fd, int op, ...);
```

DESCRIPTION

The *ioctl*(2) call for terminals and serial ports accepts many possible operation arguments. Most require a third argument, of varying type, here called *argp* or *arg*.

Use of **ioctl**() makes for nonportable programs. Use the POSIX interface described in *termios*(3) whenever possible.

Please note that **struct termios** from <*asm/termbits.h*> is different and incompatible with **struct termios** from <*termios.h*>. These ioctl calls require **struct termios** from <*asm/termbits.h*>.

Get and set terminal attributes

TCGETS

Argument: **struct termios *****argp*

Equivalent to *tcgetattr(fd, argp)*.

Get the current serial port settings.

TCSETS

Argument: **const struct termios *****argp*

Equivalent to *tcsetattr(fd, TCSANOW, argp)*.

Set the current serial port settings.

TCSETSW

Argument: **const struct termios *****argp*

Equivalent to *tcsetattr(fd, TCSADRAIN, argp)*.

Allow the output buffer to drain, and set the current serial port settings.

TCSETSF

Argument: **const struct termios *****argp*

Equivalent to *tcsetattr(fd, TCSAFLUSH, argp)*.

Allow the output buffer to drain, discard pending input, and set the current serial port settings.

The following four ioctls, added in Linux 2.6.20, are just like **TCGETS**, **TCSETS**, **TCSETSW**, **TCSETSF**, except that they take a *struct termios2 ** instead of a *struct termios **. If the structure member **c_cflag** contains the flag **BOTHER**, then the baud rate is stored in the structure members **c_ispeed** and **c_ospeed** as integer values. These ioctls are not supported on all architectures.

TCGETS2 **struct termios2 ***argp
TCSETS2 **const struct termios2 ***argp
TCSETSW2 **const struct termios2 ***argp
TCSETSF2 **const struct termios2 ***argp

The following four ioctls are just like **TCGETS**, **TCSETS**, **TCSETSW**, **TCSETSF**, except that they take a *struct termio ** instead of a *struct termios **.

TCGETA **struct termio ***argp
TCSETA **const struct termio ***argp
TCSETAW **const struct termio ***argp
TCSETAF **const struct termio ***argp

Locking the termios structure

The *termios* structure of a terminal can be locked. The lock is itself a *termios* structure, with nonzero bits or fields indicating a locked value.

TIOCGLCKTRMIOS

Argument: **struct termios ****argp*

Gets the locking status of the *termios* structure of the terminal.

TIOCSLCKTRMIOS

Argument: **const struct termios ****argp*

Sets the locking status of the *termios* structure of the terminal. Only a process with the **CAP_SYS_ADMIN** capability can do this.

Get and set window size

Window sizes are kept in the kernel, but not used by the kernel (except in the case of virtual consoles, where the kernel will update the window size when the size of the virtual console changes, for example, by loading a new font).

TIOCGWINSZ

Argument: **struct winsize ****argp*

Get window size.

TIOCSWINSZ

Argument: **const struct winsize ****argp*

Set window size.

The struct used by these ioctls is defined as

```
struct winsize {
    unsigned short ws_row;
    unsigned short ws_col;
    unsigned short ws_xpixel;   /* unused */
    unsigned short ws_ypixel;   /* unused */
};
```

When the window size changes, a **SIGWINCH** signal is sent to the foreground process group.

Sending a break

TCSBRK

Argument: **int** *arg*

Equivalent to *tcsendbreak(fd, arg)*.

If the terminal is using asynchronous serial data transmission, and *arg* is zero, then send a break (a stream of zero bits) for between 0.25 and 0.5 seconds. If the terminal is not using asynchronous serial data transmission, then either a break is sent, or the function returns without doing anything. When *arg* is nonzero, nobody knows what will happen.

(SVr4, UnixWare, Solaris, and Linux treat *tcsendbreak(fd,arg)* with nonzero *arg* like *tcdrain(fd)*. SunOS treats *arg* as a multiplier, and sends a stream of bits *arg* times as long as done for zero *arg*. DG/UX and AIX treat *arg* (when nonzero) as a time interval measured in milliseconds. HP-UX ignores *arg*.)

TCSBRKP

Argument: **int** *arg*

So-called "POSIX version" of **TCSBRK**. It treats nonzero *arg* as a time interval measured in deciseconds, and does nothing when the driver does not support breaks.

TIOCSBRK

Argument: **void**

Turn break on, that is, start sending zero bits.

TIOCCBRK

Argument: **void**

Turn break off, that is, stop sending zero bits.

Software flow control

TCXONC

Argument: **int** *arg*

Equivalent to *tcflow(fd, arg)*.

See *tcflow*(3) for the argument values **TCOOFF**, **TCOON**, **TCIOFF**, **TCION**.

Buffer count and flushing

FIONREAD

Argument: **int ***_argp_

Get the number of bytes in the input buffer.

TIOCINQ

Argument: **int ***_argp_

Same as **FIONREAD**.

TIOCOUTQ

Argument: **int ***_argp_

Get the number of bytes in the output buffer.

TCFLSH

Argument: **int** *arg*

Equivalent to *tcflush(fd, arg)*.

See *tcflush*(3) for the argument values **TCIFLUSH**, **TCOFLUSH**, **TCIOFLUSH**.

TIOCSERGETLSR

Argument: **int ***_argp_

Get line status register. Status register has **TIOCSER_TEMT** bit set when output buffer is empty and also hardware transmitter is physically empty.

Does not have to be supported by all serial tty drivers.

tcdrain(3) does not wait and returns immediately when **TIOCSER_TEMT** bit is set.

Faking input

TIOCSTI

Argument: **const char ***_argp_

Insert the given byte in the input queue.

Since Linux 6.2, this operation may require the **CAP_SYS_ADMIN** capability (if the *dev.tty.legacy_tiocsti* sysctl variable is set to false).

Redirecting console output

TIOCCONS

Argument: **void**

Redirect output that would have gone to */dev/console* or */dev/tty0* to the given terminal. If that was a pseudoterminal master, send it to the slave. Before Linux 2.6.10, anybody can do this as long as the output was not redirected yet; since Linux 2.6.10, only a process with the **CAP_SYS_ADMIN** capability may do this. If output was redirected already, then **EBUSY** is returned, but redirection can be stopped by using this ioctl with *fd* pointing at */dev/console* or */dev/tty0*.

Controlling terminal

TIOCSCTTY

Argument: **int** *arg*

Make the given terminal the controlling terminal of the calling process. The calling process must be a session leader and not have a controlling terminal already. For this case, *arg* should be specified as zero.

If this terminal is already the controlling terminal of a different session group, then the ioctl fails with **EPERM**, unless the caller has the **CAP_SYS_ADMIN** capability and *arg* equals 1,

in which case the terminal is stolen, and all processes that had it as controlling terminal lose it.

TIOCNOTTY

Argument: **void**

If the given terminal was the controlling terminal of the calling process, give up this controlling terminal. If the process was session leader, then send **SIGHUP** and **SIGCONT** to the foreground process group and all processes in the current session lose their controlling terminal.

Process group and session ID

TIOCGPGRP

Argument: **pid_t ****argp*

When successful, equivalent to **argp = tcgetpgrp(fd)*.

Get the process group ID of the foreground process group on this terminal.

TIOCSPGRP

Argument: **const pid_t ****argp*

Equivalent to *tcsetpgrp(fd, *argp)*.

Set the foreground process group ID of this terminal.

TIOCGSID

Argument: **pid_t ****argp*

When successful, equivalent to **argp = tcgetsid(fd)*.

Get the session ID of the given terminal. This fails with the error **ENOTTY** if the terminal is not a master pseudoterminal and not our controlling terminal. Strange.

Exclusive mode

TIOCEXCL

Argument: **void**

Put the terminal into exclusive mode. No further *open*(2) operations on the terminal are permitted. (They fail with **EBUSY**, except for a process with the **CAP_SYS_ADMIN** capability.)

TIOCGEXCL

Argument: **int ****argp*

(since Linux 3.8) If the terminal is currently in exclusive mode, place a nonzero value in the location pointed to by *argp*; otherwise, place zero in **argp*.

TIOCNXCL

Argument: **void**

Disable exclusive mode.

Line discipline

TIOCGETD

Argument: **int ****argp*

Get the line discipline of the terminal.

TIOCSETD

Argument: **const int ****argp*

Set the line discipline of the terminal.

Pseudoterminal ioctls

TIOCPKT

Argument: **const int ****argp*

Enable (when **argp* is nonzero) or disable packet mode. Can be applied to the master side of a pseudoterminal only (and will return **ENOTTY** otherwise). In packet mode, each subsequent *read*(2) will return a packet that either contains a single nonzero control byte, or has a single byte containing zero ('\0') followed by data written on the slave side of the pseudoterminal. If the first byte is not **TIOCPKT_DATA** (0), it is an OR of one or more of the following

bits:

TIOCPKT_FLUSHREAD	The read queue for the terminal is flushed.
TIOCPKT_FLUSHWRITE	The write queue for the terminal is flushed.
TIOCPKT_STOP	Output to the terminal is stopped.
TIOCPKT_START	Output to the terminal is restarted.
TIOCPKT_DOSTOP	The start and stop characters are **^S**/**^Q**.
TIOCPKT_NOSTOP	The start and stop characters are not **^S**/**^Q**.

While packet mode is in use, the presence of control status information to be read from the master side may be detected by a *select*(2) for exceptional conditions or a *poll*(2) for the **POLLPRI** event.

This mode is used by *rlogin*(1) and *rlogind*(8) to implement a remote-echoed, locally **^S**/**^Q** flow-controlled remote login.

TIOCGPKT

Argument: **const int ***_argp_

(since Linux 3.8) Return the current packet mode setting in the integer pointed to by *argp*.

TIOCSPTLCK

Argument: **int ***_argp_

Set (if **argp* is nonzero) or remove (if **argp* is zero) the lock on the pseudoterminal slave device. (See also *unlockpt*(3).)

TIOCGPTLCK

Argument: **int ***_argp_

(since Linux 3.8) Place the current lock state of the pseudoterminal slave device in the location pointed to by *argp*.

TIOCGPTPEER

Argument: **int** *flags*

(since Linux 4.13) Given a file descriptor in *fd* that refers to a pseudoterminal master, open (with the given *open*(2)-style *flags*) and return a new file descriptor that refers to the peer pseudoterminal slave device. This operation can be performed regardless of whether the pathname of the slave device is accessible through the calling process's mount namespace.

Security-conscious programs interacting with namespaces may wish to use this operation rather than *open*(2) with the pathname returned by *ptsname*(3), and similar library functions that have insecure APIs. (For example, confusion can occur in some cases using *ptsname*(3) with a pathname where a devpts filesystem has been mounted in a different mount namespace.)

The BSD ioctls **TIOCSTOP**, **TIOCSTART**, **TIOCUCNTL**, and **TIOCREMOTE** have not been implemented under Linux.

Modem control

TIOCMGET

Argument: **int ***_argp_

Get the status of modem bits.

TIOCMSET

Argument: **const int ***_argp_

Set the status of modem bits.

TIOCMBIC

Argument: **const int ***_argp_

Clear the indicated modem bits.

TIOCMBIS
Argument: **const int ****argp*

Set the indicated modem bits.

The following bits are used by the above ioctls:

TIOCM_LE	DSR (data set ready/line enable)
TIOCM_DTR	DTR (data terminal ready)
TIOCM_RTS	RTS (request to send)
TIOCM_ST	Secondary TXD (transmit)
TIOCM_SR	Secondary RXD (receive)
TIOCM_CTS	CTS (clear to send)
TIOCM_CAR	DCD (data carrier detect)
TIOCM_CD	see TIOCM_CAR
TIOCM_RNG	RNG (ring)
TIOCM_RI	see TIOCM_RNG
TIOCM_DSR	DSR (data set ready)

TIOCMIWAIT
Argument: **int** *arg*

Wait for any of the 4 modem bits (DCD, RI, DSR, CTS) to change. The bits of interest are specified as a bit mask in *arg*, by ORing together any of the bit values, **TIOCM_RNG**, **TIOCM_DSR**, **TIOCM_CD**, and **TIOCM_CTS**. The caller should use **TIOCGICOUNT** to see which bit has changed.

TIOCGICOUNT
Argument: **struct serial_icounter_struct ****argp*

Get counts of input serial line interrupts (DCD, RI, DSR, CTS). The counts are written to the *serial_icounter_struct* structure pointed to by *argp*.

Note: both 1->0 and 0->1 transitions are counted, except for RI, where only 0->1 transitions are counted.

Marking a line as local

TIOCGSOFTCAR
Argument: **int ****argp*

("Get software carrier flag") Get the status of the CLOCAL flag in the c_cflag field of the *termios* structure.

TIOCSSOFTCAR
Argument: **const int ****argp*

("Set software carrier flag") Set the CLOCAL flag in the *termios* structure when **argp* is nonzero, and clear it otherwise.

If the **CLOCAL** flag for a line is off, the hardware carrier detect (DCD) signal is significant, and an *open*(2) of the corresponding terminal will block until DCD is asserted, unless the **O_NONBLOCK** flag is given. If **CLOCAL** is set, the line behaves as if DCD is always asserted. The software carrier flag is usually turned on for local devices, and is off for lines with modems.

Linux-specific

For the **TIOCLINUX** ioctl, see *ioctl_console*(2).

Kernel debugging

#include <linux/tty.h>

TIOCTTYGSTRUCT
Argument: **struct tty_struct ****argp*

Get the *tty_struct* corresponding to *fd*. This operation was removed in Linux 2.5.67.

RETURN VALUE

The *ioctl*(2) system call returns 0 on success. On error, it returns −1 and sets *errno* to indicate the error.

ERRORS

EINVAL
Invalid operation parameter.

ENOIOCTLCMD
Unknown operation.

ENOTTY
Inappropriate *fd*.

EPERM
Insufficient permission.

EXAMPLES

Check the condition of DTR on the serial port.

```
#include <fcntl.h>
#include <stdio.h>
#include <sys/ioctl.h>
#include <unistd.h>

int
main(void)
{
    int fd, serial;

    fd = open("/dev/ttyS0", O_RDONLY);
    ioctl(fd, TIOCMGET, &serial);
    if (serial & TIOCM_DTR)
        puts("TIOCM_DTR is set");
    else
        puts("TIOCM_DTR is not set");
    close(fd);
}
```

Get or set arbitrary baudrate on the serial port.

NAME

ioctl_userfaultfd − create a file descriptor for handling page faults in user space

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/userfaultfd.h> /* Definition of **UFFD*** constants */
#include <sys/ioctl.h>

int ioctl(int *fd***, int** *op***, ...);**

DESCRIPTION

Various *ioctl*(2) operations can be performed on a userfaultfd object (created by a call to *userfaultfd*(2)) using calls of the form:

```
ioctl(fd, op, argp);
```

In the above, *fd* is a file descriptor referring to a userfaultfd object, *op* is one of the operations listed below, and *argp* is a pointer to a data structure that is specific to *op*.

The various *ioctl*(2) operations are described below. The **UFFDIO_API**, **UFFDIO_REGISTER**, and **UFFDIO_UNREGISTER** operations are used to *configure* userfaultfd behavior. These operations allow the caller to choose what features will be enabled and what kinds of events will be delivered to the application. The remaining operations are *range* operations. These operations enable the calling application to resolve page-fault events.

UFFDIO_API

(Since Linux 4.3.) Enable operation of the userfaultfd and perform API handshake.

The *argp* argument is a pointer to a *uffdio_api* structure, defined as:

```
struct uffdio_api {
    __u64 api;        /* Requested API version (input) */
    __u64 features;   /* Requested features (input/output) */
    __u64 ioctls;     /* Available ioctl() operations (output) */
};
```

The *api* field denotes the API version requested by the application. The kernel verifies that it can support the requested API version, and sets the *features* and *ioctls* fields to bit masks representing all the available features and the generic *ioctl*(2) operations available.

Since Linux 4.11, applications should use the *features* field to perform a two-step handshake. First, **UFFDIO_API** is called with the *features* field set to zero. The kernel responds by setting all supported feature bits.

Applications which do not require any specific features can begin using the userfaultfd immediately. Applications which do need specific features should call **UFFDIO_API** again with a subset of the reported feature bits set to enable those features.

Before Linux 4.11, the *features* field must be initialized to zero before the call to **UFFDIO_API**, and zero (i.e., no feature bits) is placed in the *features* field by the kernel upon return from *ioctl*(2).

If the application sets unsupported feature bits, the kernel will zero out the returned *uffdio_api* structure and return **EINVAL**.

The following feature bits may be set:

UFFD_FEATURE_EVENT_FORK (since Linux 4.11)
: When this feature is enabled, the userfaultfd objects associated with a parent process are duplicated into the child process during *fork*(2) and a **UFFD_EVENT_FORK** event is delivered to the userfaultfd monitor

UFFD_FEATURE_EVENT_REMAP (since Linux 4.11)
: If this feature is enabled, when the faulting process invokes *mremap*(2), the userfaultfd monitor will receive an event of type **UFFD_EVENT_REMAP**.

UFFD_FEATURE_EVENT_REMOVE (since Linux 4.11)
: If this feature is enabled, when the faulting process calls *madvise*(2) with the **MADV_DONTNEED** or **MADV_REMOVE** advice value to free a virtual memory area the userfaultfd

monitor will receive an event of type **UFFD_EVENT_REMOVE**.

UFFD_FEATURE_EVENT_UNMAP (since Linux 4.11)
If this feature is enabled, when the faulting process unmaps virtual memory either explicitly with *munmap*(2), or implicitly during either *mmap*(2) or *mremap*(2), the userfaultfd monitor will receive an event of type **UFFD_EVENT_UNMAP**.

UFFD_FEATURE_MISSING_HUGETLBFS (since Linux 4.11)
If this feature bit is set, the kernel supports registering userfaultfd ranges on hugetlbfs virtual memory areas

UFFD_FEATURE_MISSING_SHMEM (since Linux 4.11)
If this feature bit is set, the kernel supports registering userfaultfd ranges on shared memory areas. This includes all kernel shared memory APIs: System V shared memory, *tmpfs*(5), shared mappings of */dev/zero*, *mmap*(2) with the **MAP_SHARED** flag set, *memfd_create*(2), and so on.

UFFD_FEATURE_SIGBUS (since Linux 4.14)
If this feature bit is set, no page-fault events (**UFFD_EVENT_PAGEFAULT**) will be delivered. Instead, a **SIGBUS** signal will be sent to the faulting process. Applications using this feature will not require the use of a userfaultfd monitor for processing memory accesses to the regions registered with userfaultfd.

UFFD_FEATURE_THREAD_ID (since Linux 4.14)
If this feature bit is set, *uffd_msg.pagefault.feat.ptid* will be set to the faulted thread ID for each page-fault message.

UFFD_FEATURE_PAGEFAULT_FLAG_WP (since Linux 5.10)
If this feature bit is set, userfaultfd supports write-protect faults for anonymous memory. (Note that shmem / hugetlbfs support is indicated by a separate feature.)

UFFD_FEATURE_MINOR_HUGETLBFS (since Linux 5.13)
If this feature bit is set, the kernel supports registering userfaultfd ranges in minor mode on hugetlbfs-backed memory areas.

UFFD_FEATURE_MINOR_SHMEM (since Linux 5.14)
If this feature bit is set, the kernel supports registering userfaultfd ranges in minor mode on shmem-backed memory areas.

UFFD_FEATURE_EXACT_ADDRESS (since Linux 5.18)
If this feature bit is set, *uffd_msg.pagefault.address* will be set to the exact page-fault address that was reported by the hardware, and will not mask the offset within the page. Note that old Linux versions might indicate the exact address as well, even though the feature bit is not set.

UFFD_FEATURE_WP_HUGETLBFS_SHMEM (since Linux 5.19)
If this feature bit is set, userfaultfd supports write-protect faults for hugetlbfs and shmem / tmpfs memory.

UFFD_FEATURE_WP_UNPOPULATED (since Linux 6.4)
If this feature bit is set, the kernel will handle anonymous memory the same way as file memory, by allowing the user to write-protect unpopulated page table entries.

UFFD_FEATURE_POISON (since Linux 6.6)
If this feature bit is set, the kernel supports resolving faults with the **UFFDIO_POISON** ioctl.

UFFD_FEATURE_WP_ASYNC (since Linux 6.7)
If this feature bit is set, the write protection faults would be asynchronously resolved by the kernel.

The returned *ioctls* field can contain the following bits:

1 << _UFFDIO_API
The **UFFDIO_API** operation is supported.

1 << _UFFDIO_REGISTER
The **UFFDIO_REGISTER** operation is supported.

1 << _UFFDIO_UNREGISTER
The **UFFDIO_UNREGISTER** operation is supported.

This *ioctl*(2) operation returns 0 on success. On error, −1 is returned and *errno* is set to indicate the error. If an error occurs, the kernel may zero the provided *uffdio_api* structure. The caller should treat its contents as unspecified, and reinitialize it before re-attempting another **UFFDIO_API** call. Possible errors include:

EFAULT
argp refers to an address that is outside the calling process's accessible address space.

EINVAL
The API version requested in the *api* field is not supported by this kernel, or the *features* field passed to the kernel includes feature bits that are not supported by the current kernel version.

EINVAL
A previous **UFFDIO_API** call already enabled one or more features for this userfaultfd. Calling **UFFDIO_API** twice, the first time with no features set, is explicitly allowed as per the two-step feature detection handshake.

EPERM
The **UFFD_FEATURE_EVENT_FORK** feature was enabled, but the calling process doesn't have the **CAP_SYS_PTRACE** capability.

UFFDIO_REGISTER
(Since Linux 4.3.) Register a memory address range with the userfaultfd object. The pages in the range must be "compatible". Please refer to the list of register modes below for the compatible memory backends for each mode.

The *argp* argument is a pointer to a *uffdio_register* structure, defined as:

```
struct uffdio_range {
    __u64 start;    /* Start of range */
    __u64 len;      /* Length of range (bytes) */
};

struct uffdio_register {
    struct uffdio_range range;
    __u64 mode;     /* Desired mode of operation (input) */
    __u64 ioctls;   /* Available ioctl() operations (output) */
};
```

The *range* field defines a memory range starting at *start* and continuing for *len* bytes that should be handled by the userfaultfd.

The *mode* field defines the mode of operation desired for this memory region. The following values may be bitwise ORed to set the userfaultfd mode for the specified range:

UFFDIO_REGISTER_MODE_MISSING
Track page faults on missing pages. Since Linux 4.3, only private anonymous ranges are compatible. Since Linux 4.11, hugetlbfs and shared memory ranges are also compatible.

UFFDIO_REGISTER_MODE_WP
Track page faults on write-protected pages. Since Linux 5.7, only private anonymous ranges are compatible.

UFFDIO_REGISTER_MODE_MINOR
Track minor page faults. Since Linux 5.13, only hugetlbfs ranges are compatible. Since Linux 5.14, compatibility with shmem ranges was added.

If the operation is successful, the kernel modifies the *ioctls* bit-mask field to indicate which *ioctl*(2) operations are available for the specified range. This returned bit mask can contain the following bits:

1 << _UFFDIO_COPY
The **UFFDIO_COPY** operation is supported.

1 << _UFFDIO_WAKE
The **UFFDIO_WAKE** operation is supported.

1 << _UFFDIO_WRITEPROTECT
The **UFFDIO_WRITEPROTECT** operation is supported.

1 << _UFFDIO_ZEROPAGE
The **UFFDIO_ZEROPAGE** operation is supported.

1 << _UFFDIO_CONTINUE
The **UFFDIO_CONTINUE** operation is supported.

1 << _UFFDIO_POISON
The **UFFDIO_POISON** operation is supported.

This *ioctl*(2) operation returns 0 on success. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EBUSY
A mapping in the specified range is registered with another userfaultfd object.

EFAULT
argp refers to an address that is outside the calling process's accessible address space.

EINVAL
An invalid or unsupported bit was specified in the *mode* field; or the *mode* field was zero.

EINVAL
There is no mapping in the specified address range.

EINVAL
range.start or *range.len* is not a multiple of the system page size; or, *range.len* is zero; or these fields are otherwise invalid.

EINVAL
There as an incompatible mapping in the specified address range.

UFFDIO_UNREGISTER
(Since Linux 4.3.) Unregister a memory address range from userfaultfd. The pages in the range must be "compatible" (see the description of **UFFDIO_REGISTER**.)

The address range to unregister is specified in the *uffdio_range* structure pointed to by *argp*.

This *ioctl*(2) operation returns 0 on success. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EINVAL
Either the *start* or the *len* field of the *ufdio_range* structure was not a multiple of the system page size; or the *len* field was zero; or these fields were otherwise invalid.

EINVAL
There as an incompatible mapping in the specified address range.

EINVAL
There was no mapping in the specified address range.

UFFDIO_COPY
(Since Linux 4.3.) Atomically copy a continuous memory chunk into the userfault registered range and optionally wake up the blocked thread. The source and destination addresses and the number of bytes to copy are specified by the *src*, *dst*, and *len* fields of the *uffdio_copy* structure pointed to by *argp*:

```
struct uffdio_copy {
    __u64 dst;    /* Destination of copy */
    __u64 src;    /* Source of copy */
    __u64 len;    /* Number of bytes to copy */
    __u64 mode;   /* Flags controlling behavior of copy */
    __s64 copy;   /* Number of bytes copied, or negated error */
};
```

The following value may be bitwise ORed in *mode* to change the behavior of the **UFFDIO_COPY** operation:

UFFDIO_COPY_MODE_DONTWAKE
Do not wake up the thread that waits for page-fault resolution

UFFDIO_COPY_MODE_WP
Copy the page with read-only permission. This allows the user to trap the next write to the page, which will block and generate another write-protect userfault message. This is used only when both **UFFDIO_REGISTER_MODE_MISSING** and **UFFDIO_REGISTER_MODE_WP** modes are enabled for the registered range.

The *copy* field is used by the kernel to return the number of bytes that was actually copied, or an error (a negated *errno*-style value). If the value returned in *copy* doesn't match the value that was specified in *len*, the operation fails with the error **EAGAIN**. The *copy* field is output-only; it is not read by the **UFFDIO_COPY** operation.

This *ioctl*(2) operation returns 0 on success. In this case, the entire area was copied. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EAGAIN
The number of bytes copied (i.e., the value returned in the *copy* field) does not equal the value that was specified in the *len* field.

EINVAL
Either *dst* or *len* was not a multiple of the system page size, or the range specified by *src* and *len* or *dst* and *len* was invalid.

EINVAL
An invalid bit was specified in the *mode* field.

ENOENT (since Linux 4.11)
The faulting process has changed its virtual memory layout simultaneously with an outstanding **UFFDIO_COPY** operation.

ENOSPC (from Linux 4.11 until Linux 4.13)
The faulting process has exited at the time of a **UFFDIO_COPY** operation.

ESRCH (since Linux 4.13)
The faulting process has exited at the time of a **UFFDIO_COPY** operation.

UFFDIO_ZEROPAGE
(Since Linux 4.3.) Zero out a memory range registered with userfaultfd.

The requested range is specified by the *range* field of the *uffdio_zeropage* structure pointed to by *argp*:

```
struct uffdio_zeropage {
    struct uffdio_range range;
    __u64 mode;     /* Flags controlling behavior of copy */
    __s64 zeropage; /* Number of bytes zeroed, or negated error */
};
```

The following value may be bitwise ORed in *mode* to change the behavior of the **UFFDIO_ZEROPAGE** operation:

UFFDIO_ZEROPAGE_MODE_DONTWAKE
Do not wake up the thread that waits for page-fault resolution.

The *zeropage* field is used by the kernel to return the number of bytes that was actually zeroed, or an error in the same manner as **UFFDIO_COPY**. If the value returned in the *zeropage* field doesn't match the value that was specified in *range.len*, the operation fails with the error **EAGAIN**. The *zeropage* field is output-only; it is not read by the **UFFDIO_ZEROPAGE** operation.

This *ioctl*(2) operation returns 0 on success. In this case, the entire area was zeroed. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EAGAIN
The number of bytes zeroed (i.e., the value returned in the *zeropage* field) does not equal the value that was specified in the *range.len* field.

EINVAL
Either *range.start* or *range.len* was not a multiple of the system page size; or *range.len* was zero; or the range specified was invalid.

EINVAL
An invalid bit was specified in the *mode* field.

ESRCH (since Linux 4.13)
The faulting process has exited at the time of a **UFFDIO_ZEROPAGE** operation.

UFFDIO_WAKE
(Since Linux 4.3.) Wake up the thread waiting for page-fault resolution on a specified memory address range.

The **UFFDIO_WAKE** operation is used in conjunction with **UFFDIO_COPY** and **UFFDIO_ZEROPAGE** operations that have the **UFFDIO_COPY_MODE_DONTWAKE** or **UFFDIO_ZEROPAGE_MODE_DONTWAKE** bit set in the *mode* field. The userfault monitor can perform several **UFFDIO_COPY** and **UFFDIO_ZEROPAGE** operations in a batch and then explicitly wake up the faulting thread using **UFFDIO_WAKE**.

The *argp* argument is a pointer to a *uffdio_range* structure (shown above) that specifies the address range.

This *ioctl*(2) operation returns 0 on success. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EINVAL
The *start* or the *len* field of the *ufdio_range* structure was not a multiple of the system page size; or *len* was zero; or the specified range was otherwise invalid.

UFFDIO_WRITEPROTECT
(Since Linux 5.7.) Write-protect or write-unprotect a userfaultfd-registered memory range registered with mode **UFFDIO_REGISTER_MODE_WP**.

The *argp* argument is a pointer to a *uffdio_range* structure as shown below:

```
struct uffdio_writeprotect {
    struct uffdio_range range; /* Range to change write permission*/
    __u64 mode;                /* Mode to change write permission */
};
```

There are two mode bits that are supported in this structure:

UFFDIO_WRITEPROTECT_MODE_WP
When this mode bit is set, the ioctl will be a write-protect operation upon the memory range specified by *range*. Otherwise it will be a write-unprotect operation upon the specified range, which can be used to resolve a userfaultfd write-protect page fault.

UFFDIO_WRITEPROTECT_MODE_DONTWAKE
When this mode bit is set, do not wake up any thread that waits for page-fault resolution after the operation. This can be specified only if **UFFDIO_WRITEPROTECT_MODE_WP** is not specified.

This *ioctl*(2) operation returns 0 on success. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EINVAL
The *start* or the *len* field of the *ufdio_range* structure was not a multiple of the system page size; or *len* was zero; or the specified range was otherwise invalid.

EAGAIN
The process was interrupted; retry this call.

ENOENT
The range specified in *range* is not valid. For example, the virtual address does not exist, or not registered with userfaultfd write-protect mode.

EFAULT
Encountered a generic fault during processing.

UFFDIO_CONTINUE
(Since Linux 5.13.) Resolve a minor page fault by installing page table entries for existing pages in the page cache.

The *argp* argument is a pointer to a *uffdio_continue* structure as shown below:

```
struct uffdio_continue {
    struct uffdio_range range;
                  /* Range to install PTEs for and continue */
    __u64 mode;   /* Flags controlling the behavior of continue */
    __s64 mapped; /* Number of bytes mapped, or negated error */
};
```

The following value may be bitwise ORed in *mode* to change the behavior of the **UFFDIO_CONTINUE** operation:

UFFDIO_CONTINUE_MODE_DONTWAKE
Do not wake up the thread that waits for page-fault resolution.

The *mapped* field is used by the kernel to return the number of bytes that were actually mapped, or an error in the same manner as **UFFDIO_COPY**. If the value returned in the *mapped* field doesn't match the value that was specified in *range.len*, the operation fails with the error **EAGAIN**. The *mapped* field is output-only; it is not read by the **UFFDIO_CONTINUE** operation.

This *ioctl*(2) operation returns 0 on success. In this case, the entire area was mapped. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EAGAIN
The number of bytes mapped (i.e., the value returned in the *mapped* field) does not equal the value that was specified in the *range.len* field.

EEXIST
One or more pages were already mapped in the given range.

EFAULT
No existing page could be found in the page cache for the given range.

EINVAL
Either *range.start* or *range.len* was not a multiple of the system page size; or *range.len* was zero; or the range specified was invalid.

EINVAL
An invalid bit was specified in the *mode* field.

ENOENT
The faulting process has changed its virtual memory layout simultaneously with an outstanding **UFFDIO_CONTINUE** operation.

ENOMEM
Allocating memory needed to setup the page table mappings failed.

ESRCH
The faulting process has exited at the time of a **UFFDIO_CONTINUE** operation.

UFFDIO_POISON
(Since Linux 6.6.) Mark an address range as "poisoned". Future accesses to these addresses will raise a **SIGBUS** signal. Unlike **MADV_HWPOISON** this works by installing page table entries, rather than "really" poisoning the underlying physical pages. This means it only affects this particular address space.

The *argp* argument is a pointer to a *uffdio_poison* structure as shown below:

```
struct uffdio_poison {
      struct uffdio_range range;
                    /* Range to install poison PTE markers in */
      __u64 mode;   /* Flags controlling the behavior of poison */
```

```
        __s64 updated;  /* Number of bytes poisoned, or negated error */
};
```

The following value may be bitwise ORed in *mode* to change the behavior of the **UFFDIO_POISON** operation:

UFFDIO_POISON_MODE_DONTWAKE
Do not wake up the thread that waits for page-fault resolution.

The *updated* field is used by the kernel to return the number of bytes that were actually poisoned, or an error in the same manner as **UFFDIO_COPY**. If the value returned in the *updated* field doesn't match the value that was specified in *range.len*, the operation fails with the error **EAGAIN**. The *updated* field is output-only; it is not read by the **UFFDIO_POISON** operation.

This *ioctl*(2) operation returns 0 on success. In this case, the entire area was poisoned. On error, −1 is returned and *errno* is set to indicate the error. Possible errors include:

EAGAIN
The number of bytes mapped (i.e., the value returned in the *updated* field) does not equal the value that was specified in the *range.len* field.

EINVAL
Either *range.start* or *range.len* was not a multiple of the system page size; or *range.len* was zero; or the range specified was invalid.

EINVAL
An invalid bit was specified in the *mode* field.

EEXIST
One or more pages were already mapped in the given range.

ENOENT
The faulting process has changed its virtual memory layout simultaneously with an outstanding **UFFDIO_POISON** operation.

ENOMEM
Allocating memory for page table entries failed.

ESRCH
The faulting process has exited at the time of a **UFFDIO_POISON** operation.

RETURN VALUE

See descriptions of the individual operations, above.

ERRORS

See descriptions of the individual operations, above. In addition, the following general errors can occur for all of the operations described above:

EFAULT
argp does not point to a valid memory address.

EINVAL
(For all operations except **UFFDIO_API**.) The userfaultfd object has not yet been enabled (via the **UFFDIO_API** operation).

STANDARDS

Linux.

BUGS

In order to detect available userfault features and enable some subset of those features the userfaultfd file descriptor must be closed after the first **UFFDIO_API** operation that queries features availability and reopened before the second **UFFDIO_API** operation that actually enables the desired features.

EXAMPLES

See *userfaultfd*(2).

NAME

ioperm − set port input/output permissions

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/io.h>

int ioperm(unsigned long *from***, unsigned long** *num***, int** *turn_on***);**

DESCRIPTION

ioperm() sets the port access permission bits for the calling thread for *num* bits starting from port address *from*. If *turn_on* is nonzero, then permission for the specified bits is enabled; otherwise it is disabled. If *turn_on* is nonzero, the calling thread must be privileged (**CAP_SYS_RAWIO**).

Before Linux 2.6.8, only the first 0x3ff I/O ports could be specified in this manner. For more ports, the *iopl*(2) system call had to be used (with a *level* argument of 3). Since Linux 2.6.8, 65,536 I/O ports can be specified.

Permissions are inherited by the child created by *fork*(2) (but see NOTES). Permissions are preserved across *execve*(2); this is useful for giving port access permissions to unprivileged programs.

This call is mostly for the i386 architecture. On many other architectures it does not exist or will always return an error.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
Invalid values for *from* or *num*.

EIO (on PowerPC) This call is not supported.

ENOMEM
Out of memory.

EPERM
The calling thread has insufficient privilege.

VERSIONS

glibc has an **ioperm**() prototype both in <*sys/io.h*> and in <*sys/perm.h*>. Avoid the latter, it is available on i386 only.

STANDARDS

Linux.

HISTORY

Before Linux 2.4, permissions were not inherited by a child created by *fork*(2).

NOTES

The */proc/ioports* file shows the I/O ports that are currently allocated on the system.

SEE ALSO

iopl(2), *outb*(2), *capabilities*(7)

NAME

iopl − change I/O privilege level

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/io.h>

[[deprecated]] int iopl(int *level***);**

DESCRIPTION

iopl() changes the I/O privilege level of the calling thread, as specified by the two least significant bits in *level*.

The I/O privilege level for a normal thread is 0. Permissions are inherited from parents to children.

This call is deprecated, is significantly slower than *ioperm*(2), and is only provided for older X servers which require access to all 65536 I/O ports. It is mostly for the i386 architecture. On many other architectures it does not exist or will always return an error.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
: *level* is greater than 3.

ENOSYS
: This call is unimplemented.

EPERM
: The calling thread has insufficient privilege to call **iopl**(); the **CAP_SYS_RAWIO** capability is required to raise the I/O privilege level above its current value.

VERSIONS

glibc2 has a prototype both in <*sys/io.h*> and in <*sys/perm.h*>. Avoid the latter, it is available on i386 only.

STANDARDS

Linux.

HISTORY

Prior to Linux 5.5 **iopl**() allowed the thread to disable interrupts while running at a higher I/O privilege level. This will probably crash the system, and is not recommended.

Prior to Linux 3.7, on some architectures (such as i386), permissions *were* inherited by the child produced by *fork*(2) and were preserved across *execve*(2). This behavior was inadvertently changed in Linux 3.7, and won't be reinstated.

ioperm(2), *outb*(2), *capabilities*(7)

NAME

ioprio_get, ioprio_set − get/set I/O scheduling class and priority

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/ioprio.h>    /* Definition of IOPRIO_* constants */
#include <sys/syscall.h>     /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_ioprio_get, int which, int who);
int syscall(SYS_ioprio_set, int which, int who, int ioprio);
```

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

The **ioprio_get**() and **ioprio_set**() system calls get and set the I/O scheduling class and priority of one or more threads.

The *which* and *who* arguments identify the thread(s) on which the system calls operate. The *which* argument determines how *who* is interpreted, and has one of the following values:

IOPRIO_WHO_PROCESS
: *who* is a process ID or thread ID identifying a single process or thread. If *who* is 0, then operate on the calling thread.

IOPRIO_WHO_PGRP
: *who* is a process group ID identifying all the members of a process group. If *who* is 0, then operate on the process group of which the caller is a member.

IOPRIO_WHO_USER
: *who* is a user ID identifying all of the processes that have a matching real UID.

If *which* is specified as **IOPRIO_WHO_PGRP** or **IOPRIO_WHO_USER** when calling **ioprio_get**(), and more than one process matches *who*, then the returned priority will be the highest one found among all of the matching processes. One priority is said to be higher than another one if it belongs to a higher priority class (**IOPRIO_CLASS_RT** is the highest priority class; **IOPRIO_CLASS_IDLE** is the lowest) or if it belongs to the same priority class as the other process but has a higher priority level (a lower priority number means a higher priority level).

The *ioprio* argument given to **ioprio_set**() is a bit mask that specifies both the scheduling class and the priority to be assigned to the target process(es). The following macros are used for assembling and dissecting *ioprio* values:

IOPRIO_PRIO_VALUE(*class***,** *data***)**
: Given a scheduling *class* and priority (*data*), this macro combines the two values to produce an *ioprio* value, which is returned as the result of the macro.

IOPRIO_PRIO_CLASS(*mask***)**
: Given *mask* (an *ioprio* value), this macro returns its I/O class component, that is, one of the values **IOPRIO_CLASS_RT**, **IOPRIO_CLASS_BE**, or **IOPRIO_CLASS_IDLE**.

IOPRIO_PRIO_DATA(*mask***)**
: Given *mask* (an *ioprio* value), this macro returns its priority (*data*) component.

See the NOTES section for more information on scheduling classes and priorities, as well as the meaning of specifying *ioprio* as 0.

I/O priorities are supported for reads and for synchronous (**O_DIRECT**, **O_SYNC**) writes. I/O priorities are not supported for asynchronous writes because they are issued outside the context of the program dirtying the memory, and thus program-specific priorities do not apply.

RETURN VALUE

On success, **ioprio_get**() returns the *ioprio* value of the process with highest I/O priority of any of the processes that match the criteria specified in *which* and *who*. On error, −1 is returned, and *errno* is set to indicate the error.

On success, **ioprio_set**() returns 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
Invalid value for *which* or *ioprio*. Refer to the NOTES section for available scheduler classes and priority levels for *ioprio*.

EPERM
The calling process does not have the privilege needed to assign this *ioprio* to the specified process(es). See the NOTES section for more information on required privileges for **ioprio_set**().

ESRCH
No process(es) could be found that matched the specification in *which* and *who*.

STANDARDS

Linux.

HISTORY

Linux 2.6.13.

NOTES

Two or more processes or threads can share an I/O context. This will be the case when *clone*(2) was called with the **CLONE_IO** flag. However, by default, the distinct threads of a process will **not** share the same I/O context. This means that if you want to change the I/O priority of all threads in a process, you may need to call **ioprio_set**() on each of the threads. The thread ID that you would need for this operation is the one that is returned by *gettid*(2) or *clone*(2).

These system calls have an effect only when used in conjunction with an I/O scheduler that supports I/O priorities. As at kernel 2.6.17 the only such scheduler is the Completely Fair Queuing (CFQ) I/O scheduler.

If no I/O scheduler has been set for a thread, then by default the I/O priority will follow the CPU nice value (**setpriority**(2)). Before Linux 2.6.24, once an I/O priority had been set using **ioprio_set**(), there was no way to reset the I/O scheduling behavior to the default. Since Linux 2.6.24, specifying *ioprio* as 0 can be used to reset to the default I/O scheduling behavior.

Selecting an I/O scheduler

I/O schedulers are selected on a per-device basis via the special file */sys/block/*device*/queue/scheduler*.

One can view the current I/O scheduler via the */sys* filesystem. For example, the following command displays a list of all schedulers currently loaded in the kernel:

```
$ cat /sys/block/sda/queue/scheduler
noop anticipatory deadline [cfq]
```

The scheduler surrounded by brackets is the one actually in use for the device (*sda* in the example). Setting another scheduler is done by writing the name of the new scheduler to this file. For example, the following command will set the scheduler for the *sda* device to *cfq*:

```
$ su
Password:
# echo cfq > /sys/block/sda/queue/scheduler
```

The Completely Fair Queuing (CFQ) I/O scheduler

Since version 3 (also known as CFQ Time Sliced), CFQ implements I/O nice levels similar to those of CPU scheduling. These nice levels are grouped into three scheduling classes, each one containing one or more priority levels:

IOPRIO_CLASS_RT (1)
This is the real-time I/O class. This scheduling class is given higher priority than any other class: processes from this class are given first access to the disk every time. Thus, this I/O class needs to be used with some care: one I/O real-time process can starve the entire system. Within the real-time class, there are 8 levels of class data (priority) that determine exactly how much time this process needs the disk for on each service. The highest real-time priority level is 0; the lowest is 7. In the future, this might change to be more directly mappable to performance, by passing in a desired data rate instead.

IOPRIO_CLASS_BE (2)
: This is the best-effort scheduling class, which is the default for any process that hasn't set a specific I/O priority. The class data (priority) determines how much I/O bandwidth the process will get. Best-effort priority levels are analogous to CPU nice values (see *getpriority*(2)). The priority level determines a priority relative to other processes in the best-effort scheduling class. Priority levels range from 0 (highest) to 7 (lowest).

IOPRIO_CLASS_IDLE (3)
: This is the idle scheduling class. Processes running at this level get I/O time only when no one else needs the disk. The idle class has no class data. Attention is required when assigning this priority class to a process, since it may become starved if higher priority processes are constantly accessing the disk.

Refer to the kernel source file *Documentation/block/ioprio.txt* for more information on the CFQ I/O Scheduler and an example program.

Required permissions to set I/O priorities
: Permission to change a process's priority is granted or denied based on two criteria:

Process ownership
: An unprivileged process may set the I/O priority only for a process whose real UID matches the real or effective UID of the calling process. A process which has the **CAP_SYS_NICE** capability can change the priority of any process.

What is the desired priority
: Attempts to set very high priorities (**IOPRIO_CLASS_RT**) require the **CAP_SYS_ADMIN** capability. Up to Linux 2.6.24 also required **CAP_SYS_ADMIN** to set a very low priority (**IOPRIO_CLASS_IDLE**), but since Linux 2.6.25, this is no longer required.

A call to **ioprio_set**() must follow both rules, or the call will fail with the error **EPERM**.

BUGS

glibc does not yet provide a suitable header file defining the function prototypes and macros described on this page. Suitable definitions can be found in *linux/ioprio.h*.

NAME

ipc − System V IPC system calls

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/ipc.h>      /* Definition of needed constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_ipc, unsigned int call, int  first,
            unsigned long second, unsigned long third, void *ptr,
            long  fifth);
```

Note: glibc provides no wrapper for **ipc**(), necessitating the use of *syscall*(2).

DESCRIPTION

ipc() is a common kernel entry point for the System V IPC calls for messages, semaphores, and shared memory. *call* determines which IPC function to invoke; the other arguments are passed through to the appropriate call.

User-space programs should call the appropriate functions by their usual names. Only standard library implementors and kernel hackers need to know about **ipc**().

VERSIONS

On some architectures—for example x86-64 and ARM—there is no **ipc**() system call; instead, *msgctl*(2), *semctl*(2), *shmctl*(2), and so on really are implemented as separate system calls.

STANDARDS

Linux.

SEE ALSO

NAME

kcmp − compare two processes to determine if they share a kernel resource

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/kcmp.h>      /* Definition of KCMP_* constants */
#include <sys/syscall.h>     /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_kcmp, pid_t pid1, pid_t pid2, int type,
            unsigned long idx1, unsigned long idx2);
```

Note: glibc provides no wrapper for **kcmp**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **kcmp**() system call can be used to check whether the two processes identified by *pid1* and *pid2* share a kernel resource such as virtual memory, file descriptors, and so on.

Permission to employ **kcmp**() is governed by ptrace access mode **PTRACE_MODE_READ_REALCREDS** checks against both *pid1* and *pid2*; see *ptrace*(2).

The *type* argument specifies which resource is to be compared in the two processes. It has one of the following values:

KCMP_FILE
: Check whether a file descriptor *idx1* in the process *pid1* refers to the same open file description (see *open*(2)) as file descriptor *idx2* in the process *pid2*. The existence of two file descriptors that refer to the same open file description can occur as a result of *dup*(2) (and similar) *fork*(2), or passing file descriptors via a domain socket (see *unix*(7)).

KCMP_FILES
: Check whether the processes share the same set of open file descriptors. The arguments *idx1* and *idx2* are ignored. See the discussion of the **CLONE_FILES** flag in *clone*(2).

KCMP_FS
: Check whether the processes share the same filesystem information (i.e., file mode creation mask, working directory, and filesystem root). The arguments *idx1* and *idx2* are ignored. See the discussion of the **CLONE_FS** flag in *clone*(2).

KCMP_IO
: Check whether the processes share I/O context. The arguments *idx1* and *idx2* are ignored. See the discussion of the **CLONE_IO** flag in *clone*(2).

KCMP_SIGHAND
: Check whether the processes share the same table of signal dispositions. The arguments *idx1* and *idx2* are ignored. See the discussion of the **CLONE_SIGHAND** flag in *clone*(2).

KCMP_SYSVSEM
: Check whether the processes share the same list of System V semaphore undo operations. The arguments *idx1* and *idx2* are ignored. See the discussion of the **CLONE_SYSVSEM** flag in *clone*(2).

KCMP_VM
: Check whether the processes share the same address space. The arguments *idx1* and *idx2* are ignored. See the discussion of the **CLONE_VM** flag in *clone*(2).

KCMP_EPOLL_TFD (since Linux 4.13)
: Check whether the file descriptor *idx1* of the process *pid1* is present in the *epoll*(7) instance described by *idx2* of the process *pid2*. The argument *idx2* is a pointer to a structure where the target file is described. This structure has the form:

```
struct kcmp_epoll_slot {
    __u32 efd;
    __u32 tfd;
    __u64 toff;
};
```

Within this structure, *efd* is an epoll file descriptor returned from *epoll_create*(2), *tfd* is a target file descriptor number, and *toff* is a target file offset counted from zero. Several different targets may be registered with the same file descriptor number and setting a specific offset helps to investigate each of them.

Note the **kcmp**() is not protected against false positives which may occur if the processes are currently running. One should stop the processes by sending **SIGSTOP** (see *signal*(7)) prior to inspection with this system call to obtain meaningful results.

RETURN VALUE

The return value of a successful call to **kcmp**() is simply the result of arithmetic comparison of kernel pointers (when the kernel compares resources, it uses their memory addresses).

The easiest way to explain is to consider an example. Suppose that *v1* and *v2* are the addresses of appropriate resources, then the return value is one of the following:

0 *v1* is equal to *v2*; in other words, the two processes share the resource.

1 *v1* is less than *v2*.

2 *v1* is greater than *v2*.

3 *v1* is not equal to *v2*, but ordering information is unavailable.

On error, −1 is returned, and *errno* is set to indicate the error.

kcmp() was designed to return values suitable for sorting. This is particularly handy if one needs to compare a large number of file descriptors.

ERRORS

EBADF
type is **KCMP_FILE** and *fd1* or *fd2* is not an open file descriptor.

EFAULT
The epoll slot addressed by *idx2* is outside of the user's address space.

EINVAL
type is invalid.

ENOENT
The target file is not present in *epoll*(7) instance.

EPERM
Insufficient permission to inspect process resources. The **CAP_SYS_PTRACE** capability is required to inspect processes that you do not own. Other ptrace limitations may also apply, such as **CONFIG_SECURITY_YAMA**, which, when */proc/sys/kernel/yama/ptrace_scope* is 2, limits **kcmp**() to child processes; see *ptrace*(2).

ESRCH
Process *pid1* or *pid2* does not exist.

STANDARDS

Linux.

HISTORY

Linux 3.5.

Before Linux 5.12, this system call is available only if the kernel is configured with **CONFIG_CHECKPOINT_RESTORE**, since the original purpose of the system call was for the checkpoint/restore in user space (CRIU) feature. (The alternative to this system call would have been to expose suitable process information via the *proc*(5) filesystem; this was deemed to be unsuitable for security reasons.) Since Linux 5.12, this system call is also available if the kernel is configured with **CONFIG_KCMP**.

NOTES

See *clone*(2) for some background information on the shared resources referred to on this page.

EXAMPLES

The program below uses **kcmp**() to test whether pairs of file descriptors refer to the same open file description. The program tests different cases for the file descriptor pairs, as described in the program output. An example run of the program is as follows:

```
$ ./a.out
Parent PID is 1144
Parent opened file on FD 3

PID of child of fork() is 1145
      Compare duplicate FDs from different processes:
            kcmp(1145, 1144, KCMP_FILE, 3, 3) ==> same
Child opened file on FD 4
      Compare FDs from distinct open()s in same process:
            kcmp(1145, 1145, KCMP_FILE, 3, 4) ==> different
Child duplicated FD 3 to create FD 5
      Compare duplicated FDs in same process:
            kcmp(1145, 1145, KCMP_FILE, 3, 5) ==> same
```

Program source

NAME

kexec_load, kexec_file_load − load a new kernel for later execution

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/kexec.h>      /* Definition of KEXEC_* constants */
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

long syscall(SYS_kexec_load, unsigned long entry,
             unsigned long nr_segments, struct kexec_segment *segments,
             unsigned long flags);
long syscall(SYS_kexec_file_load, int kernel_fd, int initrd_fd,
             unsigned long cmdline_len, const char *cmdline,
             unsigned long flags);
```

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

The **kexec_load**() system call loads a new kernel that can be executed later by *reboot*(2).

The *flags* argument is a bit mask that controls the operation of the call. The following values can be specified in *flags*:

KEXEC_ON_CRASH (since Linux 2.6.13)
: Execute the new kernel automatically on a system crash. This "crash kernel" is loaded into an area of reserved memory that is determined at boot time using the *crashkernel* kernel command-line parameter. The location of this reserved memory is exported to user space via the */proc/iomem* file, in an entry labeled "Crash kernel". A user-space application can parse this file and prepare a list of segments (see below) that specify this reserved memory as destination. If this flag is specified, the kernel checks that the target segments specified in *segments* fall within the reserved region.

KEXEC_PRESERVE_CONTEXT (since Linux 2.6.27)
: Preserve the system hardware and software states before executing the new kernel. This could be used for system suspend. This flag is available only if the kernel was configured with **CONFIG_KEXEC_JUMP**, and is effective only if *nr_segments* is greater than 0.

The high-order bits (corresponding to the mask 0xffff0000) of *flags* contain the architecture of the to-be-executed kernel. Specify (OR) the constant **KEXEC_ARCH_DEFAULT** to use the current architecture, or one of the following architecture constants **KEXEC_ARCH_386**, **KEXEC_ARCH_68K**, **KEXEC_ARCH_X86_64**, **KEXEC_ARCH_PPC**, **KEXEC_ARCH_PPC64**, **KEXEC_ARCH_IA_64**, **KEXEC_ARCH_ARM**, **KEXEC_ARCH_S390**, **KEXEC_ARCH_SH**, **KEXEC_ARCH_MIPS**, and **KEXEC_ARCH_MIPS_LE**. The architecture must be executable on the CPU of the system.

The *entry* argument is the physical entry address in the kernel image. The *nr_segments* argument is the number of segments pointed to by the *segments* pointer; the kernel imposes an (arbitrary) limit of 16 on the number of segments. The *segments* argument is an array of *kexec_segment* structures which define the kernel layout:

```
struct kexec_segment {
    void   *buf;        /* Buffer in user space */
    size_t  bufsz;      /* Buffer length in user space */
    void   *mem;        /* Physical address of kernel */
    size_t  memsz;      /* Physical address length */
};
```

The kernel image defined by *segments* is copied from the calling process into the kernel either in regular memory or in reserved memory (if **KEXEC_ON_CRASH** is set). The kernel first performs various sanity checks on the information passed in *segments*. If these checks pass, the kernel copies the segment data to kernel memory. Each segment specified in *segments* is copied as follows:

- *buf* and *bufsz* identify a memory region in the caller's virtual address space that is the source of the copy. The value in *bufsz* may not exceed the value in the *memsz* field.
- *mem* and *memsz* specify a physical address range that is the target of the copy. The values specified in both fields must be multiples of the system page size.
- *bufsz* bytes are copied from the source buffer to the target kernel buffer. If *bufsz* is less than *memsz*, then the excess bytes in the kernel buffer are zeroed out.

In case of a normal kexec (i.e., the **KEXEC_ON_CRASH** flag is not set), the segment data is loaded in any available memory and is moved to the final destination at kexec reboot time (e.g., when the *kexec*(8) command is executed with the *−e* option).

In case of kexec on panic (i.e., the **KEXEC_ON_CRASH** flag is set), the segment data is loaded to reserved memory at the time of the call, and, after a crash, the kexec mechanism simply passes control to that kernel.

The **kexec_load**() system call is available only if the kernel was configured with **CONFIG_KEXEC**.

kexec_file_load()

The **kexec_file_load**() system call is similar to **kexec_load**(), but it takes a different set of arguments. It reads the kernel to be loaded from the file referred to by the file descriptor *kernel_fd*, and the initrd (initial RAM disk) to be loaded from file referred to by the file descriptor *initrd_fd*. The *cmdline* argument is a pointer to a buffer containing the command line for the new kernel. The *cmdline_len* argument specifies size of the buffer. The last byte in the buffer must be a null byte ('\0').

The *flags* argument is a bit mask which modifies the behavior of the call. The following values can be specified in *flags*:

KEXEC_FILE_UNLOAD
: Unload the currently loaded kernel.

KEXEC_FILE_ON_CRASH
: Load the new kernel in the memory region reserved for the crash kernel (as for **KEXEC_ON_CRASH**). This kernel is booted if the currently running kernel crashes.

KEXEC_FILE_NO_INITRAMFS
: Loading initrd/initramfs is optional. Specify this flag if no initramfs is being loaded. If this flag is set, the value passed in *initrd_fd* is ignored.

The **kexec_file_load**() system call was added to provide support for systems where "kexec" loading should be restricted to only kernels that are signed. This system call is available only if the kernel was configured with **CONFIG_KEXEC_FILE**.

RETURN VALUE

On success, these system calls returns 0. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EADDRNOTAVAIL
: The **KEXEC_ON_CRASH** flags was specified, but the region specified by the *mem* and *memsz* fields of one of the *segments* entries lies outside the range of memory reserved for the crash kernel.

EADDRNOTAVAIL
: The value in a *mem* or *memsz* field in one of the *segments* entries is not a multiple of the system page size.

EBADF
: *kernel_fd* or *initrd_fd* is not a valid file descriptor.

EBUSY
: Another crash kernel is already being loaded or a crash kernel is already in use.

EINVAL
: *flags* is invalid.

EINVAL
: The value of a *bufsz* field in one of the *segments* entries exceeds the value in the corresponding *memsz* field.

EINVAL
nr_segments exceeds **KEXEC_SEGMENT_MAX** (16).

EINVAL
Two or more of the kernel target buffers overlap.

EINVAL
The value in *cmdline[cmdline_len−1]* is not '\0'.

EINVAL
The file referred to by *kernel_fd* or *initrd_fd* is empty (length zero).

ENOEXEC
kernel_fd does not refer to an open file, or the kernel can't load this file. Currently, the file must be a bzImage and contain an x86 kernel that is loadable above 4 GiB in memory (see the kernel source file *Documentation/x86/boot.txt*).

ENOMEM
Could not allocate memory.

EPERM
The caller does not have the **CAP_SYS_BOOT** capability.

NAME

keyctl − manipulate the kernel's key management facility

LIBRARY

Standard C library (*libc*, *−lc*)

Alternatively, Linux Key Management Utilities (*libkeyutils*, *−lkeyutils*); see VERSIONS.

SYNOPSIS

```
#include <linux/keyctl.h>     /* Definition of KEY* constants */
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

long syscall(SYS_keyctl, int operation, unsigned long arg2,
             unsigned long arg3, unsigned long arg4,
             unsigned long arg5);
```

Note: glibc provides no wrapper for **keyctl**(), necessitating the use of *syscall*(2).

DESCRIPTION

keyctl() allows user-space programs to perform key manipulation.

The operation performed by **keyctl**() is determined by the value of the *operation* argument. Each of these operations is wrapped by the *libkeyutils* library (provided by the *keyutils* package) into individual functions (noted below) to permit the compiler to check types.

The permitted values for *operation* are:

KEYCTL_GET_KEYRING_ID (since Linux 2.6.10)
Map a special key ID to a real key ID for this process.

This operation looks up the special key whose ID is provided in *arg2* (cast to *key_serial_t*). If the special key is found, the ID of the corresponding real key is returned as the function result. The following values may be specified in *arg2*:

KEY_SPEC_THREAD_KEYRING
This specifies the calling thread's thread-specific keyring. See *thread-keyring*(7).

KEY_SPEC_PROCESS_KEYRING
This specifies the caller's process-specific keyring. See *process-keyring*(7).

KEY_SPEC_SESSION_KEYRING
This specifies the caller's session-specific keyring. See *session-keyring*(7).

KEY_SPEC_USER_KEYRING
This specifies the caller's UID-specific keyring. See *user-keyring*(7).

KEY_SPEC_USER_SESSION_KEYRING
This specifies the caller's UID-session keyring. See *user-session-keyring*(7).

KEY_SPEC_REQKEY_AUTH_KEY (since Linux 2.6.16)
This specifies the authorization key created by *request_key*(2) and passed to the process it spawns to generate a key. This key is available only in a *request-key*(8)-style program that was passed an authorization key by the kernel and ceases to be available once the requested key has been instantiated; see *request_key*(2).

KEY_SPEC_REQUESTOR_KEYRING (since Linux 2.6.29)
This specifies the key ID for the *request_key*(2) destination keyring. This keyring is available only in a *request-key*(8)-style program that was passed an authorization key by the kernel and ceases to be available once the requested key has been instantiated; see *request_key*(2).

The behavior if the key specified in *arg2* does not exist depends on the value of *arg3* (cast to *int*). If *arg3* contains a nonzero value, then—if it is appropriate to do so (e.g., when looking up the user, user-session, or session key)—a new key is created and its real key ID returned as the function result. Otherwise, the operation fails with the error **ENOKEY**.

If a valid key ID is specified in *arg2*, and the key exists, then this operation simply returns the key ID. If the key does not exist, the call fails with error **ENOKEY**.

The caller must have *search* permission on a keyring in order for it to be found.

The arguments *arg4* and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_get_keyring_ID*(3)

KEYCTL_JOIN_SESSION_KEYRING (since Linux 2.6.10)
Replace the session keyring this process subscribes to with a new session keyring.

If *arg2* is NULL, an anonymous keyring with the description "_ses" is created and the process is subscribed to that keyring as its session keyring, displacing the previous session keyring.

Otherwise, *arg2* (cast to *char* *) is treated as the description (name) of a keyring, and the behavior is as follows:

- If a keyring with a matching description exists, the process will attempt to subscribe to that keyring as its session keyring if possible; if that is not possible, an error is returned. In order to subscribe to the keyring, the caller must have *search* permission on the keyring.
- If a keyring with a matching description does not exist, then a new keyring with the specified description is created, and the process is subscribed to that keyring as its session keyring.

The arguments *arg3*, *arg4*, and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_join_session_keyring*(3)

KEYCTL_UPDATE (since Linux 2.6.10)
Update a key's data payload.

The *arg2* argument (cast to *key_serial_t*) specifies the ID of the key to be updated. The *arg3* argument (cast to *void* *) points to the new payload and *arg4* (cast to *size_t*) contains the new payload size in bytes.

The caller must have *write* permission on the key specified and the key type must support updating.

A negatively instantiated key (see the description of **KEYCTL_REJECT**) can be positively instantiated with this operation.

The *arg5* argument is ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_update*(3)

KEYCTL_REVOKE (since Linux 2.6.10)
Revoke the key with the ID provided in *arg2* (cast to *key_serial_t*). The key is scheduled for garbage collection; it will no longer be findable, and will be unavailable for further operations. Further attempts to use the key will fail with the error **EKEYREVOKED**.

The caller must have *write* or *setattr* permission on the key.

The arguments *arg3*, *arg4*, and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_revoke*(3)

KEYCTL_CHOWN (since Linux 2.6.10)
Change the ownership (user and group ID) of a key.

The *arg2* argument (cast to *key_serial_t*) contains the key ID. The *arg3* argument (cast to *uid_t*) contains the new user ID (or −1 in case the user ID shouldn't be changed). The *arg4* argument (cast to *gid_t*) contains the new group ID (or −1 in case the group ID shouldn't be changed).

The key must grant the caller *setattr* permission.

For the UID to be changed, or for the GID to be changed to a group the caller is not a member of, the caller must have the **CAP_SYS_ADMIN** capability (see *capabilities*(7)).

If the UID is to be changed, the new user must have sufficient quota to accept the key. The quota deduction will be removed from the old user to the new user should the UID be changed.

The *arg5* argument is ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_chown*(3)

KEYCTL_SETPERM (since Linux 2.6.10)

Change the permissions of the key with the ID provided in the *arg2* argument (cast to *key_serial_t*) to the permissions provided in the *arg3* argument (cast to *key_perm_t*).

If the caller doesn't have the **CAP_SYS_ADMIN** capability, it can change permissions only for the keys it owns. (More precisely: the caller's filesystem UID must match the UID of the key.)

The key must grant *setattr* permission to the caller *regardless* of the caller's capabilities.

The permissions in *arg3* specify masks of available operations for each of the following user categories:

possessor (since Linux 2.6.14)
: This is the permission granted to a process that possesses the key (has it attached searchably to one of the process's keyrings); see *keyrings*(7).

user
: This is the permission granted to a process whose filesystem UID matches the UID of the key.

group
: This is the permission granted to a process whose filesystem GID or any of its supplementary GIDs matches the GID of the key.

other
: This is the permission granted to other processes that do not match the *user* and *group* categories.

The *user*, *group*, and *other* categories are exclusive: if a process matches the *user* category, it will not receive permissions granted in the *group* category; if a process matches the *user* or *group* category, then it will not receive permissions granted in the *other* category.

The *possessor* category grants permissions that are cumulative with the grants from the *user*, *group*, or *other* category.

Each permission mask is eight bits in size, with only six bits currently used. The available permissions are:

view
: This permission allows reading attributes of a key.

  This permission is required for the **KEYCTL_DESCRIBE** operation.

  The permission bits for each category are **KEY_POS_VIEW**, **KEY_USR_VIEW**, **KEY_GRP_VIEW**, and **KEY_OTH_VIEW**.

read
: This permission allows reading a key's payload.

  This permission is required for the **KEYCTL_READ** operation.

  The permission bits for each category are **KEY_POS_READ**, **KEY_USR_READ**, **KEY_GRP_READ**, and **KEY_OTH_READ**.

write
: This permission allows update or instantiation of a key's payload. For a keyring, it allows keys to be linked and unlinked from the keyring,

  This permission is required for the **KEYCTL_UPDATE**, **KEYCTL_REVOKE**, **KEYCTL_CLEAR**, **KEYCTL_LINK**, and **KEYCTL_UNLINK** operations.

  The permission bits for each category are **KEY_POS_WRITE**, **KEY_USR_WRITE**, **KEY_GRP_WRITE**, and **KEY_OTH_WRITE**.

search
: This permission allows keyrings to be searched and keys to be found. Searches can recurse only into nested keyrings that have *search* permission set.

  This permission is required for the **KEYCTL_GET_KEYRING_ID**, **KEYCTL_JOIN_SESSION_KEYRING**, **KEYCTL_SEARCH**, and **KEYCTL_INVALIDATE** operations.

  The permission bits for each category are **KEY_POS_SEARCH**, **KEY_USR_SEARCH**, **KEY_GRP_SEARCH**, and **KEY_OTH_SEARCH**.

link This permission allows a key or keyring to be linked to.

This permission is required for the **KEYCTL_LINK** and **KEYCTL_SESSION_TO_PARENT** operations.

The permission bits for each category are **KEY_POS_LINK**, **KEY_USR_LINK**, **KEY_GRP_LINK**, and **KEY_OTH_LINK**.

setattr (since Linux 2.6.15).
This permission allows a key's UID, GID, and permissions mask to be changed.

This permission is required for the **KEYCTL_REVOKE**, **KEYCTL_CHOWN**, and **KEYCTL_SETPERM** operations.

The permission bits for each category are **KEY_POS_SETATTR**, **KEY_USR_SETATTR**, **KEY_GRP_SETATTR**, and **KEY_OTH_SETATTR**.

As a convenience, the following macros are defined as masks for all of the permission bits in each of the user categories: **KEY_POS_ALL**, **KEY_USR_ALL**, **KEY_GRP_ALL**, and **KEY_OTH_ALL**.

The *arg4* and *arg5* arguments are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_setperm*(3)

KEYCTL_DESCRIBE (since Linux 2.6.10)
Obtain a string describing the attributes of a specified key.

The ID of the key to be described is specified in *arg2* (cast to *key_serial_t*). The descriptive string is returned in the buffer pointed to by *arg3* (cast to *char **); *arg4* (cast to *size_t*) specifies the size of that buffer in bytes.

The key must grant the caller *view* permission.

The returned string is null-terminated and contains the following information about the key:

type;*uid*;*gid*;*perm*;*description*

In the above, *type* and *description* are strings, *uid* and *gid* are decimal strings, and *perm* is a hexadecimal permissions mask. The descriptive string is written with the following format:

```
%s;%d;%d;%08x;%s
```

Note: the intention is that the descriptive string should be extensible in future kernel versions. In particular, the *description* field will not contain semicolons; it should be parsed by working backwards from the end of the string to find the last semicolon. This allows future semicolon-delimited fields to be inserted in the descriptive string in the future.

Writing to the buffer is attempted only when *arg3* is non-NULL and the specified buffer size is large enough to accept the descriptive string (including the terminating null byte). In order to determine whether the buffer size was too small, check to see if the return value of the operation is greater than *arg4*.

The *arg5* argument is ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_describe*(3)

KEYCTL_CLEAR
Clear the contents of (i.e., unlink all keys from) a keyring.

The ID of the key (which must be of keyring type) is provided in *arg2* (cast to *key_serial_t*).

The caller must have *write* permission on the keyring.

The arguments *arg3*, *arg4*, and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_clear*(3)

KEYCTL_LINK (since Linux 2.6.10)
Create a link from a keyring to a key.

The key to be linked is specified in *arg2* (cast to *key_serial_t*); the keyring is specified in *arg3* (cast to *key_serial_t*).

If a key with the same type and description is already linked in the keyring, then that key is displaced from the keyring.

Before creating the link, the kernel checks the nesting of the keyrings and returns appropriate errors if the link would produce a cycle or if the nesting of keyrings would be too deep (The limit on the nesting of keyrings is determined by the kernel constant **KEYRING_SEARCH_MAX_DEPTH**, defined with the value 6, and is necessary to prevent overflows on the kernel stack when recursively searching keyrings).

The caller must have *link* permission on the key being added and *write* permission on the keyring.

The arguments *arg4* and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_link*(3)

KEYCTL_UNLINK (since Linux 2.6.10)
Unlink a key from a keyring.

The ID of the key to be unlinked is specified in *arg2* (cast to *key_serial_t*); the ID of the keyring from which it is to be unlinked is specified in *arg3* (cast to *key_serial_t*).

If the key is not currently linked into the keyring, an error results.

The caller must have *write* permission on the keyring from which the key is being removed.

If the last link to a key is removed, then that key will be scheduled for destruction.

The arguments *arg4* and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_unlink*(3)

KEYCTL_SEARCH (since Linux 2.6.10)
Search for a key in a keyring tree, returning its ID and optionally linking it to a specified keyring.

The tree to be searched is specified by passing the ID of the head keyring in *arg2* (cast to *key_serial_t*). The search is performed breadth-first and recursively.

The *arg3* and *arg4* arguments specify the key to be searched for: *arg3* (cast as *char* *) contains the key type (a null-terminated character string up to 32 bytes in size, including the terminating null byte), and *arg4* (cast as *char* *) contains the description of the key (a null-terminated character string up to 4096 bytes in size, including the terminating null byte).

The source keyring must grant *search* permission to the caller. When performing the recursive search, only keyrings that grant the caller *search* permission will be searched. Only keys with for which the caller has *search* permission can be found.

If the key is found, its ID is returned as the function result.

If the key is found and *arg5* (cast to *key_serial_t*) is nonzero, then, subject to the same constraints and rules as **KEYCTL_LINK**, the key is linked into the keyring whose ID is specified in *arg5*. If the destination keyring specified in *arg5* already contains a link to a key that has the same type and description, then that link will be displaced by a link to the key found by this operation.

Instead of valid existing keyring IDs, the source (*arg2*) and destination (*arg5*) keyrings can be one of the special keyring IDs listed under **KEYCTL_GET_KEYRING_ID**.

This operation is exposed by *libkeyutils* via the function *keyctl_search*(3)

KEYCTL_READ (since Linux 2.6.10)
Read the payload data of a key.

The ID of the key whose payload is to be read is specified in *arg2* (cast to *key_serial_t*). This can be the ID of an existing key, or any of the special key IDs listed for **KEYCTL_GET_KEYRING_ID**.

The payload is placed in the buffer pointed by *arg3* (cast to *char* *); the size of that buffer must be specified in *arg4* (cast to *size_t*).

The returned data will be processed for presentation according to the key type. For example, a keyring will return an array of *key_serial_t* entries representing the IDs of all the keys that are linked to it. The *user* key type will return its data as is. If a key type does not implement this function, the operation fails with the error **EOPNOTSUPP**.

If *arg3* is not NULL, as much of the payload data as will fit is copied into the buffer. On a successful return, the return value is always the total size of the payload data. To determine whether the buffer was of sufficient size, check to see that the return value is less than or equal to the value supplied in *arg4*.

The key must either grant the caller *read* permission, or grant the caller *search* permission when searched for from the process keyrings (i.e., the key is possessed).

The *arg5* argument is ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_read*(3)

KEYCTL_INSTANTIATE (since Linux 2.6.10)
(Positively) instantiate an uninstantiated key with a specified payload.

The ID of the key to be instantiated is provided in *arg2* (cast to *key_serial_t*).

The key payload is specified in the buffer pointed to by *arg3* (cast to *void* *); the size of that buffer is specified in *arg4* (cast to *size_t*).

The payload may be a null pointer and the buffer size may be 0 if this is supported by the key type (e.g., it is a keyring).

The operation may be fail if the payload data is in the wrong format or is otherwise invalid.

If *arg5* (cast to *key_serial_t*) is nonzero, then, subject to the same constraints and rules as **KEYCTL_LINK**, the instantiated key is linked into the keyring whose ID specified in *arg5*.

The caller must have the appropriate authorization key, and once the uninstantiated key has been instantiated, the authorization key is revoked. In other words, this operation is available only from a *request-key*(8)-style program. See *request_key*(2) for an explanation of uninstantiated keys and key instantiation.

This operation is exposed by *libkeyutils* via the function *keyctl_instantiate*(3)

KEYCTL_NEGATE (since Linux 2.6.10)
Negatively instantiate an uninstantiated key.

This operation is equivalent to the call:

```
keyctl(KEYCTL_REJECT, arg2, arg3, ENOKEY, arg4);
```

The *arg5* argument is ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_negate*(3)

KEYCTL_SET_REQKEY_KEYRING (since Linux 2.6.13)
Set the default keyring to which implicitly requested keys will be linked for this thread, and return the previous setting. Implicit key requests are those made by internal kernel components, such as can occur when, for example, opening files on an AFS or NFS filesystem. Setting the default keyring also has an effect when requesting a key from user space; see *request_key*(2) for details.

The *arg2* argument (cast to *int*) should contain one of the following values, to specify the new default keyring:

KEY_REQKEY_DEFL_NO_CHANGE
Don't change the default keyring. This can be used to discover the current default keyring (without changing it).

KEY_REQKEY_DEFL_DEFAULT
This selects the default behaviour, which is to use the thread-specific keyring if there is one, otherwise the process-specific keyring if there is one, otherwise the session keyring if there is one, otherwise the UID-specific session keyring, otherwise the user-specific keyring.

KEY_REQKEY_DEFL_THREAD_KEYRING
Use the thread-specific keyring (**thread−keyring**(7)) as the new default keyring.

KEY_REQKEY_DEFL_PROCESS_KEYRING
Use the process-specific keyring (**process−keyring**(7)) as the new default keyring.

KEY_REQKEY_DEFL_SESSION_KEYRING
Use the session-specific keyring (**session−keyring**(7)) as the new default keyring.

KEY_REQKEY_DEFL_USER_KEYRING
Use the UID-specific keyring (**user−keyring**(7)) as the new default keyring.

KEY_REQKEY_DEFL_USER_SESSION_KEYRING
Use the UID-specific session keyring (**user−session−keyring**(7)) as the new default keyring.

KEY_REQKEY_DEFL_REQUESTOR_KEYRING (since Linux 2.6.29)
Use the requestor keyring.

All other values are invalid.

The arguments *arg3*, *arg4*, and *arg5* are ignored.

The setting controlled by this operation is inherited by the child of *fork*(2) and preserved across *execve*(2).

This operation is exposed by *libkeyutils* via the function *keyctl_set_reqkey_keyring*(3)

KEYCTL_SET_TIMEOUT (since Linux 2.6.16)
Set a timeout on a key.

The ID of the key is specified in *arg2* (cast to *key_serial_t*). The timeout value, in seconds from the current time, is specified in *arg3* (cast to *unsigned int*). The timeout is measured against the realtime clock.

Specifying the timeout value as 0 clears any existing timeout on the key.

The */proc/keys* file displays the remaining time until each key will expire. (This is the only method of discovering the timeout on a key.)

The caller must either have the *setattr* permission on the key or hold an instantiation authorization token for the key (see *request_key*(2)).

The key and any links to the key will be automatically garbage collected after the timeout expires. Subsequent attempts to access the key will then fail with the error **EKEYEXPIRED**.

This operation cannot be used to set timeouts on revoked, expired, or negatively instantiated keys.

The arguments *arg4* and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_set_timeout*(3)

KEYCTL_ASSUME_AUTHORITY (since Linux 2.6.16)
Assume (or divest) the authority for the calling thread to instantiate a key.

The *arg2* argument (cast to *key_serial_t*) specifies either a nonzero key ID to assume authority, or the value 0 to divest authority.

If *arg2* is nonzero, then it specifies the ID of an uninstantiated key for which authority is to be assumed. That key can then be instantiated using one of **KEYCTL_INSTANTIATE**, **KEYCTL_INSTANTIATE_IOV**, **KEYCTL_REJECT**, or **KEYCTL_NEGATE**. Once the key has been instantiated, the thread is automatically divested of authority to instantiate the key.

Authority over a key can be assumed only if the calling thread has present in its keyrings the authorization key that is associated with the specified key. (In other words, the **KEYCTL_ASSUME_AUTHORITY** operation is available only from a *request-key*(8)-style program; see *request_key*(2) for an explanation of how this operation is used.) The caller must have *search* permission on the authorization key.

If the specified key has a matching authorization key, then the ID of that key is returned. The authorization key can be read (**KEYCTL_READ**) to obtain the callout information passed to *request_key*(2).

If the ID given in *arg2* is 0, then the currently assumed authority is cleared (divested), and the value 0 is returned.

The **KEYCTL_ASSUME_AUTHORITY** mechanism allows a program such as *request-key*(8) to assume the necessary authority to instantiate a new uninstantiated key that was created as a consequence of a call to *request_key*(2). For further information, see *request_key*(2) and the kernel source file *Documentation/security/keys−request−key.txt*.

The arguments *arg3*, *arg4*, and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_assume_authority*(3)

KEYCTL_GET_SECURITY (since Linux 2.6.26)
Get the LSM (Linux Security Module) security label of the specified key.

The ID of the key whose security label is to be fetched is specified in *arg2* (cast to *key_serial_t*). The security label (terminated by a null byte) will be placed in the buffer pointed to by *arg3* argument (cast to *char **); the size of the buffer must be provided in *arg4* (cast to *size_t*).

If *arg3* is specified as NULL or the buffer size specified in *arg4* is too small, the full size of the security label string (including the terminating null byte) is returned as the function result, and nothing is copied to the buffer.

The caller must have *view* permission on the specified key.

The returned security label string will be rendered in a form appropriate to the LSM in force. For example, with SELinux, it may look like:

```
unconfined_u:unconfined_r:unconfined_t:s0-s0:c0.c1023
```

If no LSM is currently in force, then an empty string is placed in the buffer.

The *arg5* argument is ignored.

This operation is exposed by *libkeyutils* via the functions *keyctl_get_security*(3) and *keyctl_get_security_alloc*(3)

KEYCTL_SESSION_TO_PARENT (since Linux 2.6.32)
Replace the session keyring to which the *parent* of the calling process subscribes with the session keyring of the calling process.

The keyring will be replaced in the parent process at the point where the parent next transitions from kernel space to user space.

The keyring must exist and must grant the caller *link* permission. The parent process must be single-threaded and have the same effective ownership as this process and must not be set-user-ID or set-group-ID. The UID of the parent process's existing session keyring (f it has one), as well as the UID of the caller's session keyring much match the caller's effective UID.

The fact that it is the parent process that is affected by this operation allows a program such as the shell to start a child process that uses this operation to change the shell's session keyring. (This is what the *keyctl*(1) **new_session** command does.)

The arguments *arg2*, *arg3*, *arg4*, and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_session_to_parent*(3)

KEYCTL_REJECT (since Linux 2.6.39)
Mark a key as negatively instantiated and set an expiration timer on the key. This operation provides a superset of the functionality of the earlier **KEYCTL_NEGATE** operation.

The ID of the key that is to be negatively instantiated is specified in *arg2* (cast to *key_serial_t*). The *arg3* (cast to *unsigned int*) argument specifies the lifetime of the key, in seconds. The *arg4* argument (cast to *unsigned int*) specifies the error to be returned when a search hits this key; typically, this is one of **EKEYREJECTED**, **EKEYREVOKED**, or **EKEYEXPIRED**.

If *arg5* (cast to *key_serial_t*) is nonzero, then, subject to the same constraints and rules as **KEYCTL_LINK**, the negatively instantiated key is linked into the keyring whose ID is specified in *arg5*.

The caller must have the appropriate authorization key. In other words, this operation is available only from a *request-key*(8)-style program. See *request_key*(2).

The caller must have the appropriate authorization key, and once the uninstantiated key has been instantiated, the authorization key is revoked. In other words, this operation is available only from a *request-key*(8)-style program. See *request_key*(2) for an explanation of uninstantiated keys and key instantiation.

This operation is exposed by *libkeyutils* via the function *keyctl_reject*(3)

KEYCTL_INSTANTIATE_IOV (since Linux 2.6.39)
Instantiate an uninstantiated key with a payload specified via a vector of buffers.

This operation is the same as **KEYCTL_INSTANTIATE**, but the payload data is specified as an array of *iovec* structures (see *iovec*(3type)).

The pointer to the payload vector is specified in *arg3* (cast as *const struct iovec* *). The number of items in the vector is specified in *arg4* (cast as *unsigned int*).

The *arg2* (key ID) and *arg5* (keyring ID) are interpreted as for **KEYCTL_INSTANTIATE**.

This operation is exposed by *libkeyutils* via the function *keyctl_instantiate_iov*(3)

KEYCTL_INVALIDATE (since Linux 3.5)
Mark a key as invalid.

The ID of the key to be invalidated is specified in *arg2* (cast to *key_serial_t*).

To invalidate a key, the caller must have *search* permission on the key.

This operation marks the key as invalid and schedules immediate garbage collection. The garbage collector removes the invalidated key from all keyrings and deletes the key when its reference count reaches zero. After this operation, the key will be ignored by all searches, even if it is not yet deleted.

Keys that are marked invalid become invisible to normal key operations immediately, though they are still visible in */proc/keys* (marked with an 'i' flag) until they are actually removed.

The arguments *arg3*, *arg4*, and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_invalidate*(3)

KEYCTL_GET_PERSISTENT (since Linux 3.13)
Get the persistent keyring (**persistent−keyring**(7)) for a specified user and link it to a specified keyring.

The user ID is specified in *arg2* (cast to *uid_t*). If the value −1 is specified, the caller's real user ID is used. The ID of the destination keyring is specified in *arg3* (cast to *key_serial_t*).

The caller must have the **CAP_SETUID** capability in its user namespace in order to fetch the persistent keyring for a user ID that does not match either the real or effective user ID of the caller.

If the call is successful, a link to the persistent keyring is added to the keyring whose ID was specified in *arg3*.

The caller must have *write* permission on the keyring.

The persistent keyring will be created by the kernel if it does not yet exist.

Each time the **KEYCTL_GET_PERSISTENT** operation is performed, the persistent keyring will have its expiration timeout reset to the value in:

```
/proc/sys/kernel/keys/persistent_keyring_expiry
```

Should the timeout be reached, the persistent keyring will be removed and everything it pins can then be garbage collected.

Persistent keyrings were added in Linux 3.13.

The arguments *arg4* and *arg5* are ignored.

This operation is exposed by *libkeyutils* via the function *keyctl_get_persistent*(3)

KEYCTL_DH_COMPUTE (since Linux 4.7)
Compute a Diffie-Hellman shared secret or public key, optionally applying key derivation function (KDF) to the result.

The *arg2* argument is a pointer to a set of parameters containing serial numbers for three *"user"* keys used in the Diffie-Hellman calculation, packaged in a structure of the following form:

```
struct keyctl_dh_params {
    int32_t private; /* The local private key */
    int32_t prime; /* The prime, known to both parties */
    int32_t base;  /* The base integer: either a shared
                      generator or the remote public key */
};
```

Each of the three keys specified in this structure must grant the caller *read* permission. The payloads of these keys are used to calculate the Diffie-Hellman result as:

```
base ^ private mod prime
```

If the base is the shared generator, the result is the local public key. If the base is the remote public key, the result is the shared secret.

The *arg3* argument (cast to *char* *) points to a buffer where the result of the calculation is placed. The size of that buffer is specified in *arg4* (cast to *size_t*).

The buffer must be large enough to accommodate the output data, otherwise an error is returned. If *arg4* is specified zero, in which case the buffer is not used and the operation returns the minimum required buffer size (i.e., the length of the prime).

Diffie-Hellman computations can be performed in user space, but require a multiple-precision integer (MPI) library. Moving the implementation into the kernel gives access to the kernel MPI implementation, and allows access to secure or acceleration hardware.

Adding support for DH computation to the **keyctl**() system call was considered a good fit due to the DH algorithm's use for deriving shared keys; it also allows the type of the key to determine which DH implementation (software or hardware) is appropriate.

If the *arg5* argument is **NULL**, then the DH result itself is returned. Otherwise (since Linux 4.12), it is a pointer to a structure which specifies parameters of the KDF operation to be applied:

```
struct keyctl_kdf_params {
    char *hashname;     /* Hash algorithm name */
    char *otherinfo;    /* SP800-56A OtherInfo */
    __u32 otherinfolen; /* Length of otherinfo data */
    __u32 __spare[8];   /* Reserved */
};
```

The *hashname* field is a null-terminated string which specifies a hash name (available in the kernel's crypto API; the list of the hashes available is rather tricky to observe; please refer to the "Kernel Crypto API Architecture" documentation for the information regarding how hash names are constructed and your kernel's source and configuration regarding what ciphers and templates with type **CRYPTO_ALG_TYPE_SHASH** are available) to be applied to DH result in KDF operation.

The *otherinfo* field is an *OtherInfo* data as described in SP800-56A section 5.8.1.2 and is algorithm-specific. This data is concatenated with the result of DH operation and is provided as an input to the KDF operation. Its size is provided in the *otherinfolen* field and is limited by **KEYCTL_KDF_MAX_OI_LEN** constant that defined in *security/keys/internal.h* to a value of 64.

The **__spare** field is currently unused. It was ignored until Linux 4.13 (but still should be user-addressable since it is copied to the kernel), and should contain zeros since Linux 4.13.

The KDF implementation complies with SP800-56A as well as with SP800-108 (the counter KDF).

This operation is exposed by *libkeyutils* (from *libkeyutils* 1.5.10 onwards) via the functions *keyctl_dh_compute*(3) and *keyctl_dh_compute_alloc*(3)

KEYCTL_RESTRICT_KEYRING (since Linux 4.12)
Apply a key-linking restriction to the keyring with the ID provided in *arg2* (cast to *key_serial_t*). The caller must have *setattr* permission on the key. If *arg3* is NULL, any attempt to add a key to the keyring is blocked; otherwise it contains a pointer to a string with a key type name and *arg4* contains a pointer to string that describes the type-specific restriction. As of Linux 4.12, only the type "asymmetric" has restrictions defined:

builtin_trusted
Allows only keys that are signed by a key linked to the built-in keyring (".builtin_trusted_keys").

builtin_and_secondary_trusted
Allows only keys that are signed by a key linked to the secondary keyring (".secondary_trusted_keys") or, by extension, a key in a built-in keyring, as the latter is linked to the former.

key_or_keyring:*key*
key_or_keyring:*key***:chain**
If *key* specifies the ID of a key of type "asymmetric", then only keys that are signed by this key are allowed.

If *key* specifies the ID of a keyring, then only keys that are signed by a key linked to this keyring are allowed.

If ":chain" is specified, keys that are signed by a keys linked to the destination keyring (that is, the keyring with the ID specified in the *arg2* argument) are also allowed.

Note that a restriction can be configured only once for the specified keyring; once a restriction is set, it can't be overridden.

The argument *arg5* is ignored.

RETURN VALUE

For a successful call, the return value depends on the operation:

KEYCTL_GET_KEYRING_ID
The ID of the requested keyring.

KEYCTL_JOIN_SESSION_KEYRING
The ID of the joined session keyring.

KEYCTL_DESCRIBE
The size of the description (including the terminating null byte), irrespective of the provided buffer size.

KEYCTL_SEARCH
The ID of the key that was found.

KEYCTL_READ
The amount of data that is available in the key, irrespective of the provided buffer size.

KEYCTL_SET_REQKEY_KEYRING
The ID of the previous default keyring to which implicitly requested keys were linked (one of **KEY_REQKEY_DEFL_USER_***).

KEYCTL_ASSUME_AUTHORITY
Either 0, if the ID given was 0, or the ID of the authorization key matching the specified key, if a nonzero key ID was provided.

KEYCTL_GET_SECURITY
The size of the LSM security label string (including the terminating null byte), irrespective of the provided buffer size.

KEYCTL_GET_PERSISTENT
The ID of the persistent keyring.

KEYCTL_DH_COMPUTE
The number of bytes copied to the buffer, or, if *arg4* is 0, the required buffer size.

All other operations
Zero.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
The requested operation wasn't permitted.

EAGAIN
operation was **KEYCTL_DH_COMPUTE** and there was an error during crypto module initialization.

EDEADLK
operation was **KEYCTL_LINK** and the requested link would result in a cycle.

EDEADLK
operation was **KEYCTL_RESTRICT_KEYRING** and the requested keyring restriction would result in a cycle.

EDQUOT
The key quota for the caller's user would be exceeded by creating a key or linking it to the keyring.

EEXIST
operation was **KEYCTL_RESTRICT_KEYRING** and keyring provided in *arg2* argument already has a restriction set.

EFAULT
operation was **KEYCTL_DH_COMPUTE** and one of the following has failed:

- copying of the *struct keyctl_dh_params*, provided in the *arg2* argument, from user space;
- copying of the *struct keyctl_kdf_params*, provided in the non-NULL *arg5* argument, from user space (in case kernel supports performing KDF operation on DH operation result);
- copying of data pointed by the *hashname* field of the *struct keyctl_kdf_params* from user space;
- copying of data pointed by the *otherinfo* field of the *struct keyctl_kdf_params* from user space if the *otherinfolen* field was nonzero;
- copying of the result to user space.

EINVAL
operation was **KEYCTL_SETPERM** and an invalid permission bit was specified in *arg3*.

EINVAL
operation was **KEYCTL_SEARCH** and the size of the description in *arg4* (including the terminating null byte) exceeded 4096 bytes.

EINVAL
size of the string (including the terminating null byte) specified in *arg3* (the key type) or *arg4* (the key description) exceeded the limit (32 bytes and 4096 bytes respectively).

EINVAL (before Linux 4.12)
operation was **KEYCTL_DH_COMPUTE**, argument *arg5* was non-NULL.

EINVAL
operation was **KEYCTL_DH_COMPUTE** And the digest size of the hashing algorithm supplied is zero.

EINVAL
operation was **KEYCTL_DH_COMPUTE** and the buffer size provided is not enough to hold the result. Provide 0 as a buffer size in order to obtain the minimum buffer size.

EINVAL
operation was **KEYCTL_DH_COMPUTE** and the hash name provided in the *hashname* field of the *struct keyctl_kdf_params* pointed by *arg5* argument is too big (the limit is implementation-specific and varies between kernel versions, but it is deemed big enough for all valid algorithm names).

EINVAL
operation was **KEYCTL_DH_COMPUTE** and the *__spare* field of the *struct keyctl_kdf_params* provided in the *arg5* argument contains nonzero values.

EKEYEXPIRED
An expired key was found or specified.

EKEYREJECTED
A rejected key was found or specified.

EKEYREVOKED
A revoked key was found or specified.

ELOOP
operation was **KEYCTL_LINK** and the requested link would cause the maximum nesting depth for keyrings to be exceeded.

EMSGSIZE
operation was **KEYCTL_DH_COMPUTE** and the buffer length exceeds **KEYCTL_KDF_MAX_OUTPUT_LEN** (which is 1024 currently) or the *otherinfolen* field of the *struct keyctl_kdf_parms* passed in *arg5* exceeds **KEYCTL_KDF_MAX_OI_LEN** (which is 64 currently).

ENFILE (before Linux 3.13)
operation was **KEYCTL_LINK** and the keyring is full. (Before Linux 3.13, the available space for storing keyring links was limited to a single page of memory; since Linux 3.13, there is no fixed limit.)

ENOENT
operation was **KEYCTL_UNLINK** and the key to be unlinked isn't linked to the keyring.

ENOENT
operation was **KEYCTL_DH_COMPUTE** and the hashing algorithm specified in the *hashname* field of the *struct keyctl_kdf_params* pointed by *arg5* argument hasn't been found.

ENOENT
operation was **KEYCTL_RESTRICT_KEYRING** and the type provided in *arg3* argument doesn't support setting key linking restrictions.

ENOKEY
No matching key was found or an invalid key was specified.

ENOKEY
The value **KEYCTL_GET_KEYRING_ID** was specified in *operation*, the key specified in *arg2* did not exist, and *arg3* was zero (meaning don't create the key if it didn't exist).

ENOMEM
One of kernel memory allocation routines failed during the execution of the syscall.

ENOTDIR
A key of keyring type was expected but the ID of a key with a different type was provided.

EOPNOTSUPP
operation was **KEYCTL_READ** and the key type does not support reading (e.g., the type is *"login"*).

EOPNOTSUPP
operation was **KEYCTL_UPDATE** and the key type does not support updating.

EOPNOTSUPP
operation was **KEYCTL_RESTRICT_KEYRING**, the type provided in *arg3* argument was "asymmetric", and the key specified in the restriction specification provided in *arg4* has type other than "asymmetric" or "keyring".

EPERM
operation was **KEYCTL_GET_PERSISTENT**, *arg2* specified a UID other than the calling thread's real or effective UID, and the caller did not have the **CAP_SETUID** capability.

EPERM
operation was **KEYCTL_SESSION_TO_PARENT** and either: all of the UIDs (GIDs) of the parent process do not match the effective UID (GID) of the calling process; the UID of the parent's existing session keyring or the UID of the caller's session keyring did not match the effective UID of the caller; the parent process is not single-thread; or the parent process is *init*(1) or a kernel thread.

ETIMEDOUT
operation was **KEYCTL_DH_COMPUTE** and the initialization of crypto modules has timed out.

VERSIONS
A wrapper is provided in the *libkeyutils* library. (The accompanying package provides the <*keyutils.h*> header file.) However, rather than using this system call directly, you probably want to use the various library functions mentioned in the descriptions of individual operations above.

STANDARDS
Linux.

HISTORY
Linux 2.6.10.

EXAMPLES
The program below provide subset of the functionality of the *request-key*(8) program provided by the *keyutils* package. For informational purposes, the program records various information in a log file.

As described in *request_key*(2), the *request-key*(8) program is invoked with command-line arguments that describe a key that is to be instantiated. The example program fetches and logs these arguments. The program assumes authority to instantiate the requested key, and then instantiates that key.

The following shell session demonstrates the use of this program. In the session, we compile the program and then use it to temporarily replace the standard *request-key*(8) program. (Note that temporarily disabling the standard *request-key*(8) program may not be safe on some systems.) While our example program is installed, we use the example program shown in *request_key*(2) to request a key.

```
$ cc -o key_instantiate key_instantiate.c -lkeyutils
$ sudo mv /sbin/request-key /sbin/request-key.backup
$ sudo cp key_instantiate /sbin/request-key
$ ./t_request_key user mykey somepayloaddata
Key ID is 20d035bf
$ sudo mv /sbin/request-key.backup /sbin/request-key
```

Looking at the log file created by this program, we can see the command-line arguments supplied to our example program:

```
$ cat /tmp/key_instantiate.log
Time: Mon Nov  7 13:06:47 2016

Command line arguments:
  argv[0]:            /sbin/request-key
  operation:          create
  key_to_instantiate: 20d035bf
  UID:                1000
  GID:                1000
  thread_keyring:     0
  process_keyring:    0
  session_keyring:    256e6a6

Key description:      user;1000;1000;3f010000;mykey
Auth key payload:     somepayloaddata
Destination keyring:  256e6a6
```

```
Auth key description: .request_key_auth;1000;1000;0b010000;20d035bf
```

The last few lines of the above output show that the example program was able to fetch:

- the description of the key to be instantiated, which included the name of the key (*mykey*);
- the payload of the authorization key, which consisted of the data (*somepayloaddata*) passed to *request_key*(2);
- the destination keyring that was specified in the call to *request_key*(2); and
- the description of the authorization key, where we can see that the name of the authorization key matches the ID of the key that is to be instantiated (*20d035bf*).

The example program in *request_key*(2) specified the destination keyring as **KEY_SPEC_SESSION_KEYRING**. By examining the contents of */proc/keys*, we can see that this was translated to the ID of the destination keyring (*0256e6a6*) shown in the log output above; we can also see the newly created key with the name *mykey* and ID *20d035bf*.

```
$ cat /proc/keys | egrep 'mykey|256e6a6'
0256e6a6 I--Q---  194 perm 3f030000  1000  1000 keyring  _ses: 3
20d035bf I--Q---    1 perm 3f010000  1000  1000 user     mykey: 16
```

NAME

kill − send signal to a process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <signal.h>

int kill(pid_t *pid***, int** *sig***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

kill():
_POSIX_C_SOURCE

DESCRIPTION

The **kill**() system call can be used to send any signal to any process group or process.

If *pid* is positive, then signal *sig* is sent to the process with the ID specified by *pid*.

If *pid* equals 0, then *sig* is sent to every process in the process group of the calling process.

If *pid* equals −1, then *sig* is sent to every process for which the calling process has permission to send signals, except for process 1 (*init*), but see below.

If *pid* is less than −1, then *sig* is sent to every process in the process group whose ID is *−pid*.

If *sig* is 0, then no signal is sent, but existence and permission checks are still performed; this can be used to check for the existence of a process ID or process group ID that the caller is permitted to signal.

For a process to have permission to send a signal, it must either be privileged (under Linux: have the **CAP_KILL** capability in the user namespace of the target process), or the real or effective user ID of the sending process must equal the real or saved set-user-ID of the target process. In the case of **SIGCONT**, it suffices when the sending and receiving processes belong to the same session. (Historically, the rules were different; see NOTES.)

RETURN VALUE

On success (at least one signal was sent), zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
An invalid signal was specified.

EPERM
The calling process does not have permission to send the signal to any of the target processes.

ESRCH
The target process or process group does not exist. Note that an existing process might be a zombie, a process that has terminated execution, but has not yet been *wait*(2)ed for.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

Linux notes

Across different kernel versions, Linux has enforced different rules for the permissions required for an unprivileged process to send a signal to another process. In Linux 1.0 to 1.2.2, a signal could be sent if the effective user ID of the sender matched effective user ID of the target, or the real user ID of the sender matched the real user ID of the target. From Linux 1.2.3 until 1.3.77, a signal could be sent if the effective user ID of the sender matched either the real or effective user ID of the target. The current rules, which conform to POSIX.1, were adopted in Linux 1.3.78.

NOTES

The only signals that can be sent to process ID 1, the *init* process, are those for which *init* has explicitly installed signal handlers. This is done to assure the system is not brought down accidentally.

POSIX.1 requires that *kill(−1,sig)* send *sig* to all processes that the calling process may send signals to,

except possibly for some implementation-defined system processes. Linux allows a process to signal itself, but on Linux the call *kill(−1,sig)* does not signal the calling process.

POSIX.1 requires that if a process sends a signal to itself, and the sending thread does not have the signal blocked, and no other thread has it unblocked or is waiting for it in *sigwait*(3), at least one unblocked signal must be delivered to the sending thread before the **kill**() returns.

BUGS

In Linux 2.6 up to and including Linux 2.6.7, there was a bug that meant that when sending signals to a process group, **kill**() failed with the error **EPERM** if the caller did not have permission to send the signal to *any* (rather than *all*) of the members of the process group. Notwithstanding this error return, the signal was still delivered to all of the processes for which the caller had permission to signal.

NAME

landlock_add_rule − add a new Landlock rule to a ruleset

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/landlock.h> /* Definition of **LANDLOCK_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */

int syscall(SYS_landlock_add_rule, int *ruleset_fd***,**
enum landlock_rule_type *rule_type***,**
const void ***rule_attr,* **uint32_t** *flags***);**

DESCRIPTION

A Landlock rule describes an action on an object. An object is currently a file hierarchy, and the related filesystem actions are defined with a set of access rights. This **landlock_add_rule**() system call enables adding a new Landlock rule to an existing ruleset created with *landlock_create_ruleset*(2). See *landlock*(7) for a global overview.

ruleset_fd is a Landlock ruleset file descriptor obtained with *landlock_create_ruleset*(2).

rule_type identifies the structure type pointed to by *rule_attr*. Currently, Linux supports the following *rule_type* value:

LANDLOCK_RULE_PATH_BENEATH
This defines the object type as a file hierarchy. In this case, *rule_attr* points to the following structure:

```
struct landlock_path_beneath_attr {
    __u64 allowed_access;
    __s32 parent_fd;
} __attribute__((packed));
```

allowed_access contains a bitmask of allowed filesystem actions for this file hierarchy (see **Filesystem actions** in *landlock*(7)).

parent_fd is an opened file descriptor, preferably with the *O_PATH* flag, which identifies the parent directory of the file hierarchy or just a file.

flags must be 0.

RETURN VALUE

On success, **landlock_add_rule**() returns 0.

ERRORS

landlock_add_rule() can fail for the following reasons:

EOPNOTSUPP
Landlock is supported by the kernel but disabled at boot time.

EINVAL
flags is not 0, or the rule accesses are inconsistent (i.e., *rule_attr−>allowed_access* is not a subset of the ruleset handled accesses).

ENOMSG
Empty accesses (i.e., *rule_attr−>allowed_access* is 0).

EBADF
ruleset_fd is not a file descriptor for the current thread, or a member of *rule_attr* is not a file descriptor as expected.

EBADFD
ruleset_fd is not a ruleset file descriptor, or a member of *rule_attr* is not the expected file descriptor type.

EPERM
ruleset_fd has no write access to the underlying ruleset.

EFAULT
rule_attr was not a valid address.

STANDARDS
Linux.

HISTORY
Linux 5.13.

EXAMPLES
See *landlock*(7).

SEE ALSO
landlock_create_ruleset(2), *landlock_restrict_self*(2), *landlock*(7)

NAME

landlock_create_ruleset − create a new Landlock ruleset

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/landlock.h> /* Definition of **LANDLOCK_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */

int syscall(SYS_landlock_create_ruleset,
const struct landlock_ruleset_attr ***attr*,**
size_t *size* **, uint32_t** *flags***);**

DESCRIPTION

A Landlock ruleset identifies a set of rules (i.e., actions on objects). This **landlock_create_ruleset**() system call enables creating a new file descriptor identifying a ruleset. This file descriptor can then be used by *landlock_add_rule*(2) and *landlock_restrict_self*(2). See *landlock*(7) for a global overview.

attr specifies the properties of the new ruleset. It points to the following structure:

```
struct landlock_ruleset_attr {
    __u64 handled_access_fs;
};
```

handled_access_fs is a bitmask of actions that is handled by this ruleset and should then be forbidden if no rule explicitly allows them (see **Filesystem actions** in *landlock*(7)). This enables simply restricting ambient rights (e.g., global filesystem access) and is needed for compatibility reasons.

size must be specified as *sizeof(struct landlock_ruleset_attr)* for compatibility reasons.

flags must be 0 if *attr* is used. Otherwise, *flags* can be set to:

LANDLOCK_CREATE_RULESET_VERSION
If *attr* is NULL and *size* is 0, then the returned value is the highest supported Landlock ABI version (starting at 1). This version can be used for a best-effort security approach, which is encouraged when user space is not pinned to a specific kernel version. All features documented in these man pages are available with the version 1.

RETURN VALUE

On success, **landlock_create_ruleset**() returns a new Landlock ruleset file descriptor, or a Landlock ABI version, according to *flags*.

ERRORS

landlock_create_ruleset() can fail for the following reasons:

EOPNOTSUPP
Landlock is supported by the kernel but disabled at boot time.

EINVAL
Unknown *flags*, or unknown access, or too small *size*.

E2BIG *size* is too big.

EFAULT
attr was not a valid address.

ENOMSG
Empty accesses (i.e., *attr−>handled_access_fs* is 0).

STANDARDS

Linux.

HISTORY

Linux 5.13.

EXAMPLES

See *landlock*(7).

NAME

landlock_restrict_self − enforce a Landlock ruleset

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/landlock.h> /* Definition of **LANDLOCK_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */

int syscall(SYS_landlock_restrict_self, int *ruleset_fd***,**
uint32_t *flags***);**

DESCRIPTION

Once a Landlock ruleset is populated with the desired rules, the **landlock_restrict_self**() system call enables enforcing this ruleset on the calling thread. See *landlock*(7) for a global overview.

A thread can be restricted with multiple rulesets that are then composed together to form the thread's Landlock domain. This can be seen as a stack of rulesets but it is implemented in a more efficient way. A domain can only be updated in such a way that the constraints of each past and future composed rulesets will restrict the thread and its future children for their entire life. It is then possible to gradually enforce tailored access control policies with multiple independent rulesets coming from different sources (e.g., init system configuration, user session policy, built-in application policy). However, most applications should only need one call to **landlock_restrict_self**() and they should avoid arbitrary numbers of such calls because of the composed rulesets limit. Instead, developers are encouraged to build a tailored ruleset thanks to multiple calls to *landlock_add_rule*(2).

In order to enforce a ruleset, either the caller must have the **CAP_SYS_ADMIN** capability in its user namespace, or the thread must already have the *no_new_privs* bit set. As for *seccomp*(2), this avoids scenarios where unprivileged processes can affect the behavior of privileged children (e.g., because of set-user-ID binaries). If that bit was not already set by an ancestor of this thread, the thread must make the following call:

```
prctl(PR_SET_NO_NEW_PRIVS, 1, 0, 0, 0);
```

ruleset_fd is a Landlock ruleset file descriptor obtained with *landlock_create_ruleset*(2) and fully populated with a set of calls to *landlock_add_rule*(2).

flags must be 0.

RETURN VALUE

On success, **landlock_restrict_self**() returns 0.

ERRORS

landlock_restrict_self() can fail for the following reasons:

EOPNOTSUPP
Landlock is supported by the kernel but disabled at boot time.

EINVAL
flags is not 0.

EBADF
ruleset_fd is not a file descriptor for the current thread.

EBADFD
ruleset_fd is not a ruleset file descriptor.

EPERM
ruleset_fd has no read access to the underlying ruleset, or the calling thread is not running with *no_new_privs*, or it doesn't have the **CAP_SYS_ADMIN** in its user namespace.

E2BIG The maximum number of composed rulesets is reached for the calling thread. This limit is currently 64.

STANDARDS

Linux.

HISTORY

Linux 5.13.

NAME

link, linkat − make a new name for a file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int link(const char *oldpath, const char *newpath);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <unistd.h>

int linkat(int olddirfd, const char *oldpath,
           int newdirfd, const char *newpath, int flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

linkat():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_ATFILE_SOURCE

DESCRIPTION

link() creates a new link (also known as a hard link) to an existing file.

If *newpath* exists, it will *not* be overwritten.

This new name may be used exactly as the old one for any operation; both names refer to the same file (and so have the same permissions and ownership) and it is impossible to tell which name was the "original".

linkat()

The **linkat**() system call operates in exactly the same way as **link**(), except for the differences described here.

If the pathname given in *oldpath* is relative, then it is interpreted relative to the directory referred to by the file descriptor *olddirfd* (rather than relative to the current working directory of the calling process, as is done by **link**() for a relative pathname).

If *oldpath* is relative and *olddirfd* is the special value **AT_FDCWD**, then *oldpath* is interpreted relative to the current working directory of the calling process (like *link*())

If *oldpath* is absolute, then *olddirfd* is ignored.

The interpretation of *newpath* is as for *oldpath*, except that a relative pathname is interpreted relative to the directory referred to by the file descriptor *newdirfd*.

The following values can be bitwise ORed in *flags*:

AT_EMPTY_PATH (since Linux 2.6.39)
If *oldpath* is an empty string, create a link to the file referenced by *olddirfd* (which may have been obtained using the *open*(2) **O_PATH** flag). In this case, *olddirfd* can refer to any type of file except a directory. This will generally not work if the file has a link count of zero (files created with **O_TMPFILE** and without **O_EXCL** are an exception). The caller must have the **CAP_DAC_READ_SEARCH** capability in order to use this flag. This flag is Linux-specific; define **_GNU_SOURCE** to obtain its definition.

AT_SYMLINK_FOLLOW (since Linux 2.6.18)
By default, **linkat**(), does not dereference *oldpath* if it is a symbolic link (like *link*())The flag **AT_SYMLINK_FOLLOW** can be specified in *flags* to cause *oldpath* to be dereferenced if it is a symbolic link. If procfs is mounted, this can be used as an alternative to **AT_EMPTY_PATH**, like this:

```
linkat(AT_FDCWD, "/proc/self/fd/<fd>", newdirfd,
       newname, AT_SYMLINK_FOLLOW);
```

Before Linux 2.6.18, the *flags* argument was unused, and had to be specified as 0.

See *openat*(2) for an explanation of the need for **linkat**().

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
Write access to the directory containing *newpath* is denied, or search permission is denied for one of the directories in the path prefix of *oldpath* or *newpath*. (See also *path_resolution*(7).)

EDQUOT
The user's quota of disk blocks on the filesystem has been exhausted.

EEXIST
newpath already exists.

EFAULT
oldpath or *newpath* points outside your accessible address space.

EIO An I/O error occurred.

ELOOP
Too many symbolic links were encountered in resolving *oldpath* or *newpath*.

EMLINK
The file referred to by *oldpath* already has the maximum number of links to it. For example, on an *ext4*(5) filesystem that does not employ the *dir_index* feature, the limit on the number of hard links to a file is 65,000; on *btrfs*(5), the limit is 65,535 links.

ENAMETOOLONG
oldpath or *newpath* was too long.

ENOENT
A directory component in *oldpath* or *newpath* does not exist or is a dangling symbolic link.

ENOMEM
Insufficient kernel memory was available.

ENOSPC
The device containing the file has no room for the new directory entry.

ENOTDIR
A component used as a directory in *oldpath* or *newpath* is not, in fact, a directory.

EPERM
oldpath is a directory.

EPERM
The filesystem containing *oldpath* and *newpath* does not support the creation of hard links.

EPERM (since Linux 3.6)
The caller does not have permission to create a hard link to this file (see the description of */proc/sys/fs/protected_hardlinks* in *proc*(5)).

EPERM
oldpath is marked immutable or append-only. (See *ioctl_iflags*(2).)

EROFS
The file is on a read-only filesystem.

EXDEV
oldpath and *newpath* are not on the same mounted filesystem. (Linux permits a filesystem to be mounted at multiple points, but **link**() does not work across different mounts, even if the same filesystem is mounted on both.)

The following additional errors can occur for **linkat**():

EBADF
oldpath (*newpath*) is relative but *olddirfd* (*newdirfd*) is neither **AT_FDCWD** nor a valid file descriptor.

EINVAL
An invalid flag value was specified in *flags*.

ENOENT
AT_EMPTY_PATH was specified in *flags*, but the caller did not have the **CAP_DAC_READ_SEARCH** capability.

ENOENT
An attempt was made to link to the */proc/self/fd/NN* file corresponding to a file descriptor created with

```
open(path, O_TMPFILE | O_EXCL, mode);
```

See *open*(2).

ENOENT
An attempt was made to link to a */proc/self/fd/NN* file corresponding to a file that has been deleted.

ENOENT
oldpath is a relative pathname and *olddirfd* refers to a directory that has been deleted, or *newpath* is a relative pathname and *newdirfd* refers to a directory that has been deleted.

ENOTDIR
oldpath is relative and *olddirfd* is a file descriptor referring to a file other than a directory; or similar for *newpath* and *newdirfd*

EPERM
AT_EMPTY_PATH was specified in *flags*, *oldpath* is an empty string, and *olddirfd* refers to a directory.

VERSIONS

POSIX.1-2001 says that **link**() should dereference *oldpath* if it is a symbolic link. However, since Linux 2.0, Linux does not do so: if *oldpath* is a symbolic link, then *newpath* is created as a (hard) link to the same symbolic link file (i.e., *newpath* becomes a symbolic link to the same file that *oldpath* refers to). Some other implementations behave in the same manner as Linux. POSIX.1-2008 changes the specification of **link**(), making it implementation-dependent whether or not *oldpath* is dereferenced if it is a symbolic link. For precise control over the treatment of symbolic links when creating a link, use **linkat**().

glibc
On older kernels where **linkat**() is unavailable, the glibc wrapper function falls back to the use of **link**(), unless the **AT_SYMLINK_FOLLOW** is specified. When *oldpath* and *newpath* are relative pathnames, glibc constructs pathnames based on the symbolic links in */proc/self/fd* that correspond to the *olddirfd* and *newdirfd* arguments.

STANDARDS

link() POSIX.1-2008.

HISTORY

link() SVr4, 4.3BSD, POSIX.1-2001 (but see VERSIONS).

linkat()
POSIX.1-2008. Linux 2.6.16, glibc 2.4.

NOTES

Hard links, as created by **link**(), cannot span filesystems. Use *symlink*(2) if this is required.

BUGS

On NFS filesystems, the return code may be wrong in case the NFS server performs the link creation and dies before it can say so. Use *stat*(2) to find out if the link got created.

ln(1), *open*(2), *rename*(2), *stat*(2), *symlink*(2), *unlink*(2), *path_resolution*(7), *symlink*(7)

NAME

listen − listen for connections on a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/socket.h>

int listen(int *sockfd***, int** *backlog***);**

DESCRIPTION

listen() marks the socket referred to by *sockfd* as a passive socket, that is, as a socket that will be used to accept incoming connection requests using *accept*(2).

The *sockfd* argument is a file descriptor that refers to a socket of type **SOCK_STREAM** or **SOCK_SEQPACKET**.

The *backlog* argument defines the maximum length to which the queue of pending connections for *sockfd* may grow. If a connection request arrives when the queue is full, the client may receive an error with an indication of **ECONNREFUSED** or, if the underlying protocol supports retransmission, the request may be ignored so that a later reattempt at connection succeeds.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EADDRINUSE
Another socket is already listening on the same port.

EADDRINUSE
(Internet domain sockets) The socket referred to by *sockfd* had not previously been bound to an address and, upon attempting to bind it to an ephemeral port, it was determined that all port numbers in the ephemeral port range are currently in use. See the discussion of */proc/sys/net/ipv4/ip_local_port_range* in *ip*(7).

EBADF
The argument *sockfd* is not a valid file descriptor.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

EOPNOTSUPP
The socket is not of a type that supports the **listen**() operation.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.4BSD (first appeared in 4.2BSD).

NOTES

To accept connections, the following steps are performed:

(1) A socket is created with *socket*(2).

(2) The socket is bound to a local address using *bind*(2), so that other sockets may be *connect*(2)ed to it.

(3) A willingness to accept incoming connections and a queue limit for incoming connections are specified with **listen**().

(4) Connections are accepted with *accept*(2).

The behavior of the *backlog* argument on TCP sockets changed with Linux 2.2. Now it specifies the queue length for *completely* established sockets waiting to be accepted, instead of the number of incomplete connection requests. The maximum length of the queue for incomplete sockets can be set using */proc/sys/net/ipv4/tcp_max_syn_backlog*. When syncookies are enabled there is no logical maximum length and this setting is ignored. See *tcp*(7) for more information.

If the *backlog* argument is greater than the value in */proc/sys/net/core/somaxconn*, then it is silently

capped to that value. Since Linux 5.4, the default in this file is 4096; in earlier kernels, the default value is 128. Before Linux 2.4.25, this limit was a hard coded value, **SOMAXCONN**, with the value 128.

EXAMPLES

See *bind*(2).

SEE ALSO

accept(2), *bind*(2), *connect*(2), *socket*(2), *socket*(7)

NAME

listxattr, llistxattr, flistxattr − list extended attribute names

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/xattr.h>

ssize_t listxattr(const char *path, char *_Nullable list, size_t size);
ssize_t llistxattr(const char *path, char *_Nullable list, size_t size);
ssize_t flistxattr(int fd, char *_Nullable list, size_t size);
```

DESCRIPTION

Extended attributes are *name*:*value* pairs associated with inodes (files, directories, symbolic links, etc.). They are extensions to the normal attributes which are associated with all inodes in the system (i.e., the *stat*(2) data). A complete overview of extended attributes concepts can be found in *xattr*(7).

listxattr() retrieves the list of extended attribute names associated with the given *path* in the filesystem. The retrieved list is placed in *list*, a caller-allocated buffer whose size (in bytes) is specified in the argument *size*. The list is the set of (null-terminated) names, one after the other. Names of extended attributes to which the calling process does not have access may be omitted from the list. The length of the attribute name *list* is returned.

llistxattr() is identical to **listxattr**(), except in the case of a symbolic link, where the list of names of extended attributes associated with the link itself is retrieved, not the file that it refers to.

flistxattr() is identical to **listxattr**(), only the open file referred to by *fd* (as returned by *open*(2)) is interrogated in place of *path*.

A single extended attribute *name* is a null-terminated string. The name includes a namespace prefix; there may be several, disjoint namespaces associated with an individual inode.

If *size* is specified as zero, these calls return the current size of the list of extended attribute names (and leave *list* unchanged). This can be used to determine the size of the buffer that should be supplied in a subsequent call. (But, bear in mind that there is a possibility that the set of extended attributes may change between the two calls, so that it is still necessary to check the return status from the second call.)

Example

The *list* of names is returned as an unordered array of null-terminated character strings (attribute names are separated by null bytes ('\0')), like this:

```
user.name1\0system.name1\0user.name2\0
```

Filesystems that implement POSIX ACLs using extended attributes might return a *list* like this:

```
system.posix_acl_access\0system.posix_acl_default\0
```

RETURN VALUE

On success, a nonnegative number is returned indicating the size of the extended attribute name list. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

E2BIG The size of the list of extended attribute names is larger than the maximum size allowed; the list cannot be retrieved. This can happen on filesystems that support an unlimited number of extended attributes per file such as XFS, for example. See BUGS.

ENOTSUP
Extended attributes are not supported by the filesystem, or are disabled.

ERANGE
The *size* of the *list* buffer is too small to hold the result.

In addition, the errors documented in *stat*(2) can also occur.

STANDARDS

Linux.

HISTORY

Linux 2.4, glibc 2.3.

BUGS

As noted in *xattr*(7), the VFS imposes a limit of 64 kB on the size of the extended attribute name list returned by **listxattr**(). If the total size of attribute names attached to a file exceeds this limit, it is no longer possible to retrieve the list of attribute names.

EXAMPLES

The following program demonstrates the usage of **listxattr**() and *getxattr*(2). For the file whose pathname is provided as a command-line argument, it lists all extended file attributes and their values.

To keep the code simple, the program assumes that attribute keys and values are constant during the execution of the program. A production program should expect and handle changes during execution of the program. For example, the number of bytes required for attribute keys might increase between the two calls to **listxattr**(). An application could handle this possibility using a loop that retries the call (perhaps up to a predetermined maximum number of attempts) with a larger buffer each time it fails with the error **ERANGE**. Calls to *getxattr*(2) could be handled similarly.

The following output was recorded by first creating a file, setting some extended file attributes, and then listing the attributes with the example program.

Example output

```
$ touch /tmp/foo
$ setfattr -n user.fred -v chocolate /tmp/foo
$ setfattr -n user.frieda -v bar /tmp/foo
$ setfattr -n user.empty /tmp/foo
$ ./listxattr /tmp/foo
user.fred: chocolate
user.frieda: bar
user.empty: <no value>
```

Program source (listxattr.c)

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/xattr.h>

int
main(int argc, char *argv[])
{
    char     *buf, *key, *val;
    ssize_t  buflen, keylen, vallen;

    if (argc != 2) {
        fprintf(stderr, "Usage: %s path\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    /*
     * Determine the length of the buffer needed.
     */
    buflen = listxattr(argv[1], NULL, 0);
    if (buflen == -1) {
        perror("listxattr");
        exit(EXIT_FAILURE);
    }
    if (buflen == 0) {
        printf("%s has no attributes.\n", argv[1]);
        exit(EXIT_SUCCESS);
    }
```

```
/*
 * Allocate the buffer.
 */
buf = malloc(buflen);
if (buf == NULL) {
    perror("malloc");
    exit(EXIT_FAILURE);
}

/*
 * Copy the list of attribute keys to the buffer.
 */
buflen = listxattr(argv[1], buf, buflen);
if (buflen == -1) {
    perror("listxattr");
    exit(EXIT_FAILURE);
}

/*
 * Loop over the list of zero terminated strings with the
 * attribute keys. Use the remaining buffer length to determine
 * the end of the list.
 */
key = buf;
while (buflen > 0) {

    /*
     * Output attribute key.
     */
    printf("%s: ", key);

    /*
     * Determine length of the value.
     */
    vallen = getxattr(argv[1], key, NULL, 0);
    if (vallen == -1)
        perror("getxattr");

    if (vallen > 0) {

        /*
         * Allocate value buffer.
         * One extra byte is needed to append 0x00.
         */
        val = malloc(vallen + 1);
        if (val == NULL) {
            perror("malloc");
            exit(EXIT_FAILURE);
        }

        /*
         * Copy value to buffer.
         */
        vallen = getxattr(argv[1], key, val, vallen);
        if (vallen == -1) {
            perror("getxattr");
        } else {
            /*
             * Output attribute value.
```

```
                     */
                    val[vallen] = 0;
                    printf("%s", val);
                }

                free(val);
            } else if (vallen == 0) {
                printf("<no value>");
            }

            printf("\n");

            /*
             * Forward to next attribute key.
             */
            keylen = strlen(key) + 1;
            buflen -= keylen;
            key += keylen;
        }

        free(buf);
        exit(EXIT_SUCCESS);
    }
```

NAME

_llseek − reposition read/write file offset

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS__llseek, unsigned int  fd, unsigned long offset_high,
        unsigned long offset_low, loff_t *result,
        unsigned int whence);
```

Note: glibc provides no wrapper for **_llseek**(), necessitating the use of *syscall*(2).

DESCRIPTION

Note: for information about the *llseek*(3) library function, see *lseek64*(3).

The **_llseek**() system call repositions the offset of the open file description associated with the file descriptor *fd* to the value

```
(offset_high << 32) | offset_low
```

This new offset is a byte offset relative to the beginning of the file, the current file offset, or the end of the file, depending on whether *whence* is **SEEK_SET**, **SEEK_CUR**, or **SEEK_END**, respectively.

The new file offset is returned in the argument *result*. The type *loff_t* is a 64-bit signed type.

This system call exists on various 32-bit platforms to support seeking to large file offsets.

RETURN VALUE

Upon successful completion, **_llseek**() returns 0. Otherwise, a value of −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF
fd is not an open file descriptor.

EFAULT
Problem with copying results to user space.

EINVAL
whence is invalid.

VERSIONS

You probably want to use the *lseek*(2) wrapper function instead.

STANDARDS

Linux.

SEE ALSO

lseek(2), *open*(2), *lseek64*(3)

NAME

lookup_dcookie − return a directory entry's path

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_lookup_dcookie, uint64_t *cookie***, char *****buffer***,**
size_t *len***);**

Note: glibc provides no wrapper for **lookup_dcookie**(), necessitating the use of *syscall*(2).

DESCRIPTION

Look up the full path of the directory entry specified by the value *cookie*. The cookie is an opaque identifier uniquely identifying a particular directory entry. The buffer given is filled in with the full path of the directory entry.

For **lookup_dcookie**() to return successfully, the kernel must still hold a cookie reference to the directory entry.

RETURN VALUE

On success, **lookup_dcookie**() returns the length of the path string copied into the buffer. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
The buffer was not valid.

EINVAL
The kernel has no registered cookie/directory entry mappings at the time of lookup, or the cookie does not refer to a valid directory entry.

ENAMETOOLONG
The name could not fit in the buffer.

ENOMEM
The kernel could not allocate memory for the temporary buffer holding the path.

EPERM
The process does not have the capability **CAP_SYS_ADMIN** required to look up cookie values.

ERANGE
The buffer was not large enough to hold the path of the directory entry.

STANDARDS

Linux.

HISTORY

Linux 2.5.43.

The **ENAMETOOLONG** error was added in Linux 2.5.70.

NOTES

lookup_dcookie() is a special-purpose system call, currently used only by the *oprofile*(1) profiler. It relies on a kernel driver to register cookies for directory entries.

The path returned may be suffixed by the string " (deleted)" if the directory entry has been removed.

SEE ALSO

oprofile(1)

NAME

lseek − reposition read/write file offset

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

off_t lseek(int *fd***, off_t** *offset***, int** *whence***);**

DESCRIPTION

lseek() repositions the file offset of the open file description associated with the file descriptor *fd* to the argument *offset* according to the directive *whence* as follows:

SEEK_SET
The file offset is set to *offset* bytes.

SEEK_CUR
The file offset is set to its current location plus *offset* bytes.

SEEK_END
The file offset is set to the size of the file plus *offset* bytes.

lseek() allows the file offset to be set beyond the end of the file (but this does not change the size of the file). If data is later written at this point, subsequent reads of the data in the gap (a "hole") return null bytes ('\0') until data is actually written into the gap.

Seeking file data and holes

Since Linux 3.1, Linux supports the following additional values for *whence*:

SEEK_DATA
Adjust the file offset to the next location in the file greater than or equal to *offset* containing data. If *offset* points to data, then the file offset is set to *offset*.

SEEK_HOLE
Adjust the file offset to the next hole in the file greater than or equal to *offset*. If *offset* points into the middle of a hole, then the file offset is set to *offset*. If there is no hole past *offset*, then the file offset is adjusted to the end of the file (i.e., there is an implicit hole at the end of any file).

In both of the above cases, **lseek**() fails if *offset* points past the end of the file.

These operations allow applications to map holes in a sparsely allocated file. This can be useful for applications such as file backup tools, which can save space when creating backups and preserve holes, if they have a mechanism for discovering holes.

For the purposes of these operations, a hole is a sequence of zeros that (normally) has not been allocated in the underlying file storage. However, a filesystem is not obliged to report holes, so these operations are not a guaranteed mechanism for mapping the storage space actually allocated to a file. (Furthermore, a sequence of zeros that actually has been written to the underlying storage may not be reported as a hole.) In the simplest implementation, a filesystem can support the operations by making **SEEK_HOLE** always return the offset of the end of the file, and making **SEEK_DATA** always return *offset* (i.e., even if the location referred to by *offset* is a hole, it can be considered to consist of data that is a sequence of zeros).

The **_GNU_SOURCE** feature test macro must be defined in order to obtain the definitions of **SEEK_DATA** and **SEEK_HOLE** from *<unistd.h>*.

The **SEEK_HOLE** and **SEEK_DATA** operations are supported for the following filesystems:

- Btrfs (since Linux 3.1)
- OCFS (since Linux 3.2)
- XFS (since Linux 3.5)
- ext4 (since Linux 3.8)

- *tmpfs*(5) (since Linux 3.8)
- NFS (since Linux 3.18)
- FUSE (since Linux 4.5)
- GFS2 (since Linux 4.15)

RETURN VALUE

Upon successful completion, **lseek**() returns the resulting offset location as measured in bytes from the beginning of the file. On error, the value *(off_t) −1* is returned and *errno* is set to indicate the error.

ERRORS

EBADF
fd is not an open file descriptor.

EINVAL
whence is not valid. Or: the resulting file offset would be negative, or beyond the end of a seekable device.

ENXIO
whence is **SEEK_DATA** or **SEEK_HOLE**, and *offset* is beyond the end of the file, or *whence* is **SEEK_DATA** and *offset* is within a hole at the end of the file.

EOVERFLOW
The resulting file offset cannot be represented in an *off_t*.

ESPIPE
fd is associated with a pipe, socket, or FIFO.

VERSIONS

On Linux, using **lseek**() on a terminal device fails with the error **ESPIPE**.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

SEEK_DATA and **SEEK_HOLE** are nonstandard extensions also present in Solaris, FreeBSD, and DragonFly BSD; they are proposed for inclusion in the next POSIX revision (Issue 8).

NOTES

See *open*(2) for a discussion of the relationship between file descriptors, open file descriptions, and files.

If the **O_APPEND** file status flag is set on the open file description, then a *write*(2) *always* moves the file offset to the end of the file, regardless of the use of **lseek**().

Some devices are incapable of seeking and POSIX does not specify which devices must support **lseek**().

NAME

madvise − give advice about use of memory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/mman.h>

int madvise(void *addr***[.***length***], size_t** *length***, int** *advice***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

madvise():
Since glibc 2.19:
_DEFAULT_SOURCE
Up to and including glibc 2.19:
_BSD_SOURCE

DESCRIPTION

The **madvise**() system call is used to give advice or directions to the kernel about the address range beginning at address *addr* and with size *length*. **madvise**() only operates on whole pages, therefore *addr* must be page-aligned. The value of *length* is rounded up to a multiple of page size. In most cases, the goal of such advice is to improve system or application performance.

Initially, the system call supported a set of "conventional" *advice* values, which are also available on several other implementations. (Note, though, that **madvise**() is not specified in POSIX.) Subsequently, a number of Linux-specific *advice* values have been added.

Conventional advice values

The *advice* values listed below allow an application to tell the kernel how it expects to use some mapped or shared memory areas, so that the kernel can choose appropriate read-ahead and caching techniques. These *advice* values do not influence the semantics of the application (except in the case of **MADV_DONTNEED**), but may influence its performance. All of the *advice* values listed here have analogs in the POSIX-specified *posix_madvise*(3) function, and the values have the same meanings, with the exception of **MADV_DONTNEED**.

The advice is indicated in the *advice* argument, which is one of the following:

MADV_NORMAL
No special treatment. This is the default.

MADV_RANDOM
Expect page references in random order. (Hence, read ahead may be less useful than normally.)

MADV_SEQUENTIAL
Expect page references in sequential order. (Hence, pages in the given range can be aggressively read ahead, and may be freed soon after they are accessed.)

MADV_WILLNEED
Expect access in the near future. (Hence, it might be a good idea to read some pages ahead.)

MADV_DONTNEED
Do not expect access in the near future. (For the time being, the application is finished with the given range, so the kernel can free resources associated with it.)

After a successful **MADV_DONTNEED** operation, the semantics of memory access in the specified region are changed: subsequent accesses of pages in the range will succeed, but will result in either repopulating the memory contents from the up-to-date contents of the underlying mapped file (for shared file mappings, shared anonymous mappings, and shmem-based techniques such as System V shared memory segments) or zero-fill-on-demand pages for anonymous private mappings.

Note that, when applied to shared mappings, **MADV_DONTNEED** might not lead to immediate freeing of the pages in the range. The kernel is free to delay freeing the pages until an appropriate moment. The resident set size (RSS) of the calling process will be immediately reduced however.

MADV_DONTNEED cannot be applied to locked pages, or **VM_PFNMAP** pages. (Pages marked with the kernel-internal **VM_PFNMAP** flag are special memory areas that are not managed by the virtual memory subsystem. Such pages are typically created by device drivers that map the pages into user space.)

Support for Huge TLB pages was added in Linux v5.18. Addresses within a mapping backed by Huge TLB pages must be aligned to the underlying Huge TLB page size, and the range length is rounded up to a multiple of the underlying Huge TLB page size.

Linux-specific advice values

The following Linux-specific *advice* values have no counterparts in the POSIX-specified *posix_madvise*(3), and may or may not have counterparts in the **madvise**() interface available on other implementations. Note that some of these operations change the semantics of memory accesses.

MADV_REMOVE (since Linux 2.6.16)

Free up a given range of pages and its associated backing store. This is equivalent to punching a hole in the corresponding range of the backing store (see *fallocate*(2)). Subsequent accesses in the specified address range will see data with a value of zero.

The specified address range must be mapped shared and writable. This flag cannot be applied to locked pages, or **VM_PFNMAP** pages.

In the initial implementation, only *tmpfs*(5) supported **MADV_REMOVE**; but since Linux 3.5, any filesystem which supports the *fallocate*(2) **FALLOC_FL_PUNCH_HOLE** mode also supports **MADV_REMOVE**. Filesystems which do not support **MADV_REMOVE** fail with the error **EOPNOTSUPP**.

Support for the Huge TLB filesystem was added in Linux v4.3.

MADV_DONTFORK (since Linux 2.6.16)

Do not make the pages in this range available to the child after a *fork*(2). This is useful to prevent copy-on-write semantics from changing the physical location of a page if the parent writes to it after a *fork*(2). (Such page relocations cause problems for hardware that DMAs into the page.)

MADV_DOFORK (since Linux 2.6.16)

Undo the effect of **MADV_DONTFORK**, restoring the default behavior, whereby a mapping is inherited across *fork*(2).

MADV_HWPOISON (since Linux 2.6.32)

Poison the pages in the range specified by *addr* and *length* and handle subsequent references to those pages like a hardware memory corruption. This operation is available only for privileged (**CAP_SYS_ADMIN**) processes. This operation may result in the calling process receiving a **SIGBUS** and the page being unmapped.

This feature is intended for testing of memory error-handling code; it is available only if the kernel was configured with **CONFIG_MEMORY_FAILURE**.

MADV_MERGEABLE (since Linux 2.6.32)

Enable Kernel Samepage Merging (KSM) for the pages in the range specified by *addr* and *length*. The kernel regularly scans those areas of user memory that have been marked as mergeable, looking for pages with identical content. These are replaced by a single write-protected page (which is automatically copied if a process later wants to update the content of the page). KSM merges only private anonymous pages (see *mmap*(2)).

The KSM feature is intended for applications that generate many instances of the same data (e.g., virtualization systems such as KVM). It can consume a lot of processing power; use with care. See the Linux kernel source file *Documentation/admin−guide/mm/ksm.rst* for more details.

The **MADV_MERGEABLE** and **MADV_UNMERGEABLE** operations are available only if the kernel was configured with **CONFIG_KSM**.

MADV_UNMERGEABLE (since Linux 2.6.32)

Undo the effect of an earlier **MADV_MERGEABLE** operation on the specified address range; KSM unmerges whatever pages it had merged in the address range specified by *addr* and *length*.

MADV_SOFT_OFFLINE (since Linux 2.6.33)
Soft offline the pages in the range specified by *addr* and *length*. The memory of each page in the specified range is preserved (i.e., when next accessed, the same content will be visible, but in a new physical page frame), and the original page is offlined (i.e., no longer used, and taken out of normal memory management). The effect of the **MADV_SOFT_OFFLINE** operation is invisible to (i.e., does not change the semantics of) the calling process.

This feature is intended for testing of memory error-handling code; it is available only if the kernel was configured with **CONFIG_MEMORY_FAILURE**.

MADV_HUGEPAGE (since Linux 2.6.38)
Enable Transparent Huge Pages (THP) for pages in the range specified by *addr* and *length*. The kernel will regularly scan the areas marked as huge page candidates to replace them with huge pages. The kernel will also allocate huge pages directly when the region is naturally aligned to the huge page size (see *posix_memalign*(2)).

This feature is primarily aimed at applications that use large mappings of data and access large regions of that memory at a time (e.g., virtualization systems such as QEMU). It can very easily waste memory (e.g., a 2 MB mapping that only ever accesses 1 byte will result in 2 MB of wired memory instead of one 4 KB page). See the Linux kernel source file *Documentation/admin−guide/mm/transhuge.rst* for more details.

Most common kernels configurations provide **MADV_HUGEPAGE**-style behavior by default, and thus **MADV_HUGEPAGE** is normally not necessary. It is mostly intended for embedded systems, where **MADV_HUGEPAGE**-style behavior may not be enabled by default in the kernel. On such systems, this flag can be used in order to selectively enable THP. Whenever **MADV_HUGEPAGE** is used, it should always be in regions of memory with an access pattern that the developer knows in advance won't risk to increase the memory footprint of the application when transparent hugepages are enabled.

Since Linux 5.4, automatic scan of eligible areas and replacement by huge pages works with private anonymous pages (see *mmap*(2)), shmem pages, and file-backed pages. For all memory types, memory may only be replaced by huge pages on hugepage-aligned boundaries. For file-mapped memory —including tmpfs (see *tmpfs*(2))— the mapping must also be naturally hugepage-aligned within the file. Additionally, for file-backed, non-tmpfs memory, the file must not be open for write and the mapping must be executable.

The VMA must not be marked **VM_NOHUGEPAGE**, **VM_HUGETLB**, **VM_IO**, **VM_DONTEXPAND**, **VM_MIXEDMAP**, or **VM_PFNMAP**, nor can it be stack memory or backed by a DAX-enabled device (unless the DAX device is hot-plugged as System RAM). The process must also not have **PR_SET_THP_DISABLE** set (see *prctl*(2)).

The **MADV_HUGEPAGE**, **MADV_NOHUGEPAGE**, and **MADV_COLLAPSE** operations are available only if the kernel was configured with **CONFIG_TRANSPARENT_HUGEPAGE** and file/shmem memory is only supported if the kernel was configured with **CONFIG_READ_ONLY_THP_FOR_FS**.

MADV_NOHUGEPAGE (since Linux 2.6.38)
Ensures that memory in the address range specified by *addr* and *length* will not be backed by transparent hugepages.

MADV_COLLAPSE (since Linux 6.1)
Perform a best-effort synchronous collapse of the native pages mapped by the memory range into Transparent Huge Pages (THPs). **MADV_COLLAPSE** operates on the current state of memory of the calling process and makes no persistent changes or guarantees on how pages will be mapped, constructed, or faulted in the future.

MADV_COLLAPSE supports private anonymous pages (see *mmap*(2)), shmem pages, and file-backed pages. See **MADV_HUGEPAGE** for general information on memory requirements for THP. If the range provided spans multiple VMAs, the semantics of the collapse over each VMA is independent from the others. If collapse of a given huge page-aligned/sized region fails, the operation may continue to attempt collapsing the remainder of the specified memory. **MADV_COLLAPSE** will automatically clamp the provided range to be hugepage-aligned.

All non-resident pages covered by the range will first be swapped/faulted-in, before being copied onto a freshly allocated hugepage. If the native pages compose the same PTE-mapped hugepage, and are suitably aligned, allocation of a new hugepage may be elided and collapse may happen in-place. Unmapped pages will have their data directly initialized to 0 in the new hugepage. However, for every eligible hugepage-aligned/sized region to be collapsed, at least one page must currently be backed by physical memory.

MADV_COLLAPSE is independent of any sysfs (see *sysfs*(5)) setting under */sys/kernel/mm/transparent_hugepage*, both in terms of determining THP eligibility, and allocation semantics. See Linux kernel source file *Documentation/admin−guide/mm/transhuge.rst* for more information. **MADV_COLLAPSE** also ignores **huge=** tmpfs mount when operating on tmpfs files. Allocation for the new hugepage may enter direct reclaim and/or compaction, regardless of VMA flags (though **VM_NOHUGEPAGE** is still respected).

When the system has multiple NUMA nodes, the hugepage will be allocated from the node providing the most native pages.

If all hugepage-sized/aligned regions covered by the provided range were either successfully collapsed, or were already PMD-mapped THPs, this operation will be deemed successful. Note that this doesn't guarantee anything about other possible mappings of the memory. In the event multiple hugepage-aligned/sized areas fail to collapse, only the most-recently–failed code will be set in *errno*.

MADV_DONTDUMP (since Linux 3.4)
Exclude from a core dump those pages in the range specified by *addr* and *length*. This is useful in applications that have large areas of memory that are known not to be useful in a core dump. The effect of **MADV_DONTDUMP** takes precedence over the bit mask that is set via the */proc/*pid*/coredump_filter* file (see *core*(5)).

MADV_DODUMP (since Linux 3.4)
Undo the effect of an earlier **MADV_DONTDUMP**.

MADV_FREE (since Linux 4.5)
The application no longer requires the pages in the range specified by *addr* and *len*. The kernel can thus free these pages, but the freeing could be delayed until memory pressure occurs. For each of the pages that has been marked to be freed but has not yet been freed, the free operation will be canceled if the caller writes into the page. After a successful **MADV_FREE** operation, any stale data (i.e., dirty, unwritten pages) will be lost when the kernel frees the pages. However, subsequent writes to pages in the range will succeed and then kernel cannot free those dirtied pages, so that the caller can always see just written data. If there is no subsequent write, the kernel can free the pages at any time. Once pages in the range have been freed, the caller will see zero-fill-on-demand pages upon subsequent page references.

The **MADV_FREE** operation can be applied only to private anonymous pages (see *mmap*(2)). Before Linux 4.12, when freeing pages on a swapless system, the pages in the given range are freed instantly, regardless of memory pressure.

MADV_WIPEONFORK (since Linux 4.14)
Present the child process with zero-filled memory in this range after a *fork*(2). This is useful in forking servers in order to ensure that sensitive per-process data (for example, PRNG seeds, cryptographic secrets, and so on) is not handed to child processes.

The **MADV_WIPEONFORK** operation can be applied only to private anonymous pages (see *mmap*(2)).

Within the child created by *fork*(2), the **MADV_WIPEONFORK** setting remains in place on the specified address range. This setting is cleared during *execve*(2).

MADV_KEEPONFORK (since Linux 4.14)
Undo the effect of an earlier **MADV_WIPEONFORK**.

MADV_COLD (since Linux 5.4)
Deactivate a given range of pages. This will make the pages a more probable reclaim target should there be a memory pressure. This is a nondestructive operation. The advice might be ignored for some pages in the range when it is not applicable.

MADV_PAGEOUT (since Linux 5.4)
Reclaim a given range of pages. This is done to free up memory occupied by these pages. If a page is anonymous, it will be swapped out. If a page is file-backed and dirty, it will be written back to the backing storage. The advice might be ignored for some pages in the range when it is not applicable.

MADV_POPULATE_READ (since Linux 5.14)
"Populate (prefault) page tables readable, faulting in all pages in the range just as if manually reading from each page; however, avoid the actual memory access that would have been performed after handling the fault.

In contrast to **MAP_POPULATE**, **MADV_POPULATE_READ** does not hide errors, can be applied to (parts of) existing mappings and will always populate (prefault) page tables readable. One example use case is prefaulting a file mapping, reading all file content from disk; however, pages won't be dirtied and consequently won't have to be written back to disk when evicting the pages from memory.

Depending on the underlying mapping, map the shared zeropage, preallocate memory or read the underlying file; files with holes might or might not preallocate blocks. If populating fails, a **SIGBUS** signal is not generated; instead, an error is returned.

If **MADV_POPULATE_READ** succeeds, all page tables have been populated (prefaulted) readable once. If **MADV_POPULATE_READ** fails, some page tables might have been populated.

MADV_POPULATE_READ cannot be applied to mappings without read permissions and special mappings, for example, mappings marked with kernel-internal flags such as **VM_PFNMAP** or **VM_IO**, or secret memory regions created using **memfd_secret(2)**.

Note that with **MADV_POPULATE_READ**, the process can be killed at any moment when the system runs out of memory.

MADV_POPULATE_WRITE (since Linux 5.14)
Populate (prefault) page tables writable, faulting in all pages in the range just as if manually writing to each each page; however, avoid the actual memory access that would have been performed after handling the fault.

In contrast to **MAP_POPULATE**, MADV_POPULATE_WRITE does not hide errors, can be applied to (parts of) existing mappings and will always populate (prefault) page tables writable. One example use case is preallocating memory, breaking any CoW (Copy on Write).

Depending on the underlying mapping, preallocate memory or read the underlying file; files with holes will preallocate blocks. If populating fails, a **SIGBUS** signal is not generated; instead, an error is returned.

If **MADV_POPULATE_WRITE** succeeds, all page tables have been populated (prefaulted) writable once. If **MADV_POPULATE_WRITE** fails, some page tables might have been populated.

MADV_POPULATE_WRITE cannot be applied to mappings without write permissions and special mappings, for example, mappings marked with kernel-internal flags such as **VM_PFNMAP** or **VM_IO**, or secret memory regions created using **memfd_secret(2)**.

Note that with **MADV_POPULATE_WRITE**, the process can be killed at any moment when the system runs out of memory.

RETURN VALUE
On success, **madvise**() returns zero. On error, it returns −1 and *errno* is set to indicate the error.

ERRORS
EACCES
advice is **MADV_REMOVE**, but the specified address range is not a shared writable mapping.

EAGAIN
A kernel resource was temporarily unavailable.

EBADF
The map exists, but the area maps something that isn't a file.

EBUSY
(for **MADV_COLLAPSE**) Could not charge hugepage to cgroup: cgroup limit exceeded.

EFAULT
advice is **MADV_POPULATE_READ** or **MADV_POPULATE_WRITE**, and populating (prefaulting) page tables failed because a **SIGBUS** would have been generated on actual memory access and the reason is not a HW poisoned page (HW poisoned pages can, for example, be created using the **MADV_HWPOISON** flag described elsewhere in this page).

EINVAL
addr is not page-aligned or *length* is negative.

EINVAL
advice is not a valid.

EINVAL
advice is **MADV_COLD** or **MADV_PAGEOUT** and the specified address range includes locked, Huge TLB pages, or **VM_PFNMAP** pages.

EINVAL
advice is **MADV_DONTNEED** or **MADV_REMOVE** and the specified address range includes locked, Huge TLB pages, or **VM_PFNMAP** pages.

EINVAL
advice is **MADV_MERGEABLE** or **MADV_UNMERGEABLE**, but the kernel was not configured with **CONFIG_KSM**.

EINVAL
advice is **MADV_FREE** or **MADV_WIPEONFORK** but the specified address range includes file, Huge TLB, **MAP_SHARED**, or **VM_PFNMAP** ranges.

EINVAL
advice is **MADV_POPULATE_READ** or **MADV_POPULATE_WRITE**, but the specified address range includes ranges with insufficient permissions or special mappings, for example, mappings marked with kernel-internal flags such a **VM_IO** or **VM_PFNMAP**, or secret memory regions created using **memfd_secret(2)**.

EIO (for **MADV_WILLNEED**) Paging in this area would exceed the process's maximum resident set size.

ENOMEM
(for **MADV_WILLNEED**) Not enough memory: paging in failed.

ENOMEM
(for **MADV_COLLAPSE**) Not enough memory: could not allocate hugepage.

ENOMEM
Addresses in the specified range are not currently mapped, or are outside the address space of the process.

ENOMEM
advice is **MADV_POPULATE_READ** or **MADV_POPULATE_WRITE**, and populating (prefaulting) page tables failed because there was not enough memory.

EPERM
advice is **MADV_HWPOISON**, but the caller does not have the **CAP_SYS_ADMIN** capability.

EHWPOISON
advice is **MADV_POPULATE_READ** or **MADV_POPULATE_WRITE**, and populating (prefaulting) page tables failed because a HW poisoned page (HW poisoned pages can, for example, be created using the **MADV_HWPOISON** flag described elsewhere in this page) was encountered.

VERSIONS

Versions of this system call, implementing a wide variety of *advice* values, exist on many other implementations. Other implementations typically implement at least the flags listed above under *Conventional advice flags*, albeit with some variation in semantics.

POSIX.1-2001 describes *posix_madvise*(3) with constants **POSIX_MADV_NORMAL**, **POSIX_MADV_RANDOM**, **POSIX_MADV_SEQUENTIAL**, **POSIX_MADV_WILLNEED**, and **POSIX_MADV_DONTNEED**, and so on, with behavior close to the similarly named flags listed above.

Linux

The Linux implementation requires that the address *addr* be page-aligned, and allows *length* to be zero. If there are some parts of the specified address range that are not mapped, the Linux version of **madvise**() ignores them and applies the call to the rest (but returns **ENOMEM** from the system call, as it should).

madvise(0, 0, advice) will return zero iff *advice* is supported by the kernel and can be relied on to probe for support.

STANDARDS

None.

HISTORY

First appeared in 4.4BSD.

Since Linux 3.18, support for this system call is optional, depending on the setting of the **CONFIG_ADVISE_SYSCALLS** configuration option.

NAME

mbind − set memory policy for a memory range

LIBRARY

NUMA (Non-Uniform Memory Access) policy library (*libnuma*, *−lnuma*)

SYNOPSIS

#include <numaif.h>

long mbind(void *addr***[.***len***], unsigned long** *len***, int** *mode***,**
const unsigned long *nodemask***[(.***maxnode* **+ ULONG_WIDTH - 1)**
/ ULONG_WIDTH],
unsigned long *maxnode***, unsigned int** *flags***);**

DESCRIPTION

mbind() sets the NUMA memory policy, which consists of a policy mode and zero or more nodes, for the memory range starting with *addr* and continuing for *len* bytes. The memory policy defines from which node memory is allocated.

If the memory range specified by the *addr* and *len* arguments includes an "anonymous" region of memory—that is a region of memory created using the *mmap*(2) system call with the **MAP_ANONYMOUS**—or a memory-mapped file, mapped using the *mmap*(2) system call with the **MAP_PRIVATE** flag, pages will be allocated only according to the specified policy when the application writes (stores) to the page. For anonymous regions, an initial read access will use a shared page in the kernel containing all zeros. For a file mapped with **MAP_PRIVATE**, an initial read access will allocate pages according to the memory policy of the thread that causes the page to be allocated. This may not be the thread that called **mbind**().

The specified policy will be ignored for any **MAP_SHARED** mappings in the specified memory range. Rather the pages will be allocated according to the memory policy of the thread that caused the page to be allocated. Again, this may not be the thread that called **mbind**().

If the specified memory range includes a shared memory region created using the *shmget*(2) system call and attached using the *shmat*(2) system call, pages allocated for the anonymous or shared memory region will be allocated according to the policy specified, regardless of which process attached to the shared memory segment causes the allocation. If, however, the shared memory region was created with the **SHM_HUGETLB** flag, the huge pages will be allocated according to the policy specified only if the page allocation is caused by the process that calls **mbind**() for that region.

By default, **mbind**() has an effect only for new allocations; if the pages inside the range have been already touched before setting the policy, then the policy has no effect. This default behavior may be overridden by the **MPOL_MF_MOVE** and **MPOL_MF_MOVE_ALL** flags described below.

The *mode* argument must specify one of **MPOL_DEFAULT**, **MPOL_BIND**, **MPOL_INTERLEAVE**, **MPOL_PREFERRED**, or **MPOL_LOCAL** (which are described in detail below). All policy modes except **MPOL_DEFAULT** require the caller to specify the node or nodes to which the mode applies, via the *nodemask* argument.

The *mode* argument may also include an optional *mode flag*. The supported *mode flags* are:

MPOL_F_NUMA_BALANCING (since Linux 5.15)
When *mode* is **MPOL_BIND**, enable the kernel NUMA balancing for the task if it is supported by the kernel. If the flag isn't supported by the kernel, or is used with *mode* other than **MPOL_BIND**, −1 is returned and *errno* is set to **EINVAL**.

MPOL_F_STATIC_NODES (since Linux-2.6.26)
A nonempty *nodemask* specifies physical node IDs. Linux does not remap the *nodemask* when the thread moves to a different cpuset context, nor when the set of nodes allowed by the thread's current cpuset context changes.

MPOL_F_RELATIVE_NODES (since Linux-2.6.26)
A nonempty *nodemask* specifies node IDs that are relative to the set of node IDs allowed by the thread's current cpuset.

nodemask points to a bit mask of nodes containing up to *maxnode* bits. The bit mask size is rounded to the next multiple of *sizeof(unsigned long)*, but the kernel will use bits only up to *maxnode*. A NULL value of *nodemask* or a *maxnode* value of zero specifies the empty set of nodes. If the value of

maxnode is zero, the *nodemask* argument is ignored. Where a *nodemask* is required, it must contain at least one node that is on-line, allowed by the thread's current cpuset context (unless the **MPOL_F_STATIC_NODES** mode flag is specified), and contains memory.

The *mode* argument must include one of the following values:

MPOL_DEFAULT
: This mode requests that any nondefault policy be removed, restoring default behavior. When applied to a range of memory via **mbind**(), this means to use the thread memory policy, which may have been set with *set_mempolicy*(2). If the mode of the thread memory policy is also **MPOL_DEFAULT**, the system-wide default policy will be used. The system-wide default policy allocates pages on the node of the CPU that triggers the allocation. For **MPOL_DEFAULT**, the *nodemask* and *maxnode* arguments must be specify the empty set of nodes.

MPOL_BIND
: This mode specifies a strict policy that restricts memory allocation to the nodes specified in *nodemask*. If *nodemask* specifies more than one node, page allocations will come from the node with sufficient free memory that is closest to the node where the allocation takes place. Pages will not be allocated from any node not specified in the IR nodemask . (Before Linux 2.6.26, page allocations came from the node with the lowest numeric node ID first, until that node contained no free memory. Allocations then came from the node with the next highest node ID specified in *nodemask* and so forth, until none of the specified nodes contained free memory.)

MPOL_INTERLEAVE
: This mode specifies that page allocations be interleaved across the set of nodes specified in *nodemask*. This optimizes for bandwidth instead of latency by spreading out pages and memory accesses to those pages across multiple nodes. To be effective the memory area should be fairly large, at least 1 MB or bigger with a fairly uniform access pattern. Accesses to a single page of the area will still be limited to the memory bandwidth of a single node.

MPOL_PREFERRED
: This mode sets the preferred node for allocation. The kernel will try to allocate pages from this node first and fall back to other nodes if the preferred nodes is low on free memory. If *nodemask* specifies more than one node ID, the first node in the mask will be selected as the preferred node. If the *nodemask* and *maxnode* arguments specify the empty set, then the memory is allocated on the node of the CPU that triggered the allocation.

MPOL_LOCAL (since Linux 3.8)
: This mode specifies "local allocation"; the memory is allocated on the node of the CPU that triggered the allocation (the "local node"). The *nodemask* and *maxnode* arguments must specify the empty set. If the "local node" is low on free memory, the kernel will try to allocate memory from other nodes. The kernel will allocate memory from the "local node" whenever memory for this node is available. If the "local node" is not allowed by the thread's current cpuset context, the kernel will try to allocate memory from other nodes. The kernel will allocate memory from the "local node" whenever it becomes allowed by the thread's current cpuset context. By contrast, **MPOL_DEFAULT** reverts to the memory policy of the thread (which may be set via *set_mempolicy*(2)); that policy may be something other than "local allocation".

If **MPOL_MF_STRICT** is passed in *flags* and *mode* is not **MPOL_DEFAULT**, then the call fails with the error **EIO** if the existing pages in the memory range don't follow the policy.

If **MPOL_MF_MOVE** is specified in *flags*, then the kernel will attempt to move all the existing pages in the memory range so that they follow the policy. Pages that are shared with other processes will not be moved. If **MPOL_MF_STRICT** is also specified, then the call fails with the error **EIO** if some pages could not be moved. If the **MPOL_INTERLEAVE** policy was specified, pages already residing on the specified nodes will not be moved such that they are interleaved.

If **MPOL_MF_MOVE_ALL** is passed in *flags*, then the kernel will attempt to move all existing pages in the memory range regardless of whether other processes use the pages. The calling thread must be privileged (**CAP_SYS_NICE**) to use this flag. If **MPOL_MF_STRICT** is also specified, then the call fails with the error **EIO** if some pages could not be moved. If the **MPOL_INTERLEAVE** policy was specified, pages already residing on the specified nodes will not be moved such that they are

interleaved.

RETURN VALUE

On success, **mbind**() returns 0; on error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
: Part or all of the memory range specified by *nodemask* and *maxnode* points outside your accessible address space. Or, there was an unmapped hole in the specified memory range specified by *addr* and *len*.

EINVAL
: An invalid value was specified for *flags* or *mode*; or *addr* + *len* was less than *addr*; or *addr* is not a multiple of the system page size. Or, *mode* is **MPOL_DEFAULT** and *nodemask* specified a nonempty set; or *mode* is **MPOL_BIND** or **MPOL_INTERLEAVE** and *nodemask* is empty. Or, *maxnode* exceeds a kernel-imposed limit. Or, *nodemask* specifies one or more node IDs that are greater than the maximum supported node ID. Or, none of the node IDs specified by *nodemask* are on-line and allowed by the thread's current cpuset context, or none of the specified nodes contain memory. Or, the *mode* argument specified both **MPOL_F_STATIC_NODES** and **MPOL_F_RELATIVE_NODES**.

EIO
: **MPOL_MF_STRICT** was specified and an existing page was already on a node that does not follow the policy; or **MPOL_MF_MOVE** or **MPOL_MF_MOVE_ALL** was specified and the kernel was unable to move all existing pages in the range.

ENOMEM
: Insufficient kernel memory was available.

EPERM
: The *flags* argument included the **MPOL_MF_MOVE_ALL** flag and the caller does not have the **CAP_SYS_NICE** privilege.

STANDARDS

Linux.

HISTORY

Linux 2.6.7.

Support for huge page policy was added with Linux 2.6.16. For interleave policy to be effective on huge page mappings the policied memory needs to be tens of megabytes or larger.

Before Linux 5.7. **MPOL_MF_STRICT** was ignored on huge page mappings.

MPOL_MF_MOVE and **MPOL_MF_MOVE_ALL** are available only on Linux 2.6.16 and later.

NOTES

For information on library support, see *numa*(7).

NUMA policy is not supported on a memory-mapped file range that was mapped with the **MAP_SHARED** flag.

The **MPOL_DEFAULT** mode can have different effects for **mbind**() and *set_mempolicy*(2). When **MPOL_DEFAULT** is specified for *set_mempolicy*(2), the thread's memory policy reverts to the system default policy or local allocation. When **MPOL_DEFAULT** is specified for a range of memory using **mbind**(), any pages subsequently allocated for that range will use the thread's memory policy, as set by *set_mempolicy*(2). This effectively removes the explicit policy from the specified range, "falling back" to a possibly nondefault policy. To select explicit "local allocation" for a memory range, specify a *mode* of **MPOL_LOCAL** or **MPOL_PREFERRED** with an empty set of nodes. This method will work for *set_mempolicy*(2), as well.

NAME

membarrier − issue memory barriers on a set of threads

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/membarrier.h> /* Definition of **MEMBARRIER_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_membarrier, int *cmd***, unsigned int** *flags***, int** *cpu_id***);**

Note: glibc provides no wrapper for **membarrier**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **membarrier**() system call helps reducing the overhead of the memory barrier instructions required to order memory accesses on multi-core systems. However, this system call is heavier than a memory barrier, so using it effectively is *not* as simple as replacing memory barriers with this system call, but requires understanding of the details below.

Use of memory barriers needs to be done taking into account that a memory barrier always needs to be either matched with its memory barrier counterparts, or that the architecture's memory model doesn't require the matching barriers.

There are cases where one side of the matching barriers (which we will refer to as "fast side") is executed much more often than the other (which we will refer to as "slow side"). This is a prime target for the use of **membarrier**(). The key idea is to replace, for these matching barriers, the fast-side memory barriers by simple compiler barriers, for example:

```
asm volatile ("" : : : "memory")
```

and replace the slow-side memory barriers by calls to **membarrier**().

This will add overhead to the slow side, and remove overhead from the fast side, thus resulting in an overall performance increase as long as the slow side is infrequent enough that the overhead of the **membarrier**() calls does not outweigh the performance gain on the fast side.

The *cmd* argument is one of the following:

MEMBARRIER_CMD_QUERY (since Linux 4.3)
: Query the set of supported commands. The return value of the call is a bit mask of supported commands. **MEMBARRIER_CMD_QUERY**, which has the value 0, is not itself included in this bit mask. This command is always supported (on kernels where **membarrier**() is provided).

MEMBARRIER_CMD_GLOBAL (since Linux 4.16)
: Ensure that all threads from all processes on the system pass through a state where all memory accesses to user-space addresses match program order between entry to and return from the **membarrier**() system call. All threads on the system are targeted by this command.

MEMBARRIER_CMD_GLOBAL_EXPEDITED (since Linux 4.16)
: Execute a memory barrier on all running threads of all processes that previously registered with **MEMBARRIER_CMD_REGISTER_GLOBAL_EXPEDITED**.

  Upon return from the system call, the calling thread has a guarantee that all running threads have passed through a state where all memory accesses to user-space addresses match program order between entry to and return from the system call (non-running threads are de facto in such a state). This guarantee is provided only for the threads of processes that previously registered with **MEMBARRIER_CMD_REGISTER_GLOBAL_EXPEDITED**.

  Given that registration is about the intent to receive the barriers, it is valid to invoke **MEMBARRIER_CMD_GLOBAL_EXPEDITED** from a process that has not employed **MEMBARRIER_CMD_REGISTER_GLOBAL_EXPEDITED**.

  The "expedited" commands complete faster than the non-expedited ones; they never block, but have the downside of causing extra overhead.

MEMBARRIER_CMD_REGISTER_GLOBAL_EXPEDITED (since Linux 4.16)
Register the process's intent to receive **MEMBARRIER_CMD_GLOBAL_EXPEDITED** memory barriers.

MEMBARRIER_CMD_PRIVATE_EXPEDITED (since Linux 4.14)
Execute a memory barrier on each running thread belonging to the same process as the calling thread.

Upon return from the system call, the calling thread has a guarantee that all its running thread siblings have passed through a state where all memory accesses to user-space addresses match program order between entry to and return from the system call (non-running threads are de facto in such a state). This guarantee is provided only for threads in the same process as the calling thread.

The "expedited" commands complete faster than the non-expedited ones; they never block, but have the downside of causing extra overhead.

A process must register its intent to use the private expedited command prior to using it.

MEMBARRIER_CMD_REGISTER_PRIVATE_EXPEDITED (since Linux 4.14)
Register the process's intent to use **MEMBARRIER_CMD_PRIVATE_EXPEDITED**.

MEMBARRIER_CMD_PRIVATE_EXPEDITED_SYNC_CORE (since Linux 4.16)
In addition to providing the memory ordering guarantees described in **MEMBARRIER_CMD_PRIVATE_EXPEDITED**, upon return from system call the calling thread has a guarantee that all its running thread siblings have executed a core serializing instruction. This guarantee is provided only for threads in the same process as the calling thread.

The "expedited" commands complete faster than the non-expedited ones, they never block, but have the downside of causing extra overhead.

A process must register its intent to use the private expedited sync core command prior to using it.

MEMBARRIER_CMD_REGISTER_PRIVATE_EXPEDITED_SYNC_CORE (since Linux 4.16)
Register the process's intent to use **MEMBARRIER_CMD_PRIVATE_EXPEDITED_SYNC_CORE**.

MEMBARRIER_CMD_PRIVATE_EXPEDITED_RSEQ (since Linux 5.10)
Ensure the caller thread, upon return from system call, that all its running thread siblings have any currently running rseq critical sections restarted if *flags* parameter is 0; if *flags* parameter is **MEMBARRIER_CMD_FLAG_CPU**, then this operation is performed only on CPU indicated by *cpu_id*. This guarantee is provided only for threads in the same process as the calling thread.

RSEQ membarrier is only available in the "private expedited" form.

A process must register its intent to use the private expedited rseq command prior to using it.

MEMBARRIER_CMD_REGISTER_PRIVATE_EXPEDITED_RSEQ (since Linux 5.10)
Register the process's intent to use **MEMBARRIER_CMD_PRIVATE_EXPEDITED_RSEQ**.

MEMBARRIER_CMD_SHARED (since Linux 4.3)
This is an alias for **MEMBARRIER_CMD_GLOBAL** that exists for header backward compatibility.

The *flags* argument must be specified as 0 unless the command is **MEMBARRIER_CMD_PRIVATE_EXPEDITED_RSEQ**, in which case *flags* can be either 0 or **MEMBARRIER_CMD_FLAG_CPU**.

The *cpu_id* argument is ignored unless *flags* is **MEMBARRIER_CMD_FLAG_CPU**, in which case it must specify the CPU targeted by this membarrier command.

All memory accesses performed in program order from each targeted thread are guaranteed to be ordered with respect to **membarrier**().

If we use the semantic *barrier()* to represent a compiler barrier forcing memory accesses to be performed in program order across the barrier, and *smp_mb()* to represent explicit memory barriers forcing

full memory ordering across the barrier, we have the following ordering table for each pairing of *barrier()*, **membarrier**(), and *smp_mb()*. The pair ordering is detailed as (O: ordered, X: not ordered):

	barrier()	smp_mb()	membarrier()
barrier()	X	X	O
smp_mb()	X	O	O
membarrier()	O	O	O

RETURN VALUE

On success, the **MEMBARRIER_CMD_QUERY** operation returns a bit mask of supported commands, and the **MEMBARRIER_CMD_GLOBAL**, **MEMBARRIER_CMD_GLOBAL_EXPEDITED**, **MEMBARRIER_CMD_REGISTER_GLOBAL_EXPEDITED**, **MEMBARRIER_CMD_PRIVATE_EXPEDITED**, **MEMBARRIER_CMD_REGISTER_PRIVATE_EXPEDITED**, **MEMBARRIER_CMD_PRIVATE_EXPEDITED_SYNC_CORE**, and **MEMBARRIER_CMD_REGISTER_PRIVATE_EXPEDITED_SYNC_CORE** operations return zero. On error, −1 is returned, and *errno* is set to indicate the error.

For a given command, with *flags* set to 0, this system call is guaranteed to always return the same value until reboot. Further calls with the same arguments will lead to the same result. Therefore, with *flags* set to 0, error handling is required only for the first call to **membarrier**().

ERRORS

EINVAL

cmd is invalid, or *flags* is nonzero, or the **MEMBARRIER_CMD_GLOBAL** command is disabled because the *nohz_full* CPU parameter has been set, or the **MEMBARRIER_CMD_PRIVATE_EXPEDITED_SYNC_CORE** and **MEMBARRIER_CMD_REGISTER_PRIVATE_EXPEDITED_SYNC_CORE** commands are not implemented by the architecture.

ENOSYS

The **membarrier**() system call is not implemented by this kernel.

EPERM

The current process was not registered prior to using private expedited commands.

STANDARDS

Linux.

HISTORY

Linux 4.3.

Before Linux 5.10, the prototype was:

```
int membarrier(int cmd, int flags);
```

NOTES

A memory barrier instruction is part of the instruction set of architectures with weakly ordered memory models. It orders memory accesses prior to the barrier and after the barrier with respect to matching barriers on other cores. For instance, a load fence can order loads prior to and following that fence with respect to stores ordered by store fences.

Program order is the order in which instructions are ordered in the program assembly code.

Examples where **membarrier**() can be useful include implementations of Read-Copy-Update libraries and garbage collectors.

EXAMPLES

Assuming a multithreaded application where "fast_path()" is executed very frequently, and where "slow_path()" is executed infrequently, the following code (x86) can be transformed using **membarrier**():

```
#include <stdlib.h>

static volatile int a, b;

static void
fast_path(int *read_b)
{
```

```
    a = 1;
    asm volatile ("mfence" : : : "memory");
    *read_b = b;
}

static void
slow_path(int *read_a)
{
    b = 1;
    asm volatile ("mfence" : : : "memory");
    *read_a = a;
}

int
main(void)
{
    int read_a, read_b;

    /*
     * Real applications would call fast_path() and slow_path()
     * from different threads. Call those from main() to keep
     * this example short.
     */

    slow_path(&read_a);
    fast_path(&read_b);

    /*
     * read_b == 0 implies read_a == 1 and
     * read_a == 0 implies read_b == 1.
     */

    if (read_b == 0 && read_a == 0)
        abort();

    exit(EXIT_SUCCESS);
}
```

The code above transformed to use **membarrier**() becomes:

```
#define _GNU_SOURCE
#include <stdlib.h>
#include <stdio.h>
#include <unistd.h>
#include <sys/syscall.h>
#include <linux/membarrier.h>

static volatile int a, b;

static int
membarrier(int cmd, unsigned int flags, int cpu_id)
{
    return syscall(__NR_membarrier, cmd, flags, cpu_id);
}

static int
init_membarrier(void)
{
    int ret;
```

```
    /* Check that membarrier() is supported. */

    ret = membarrier(MEMBARRIER_CMD_QUERY, 0, 0);
    if (ret < 0) {
        perror("membarrier");
        return -1;
    }

    if (!(ret & MEMBARRIER_CMD_GLOBAL)) {
        fprintf(stderr,
            "membarrier does not support MEMBARRIER_CMD_GLOBAL\n");
        return -1;
    }

    return 0;
}

static void
fast_path(int *read_b)
{
    a = 1;
    asm volatile ("" : : : "memory");
    *read_b = b;
}

static void
slow_path(int *read_a)
{
    b = 1;
    membarrier(MEMBARRIER_CMD_GLOBAL, 0, 0);
    *read_a = a;
}

int
main(int argc, char *argv[])
{
    int read_a, read_b;

    if (init_membarrier())
        exit(EXIT_FAILURE);

    /*
     * Real applications would call fast_path() and slow_path()
     * from different threads. Call those from main() to keep
     * this example short.
     */

    slow_path(&read_a);
    fast_path(&read_b);

    /*
     * read_b == 0 implies read_a == 1 and
     * read_a == 0 implies read_b == 1.
     */

    if (read_b == 0 && read_a == 0)
        abort();

    exit(EXIT_SUCCESS);
```

```
}
```

NAME

memfd_create − create an anonymous file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sys/mman.h>

int memfd_create(const char *name, unsigned int flags);
```

DESCRIPTION

memfd_create() creates an anonymous file and returns a file descriptor that refers to it. The file behaves like a regular file, and so can be modified, truncated, memory-mapped, and so on. However, unlike a regular file, it lives in RAM and has a volatile backing storage. Once all references to the file are dropped, it is automatically released. Anonymous memory is used for all backing pages of the file. Therefore, files created by **memfd_create**() have the same semantics as other anonymous memory allocations such as those allocated using *mmap*(2) with the **MAP_ANONYMOUS** flag.

The initial size of the file is set to 0. Following the call, the file size should be set using *ftruncate*(2). (Alternatively, the file may be populated by calls to *write*(2) or similar.)

The name supplied in *name* is used as a filename and will be displayed as the target of the corresponding symbolic link in the directory */proc/self/fd/*. The displayed name is always prefixed with *memfd:* and serves only for debugging purposes. Names do not affect the behavior of the file descriptor, and as such multiple files can have the same name without any side effects.

The following values may be bitwise ORed in *flags* to change the behavior of **memfd_create**():

MFD_CLOEXEC
: Set the close-on-exec (**FD_CLOEXEC**) flag on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

MFD_ALLOW_SEALING
: Allow sealing operations on this file. See the discussion of the **F_ADD_SEALS** and **F_GET_SEALS** operations in *fcntl*(2), and also NOTES, below. The initial set of seals is empty. If this flag is not set, the initial set of seals will be **F_SEAL_SEAL**, meaning that no other seals can be set on the file.

MFD_HUGETLB (since Linux 4.14)
: The anonymous file will be created in the hugetlbfs filesystem using huge pages. See the Linux kernel source file *Documentation/admin−guide/mm/hugetlbpage.rst* for more information about hugetlbfs. Specifying both **MFD_HUGETLB** and **MFD_ALLOW_SEALING** in *flags* is supported since Linux 4.16.

MFD_HUGE_2MB
MFD_HUGE_1GB
...
: Used in conjunction with **MFD_HUGETLB** to select alternative hugetlb page sizes (respectively, 2 MB, 1 GB, ...) on systems that support multiple hugetlb page sizes. Definitions for known huge page sizes are included in the header file <*linux/memfd.h*>.

  For details on encoding huge page sizes not included in the header file, see the discussion of the similarly named constants in *mmap*(2).

Unused bits in *flags* must be 0.

As its return value, **memfd_create**() returns a new file descriptor that can be used to refer to the file. This file descriptor is opened for both reading and writing (**O_RDWR**) and **O_LARGEFILE** is set for the file descriptor.

With respect to *fork*(2) and *execve*(2), the usual semantics apply for the file descriptor created by **memfd_create**(). A copy of the file descriptor is inherited by the child produced by *fork*(2) and refers to the same file. The file descriptor is preserved across *execve*(2), unless the close-on-exec flag has been set.

RETURN VALUE

On success, **memfd_create**() returns a new file descriptor. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
The address in *name* points to invalid memory.

EINVAL
flags included unknown bits.

EINVAL
name was too long. (The limit is 249 bytes, excluding the terminating null byte.)

EINVAL
Both **MFD_HUGETLB** and **MFD_ALLOW_SEALING** were specified in *flags*.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENOMEM
There was insufficient memory to create a new anonymous file.

EPERM
The **MFD_HUGETLB** flag was specified, but the caller was not privileged (did not have the **CAP_IPC_LOCK** capability) and is not a member of the *sysctl_hugetlb_shm_group* group; see the description of */proc/sys/vm/sysctl_hugetlb_shm_group* in *proc*(5).

STANDARDS

Linux.

HISTORY

Linux 3.17, glibc 2.27.

NOTES

The **memfd_create**() system call provides a simple alternative to manually mounting a *tmpfs*(5) filesystem and creating and opening a file in that filesystem. The primary purpose of **memfd_create**() is to create files and associated file descriptors that are used with the file-sealing APIs provided by *fcntl*(2).

The **memfd_create**() system call also has uses without file sealing (which is why file-sealing is disabled, unless explicitly requested with the **MFD_ALLOW_SEALING** flag). In particular, it can be used as an alternative to creating files in *tmp* or as an alternative to using the *open*(2) **O_TMPFILE** in cases where there is no intention to actually link the resulting file into the filesystem.

File sealing

In the absence of file sealing, processes that communicate via shared memory must either trust each other, or take measures to deal with the possibility that an untrusted peer may manipulate the shared memory region in problematic ways. For example, an untrusted peer might modify the contents of the shared memory at any time, or shrink the shared memory region. The former possibility leaves the local process vulnerable to time-of-check-to-time-of-use race conditions (typically dealt with by copying data from the shared memory region before checking and using it). The latter possibility leaves the local process vulnerable to **SIGBUS** signals when an attempt is made to access a now-nonexistent location in the shared memory region. (Dealing with this possibility necessitates the use of a handler for the **SIGBUS** signal.)

Dealing with untrusted peers imposes extra complexity on code that employs shared memory. Memory sealing enables that extra complexity to be eliminated, by allowing a process to operate secure in the knowledge that its peer can't modify the shared memory in an undesired fashion.

An example of the usage of the sealing mechanism is as follows:

(1) The first process creates a *tmpfs*(5) file using **memfd_create**(). The call yields a file descriptor used in subsequent steps.

(2) The first process sizes the file created in the previous step using *ftruncate*(2), maps it using *mmap*(2), and populates the shared memory with the desired data.

(3) The first process uses the *fcntl*(2) **F_ADD_SEALS** operation to place one or more seals on the file, in order to restrict further modifications on the file. (If placing the seal **F_SEAL_WRITE**, then it will be necessary to first unmap the shared writable mapping created in the previous step. Otherwise, behavior similar to **F_SEAL_WRITE** can be achieved by using **F_SEAL_FUTURE_WRITE**, which will prevent future writes via *mmap*(2) and *write*(2) from succeeding while keeping existing shared writable mappings).

(4) A second process obtains a file descriptor for the *tmpfs*(5) file and maps it. Among the possible ways in which this could happen are the following:

- The process that called **memfd_create**() could transfer the resulting file descriptor to the second process via a UNIX domain socket (see *unix*(7) and *cmsg*(3)). The second process then maps the file using *mmap*(2).
- The second process is created via *fork*(2) and thus automatically inherits the file descriptor and mapping. (Note that in this case and the next, there is a natural trust relationship between the two processes, since they are running under the same user ID. Therefore, file sealing would not normally be necessary.)
- The second process opens the file */proc/*pid*/fd/*fd, where *<pid>* is the PID of the first process (the one that called *memfd_create*()), and *<fd>* is the number of the file descriptor returned by the call to **memfd_create**() in that process. The second process then maps the file using *mmap*(2).

(5) The second process uses the *fcntl*(2) **F_GET_SEALS** operation to retrieve the bit mask of seals that has been applied to the file. This bit mask can be inspected in order to determine what kinds of restrictions have been placed on file modifications. If desired, the second process can apply further seals to impose additional restrictions (so long as the **F_SEAL_SEAL** seal has not yet been applied).

EXAMPLES

Below are shown two example programs that demonstrate the use of **memfd_create**() and the file sealing API.

The first program, *t_memfd_create.c*, creates a *tmpfs*(5) file using **memfd_create**(), sets a size for the file, maps it into memory, and optionally places some seals on the file. The program accepts up to three command-line arguments, of which the first two are required. The first argument is the name to associate with the file, the second argument is the size to be set for the file, and the optional third argument is a string of characters that specify seals to be set on the file.

The second program, *t_get_seals.c*, can be used to open an existing file that was created via **memfd_create**() and inspect the set of seals that have been applied to that file.

The following shell session demonstrates the use of these programs. First we create a *tmpfs*(5) file and set some seals on it:

```
$ ./t_memfd_create my_memfd_file 4096 sw &
[1] 11775
PID: 11775; fd: 3; /proc/11775/fd/3
```

At this point, the *t_memfd_create* program continues to run in the background. From another program, we can obtain a file descriptor for the file created by **memfd_create**() by opening the */proc/*pid*/fd* file that corresponds to the file descriptor opened by **memfd_create**(). Using that pathname, we inspect the content of the */proc/*pid*/fd* symbolic link, and use our *t_get_seals* program to view the seals that have been placed on the file:

```
$ readlink /proc/11775/fd/3
/memfd:my_memfd_file (deleted)
$ ./t_get_seals /proc/11775/fd/3
Existing seals: WRITE SHRINK
```

Program source: t_memfd_create.c

```
#define _GNU_SOURCE
```

```
#include <err.h>
#include <fcntl.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/mman.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int           fd;
    char          *name, *seals_arg;
    ssize_t       len;
    unsigned int  seals;

    if (argc < 3) {
        fprintf(stderr, "%s name size [seals]\n", argv[0]);
        fprintf(stderr, "\t'seals' can contain any of the "
                "following characters:\n");
        fprintf(stderr, "\t\tg - F_SEAL_GROW\n");
        fprintf(stderr, "\t\ts - F_SEAL_SHRINK\n");
        fprintf(stderr, "\t\tw - F_SEAL_WRITE\n");
        fprintf(stderr, "\t\tW - F_SEAL_FUTURE_WRITE\n");

SEE ALSO

fcntl(2), *ftruncate*(2), *memfd_secret*(2), *mmap*(2), *shmget*(2), *shm_open*(3)

NAME

memfd_secret − create an anonymous RAM-based file to access secret memory regions

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_memfd_secret, unsigned int  flags);
```

Note: glibc provides no wrapper for **memfd_secret**(), necessitating the use of *syscall*(2).

DESCRIPTION

memfd_secret() creates an anonymous RAM-based file and returns a file descriptor that refers to it. The file provides a way to create and access memory regions with stronger protection than usual RAM-based files and anonymous memory mappings. Once all open references to the file are closed, it is automatically released. The initial size of the file is set to 0. Following the call, the file size should be set using *ftruncate*(2).

The memory areas backing the file created with *memfd_secret*(2) are visible only to the processes that have access to the file descriptor. The memory region is removed from the kernel page tables and only the page tables of the processes holding the file descriptor map the corresponding physical memory. (Thus, the pages in the region can't be accessed by the kernel itself, so that, for example, pointers to the region can't be passed to system calls.)

The following values may be bitwise ORed in *flags* to control the behavior of **memfd_secret**():

FD_CLOEXEC
: Set the close-on-exec flag on the new file descriptor, which causes the region to be removed from the process on *execve*(2). See the description of the **O_CLOEXEC** flag in *open*(2)

As its return value, **memfd_secret**() returns a new file descriptor that refers to an anonymous file. This file descriptor is opened for both reading and writing (**O_RDWR**) and **O_LARGEFILE** is set for the file descriptor.

With respect to *fork*(2) and *execve*(2), the usual semantics apply for the file descriptor created by **memfd_secret**(). A copy of the file descriptor is inherited by the child produced by *fork*(2) and refers to the same file. The file descriptor is preserved across *execve*(2), unless the close-on-exec flag has been set.

The memory region is locked into memory in the same way as with *mlock*(2), so that it will never be written into swap, and hibernation is inhibited for as long as any **memfd_secret**() descriptions exist. However the implementation of **memfd_secret**() will not try to populate the whole range during the *mmap*(2) call that attaches the region into the process's address space; instead, the pages are only actually allocated as they are faulted in. The amount of memory allowed for memory mappings of the file descriptor obeys the same rules as *mlock*(2) and cannot exceed **RLIMIT_MEMLOCK**.

RETURN VALUE

On success, **memfd_secret**() returns a new file descriptor. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EINVAL
: *flags* included unknown bits.

EMFILE
: The per-process limit on the number of open file descriptors has been reached.

EMFILE
: The system-wide limit on the total number of open files has been reached.

ENOMEM
: There was insufficient memory to create a new anonymous file.

ENOSYS
: **memfd_secret**() is not implemented on this architecture, or has not been enabled on the kernel command-line with **secretmem_enable**=1.

STANDARDS

Linux.

HISTORY

Linux 5.14.

NOTES

The **memfd_secret**() system call is designed to allow a user-space process to create a range of memory that is inaccessible to anybody else - kernel included. There is no 100% guarantee that kernel won't be able to access memory ranges backed by **memfd_secret**() in any circumstances, but nevertheless, it is much harder to exfiltrate data from these regions.

memfd_secret() provides the following protections:

- Enhanced protection (in conjunction with all the other in-kernel attack prevention systems) against ROP attacks. Absence of any in-kernel primitive for accessing memory backed by **memfd_secret**() means that one-gadget ROP attack can't work to perform data exfiltration. The attacker would need to find enough ROP gadgets to reconstruct the missing page table entries, which significantly increases difficulty of the attack, especially when other protections like the kernel stack size limit and address space layout randomization are in place.
- Prevent cross-process user-space memory exposures. Once a region for a **memfd_secret**() memory mapping is allocated, the user can't accidentally pass it into the kernel to be transmitted somewhere. The memory pages in this region cannot be accessed via the direct map and they are disallowed in get_user_pages.
- Harden against exploited kernel flaws. In order to access memory areas backed by **memfd_secret**(), a kernel-side attack would need to either walk the page tables and create new ones, or spawn a new privileged user-space process to perform secrets exfiltration using *ptrace*(2).

The way **memfd_secret**() allocates and locks the memory may impact overall system performance, therefore the system call is disabled by default and only available if the system administrator turned it on using "secretmem.enable=y" kernel parameter.

To prevent potential data leaks of memory regions backed by **memfd_secret**() from a hybernation image, hybernation is prevented when there are active **memfd_secret**() users.

NAME

migrate_pages − move all pages in a process to another set of nodes

LIBRARY

NUMA (Non-Uniform Memory Access) policy library (*libnuma*, −*lnuma*)

SYNOPSIS

#include <numaif.h>

long migrate_pages(int *pid***, unsigned long** *maxnode*,
**const unsigned long ***_old_nodes_,
const unsigned long ***_new_nodes_);**

DESCRIPTION

migrate_pages() attempts to move all pages of the process *pid* that are in memory nodes *old_nodes* to the memory nodes in *new_nodes*. Pages not located in any node in *old_nodes* will not be migrated. As far as possible, the kernel maintains the relative topology relationship inside *old_nodes* during the migration to *new_nodes*.

The *old_nodes* and *new_nodes* arguments are pointers to bit masks of node numbers, with up to *maxnode* bits in each mask. These masks are maintained as arrays of unsigned *long* integers (in the last *long* integer, the bits beyond those specified by *maxnode* are ignored). The *maxnode* argument is the maximum node number in the bit mask plus one (this is the same as in *mbind*(2), but different from *select*(2)).

The *pid* argument is the ID of the process whose pages are to be moved. To move pages in another process, the caller must be privileged (**CAP_SYS_NICE**) or the real or effective user ID of the calling process must match the real or saved-set user ID of the target process. If *pid* is 0, then **migrate_pages**() moves pages of the calling process.

Pages shared with another process will be moved only if the initiating process has the **CAP_SYS_NICE** privilege.

RETURN VALUE

On success **migrate_pages**() returns the number of pages that could not be moved (i.e., a return of zero means that all pages were successfully moved). On error, it returns −1, and sets *errno* to indicate the error.

ERRORS

EFAULT
Part or all of the memory range specified by *old_nodes*/*new_nodes* and *maxnode* points outside your accessible address space.

EINVAL
The value specified by *maxnode* exceeds a kernel-imposed limit. Or, *old_nodes* or *new_nodes* specifies one or more node IDs that are greater than the maximum supported node ID. Or, none of the node IDs specified by *new_nodes* are on-line and allowed by the process's current cpuset context, or none of the specified nodes contain memory.

EPERM
Insufficient privilege (**CAP_SYS_NICE**) to move pages of the process specified by *pid*, or insufficient privilege (**CAP_SYS_NICE**) to access the specified target nodes.

ESRCH
No process matching *pid* could be found.

STANDARDS

Linux.

HISTORY

Linux 2.6.16.

NOTES

For information on library support, see *numa*(7).

Use *get_mempolicy*(2) with the **MPOL_F_MEMS_ALLOWED** flag to obtain the set of nodes that are allowed by the calling process's cpuset. Note that this information is subject to change at any time by manual or automatic reconfiguration of the cpuset.

Use of **migrate_pages**() may result in pages whose location (node) violates the memory policy established for the specified addresses (see *mbind*(2)) and/or the specified process (see *set_mempolicy*(2)). That is, memory policy does not constrain the destination nodes used by **migrate_pages**().

The <*numaif.h*> header is not included with glibc, but requires installing *libnuma−devel* or a similar package.

NAME

mincore − determine whether pages are resident in memory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/mman.h>

int mincore(void *addr***[.***length***], size_t** *length***, unsigned char *** *vec***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

mincore():
Since glibc 2.19:
_DEFAULT_SOURCE
glibc 2.19 and earlier:
_BSD_SOURCE || _SVID_SOURCE

DESCRIPTION

mincore() returns a vector that indicates whether pages of the calling process's virtual memory are resident in core (RAM), and so will not cause a disk access (page fault) if referenced. The kernel returns residency information about the pages starting at the address *addr*, and continuing for *length* bytes.

The *addr* argument must be a multiple of the system page size. The *length* argument need not be a multiple of the page size, but since residency information is returned for whole pages, *length* is effectively rounded up to the next multiple of the page size. One may obtain the page size (**PAGE_SIZE**) using *sysconf(_SC_PAGESIZE)*.

The *vec* argument must point to an array containing at least *(length+PAGE_SIZE−1) / PAGE_SIZE* bytes. On return, the least significant bit of each byte will be set if the corresponding page is currently resident in memory, and be clear otherwise. (The settings of the other bits in each byte are undefined; these bits are reserved for possible later use.) Of course the information returned in *vec* is only a snapshot: pages that are not locked in memory can come and go at any moment, and the contents of *vec* may already be stale by the time this call returns.

RETURN VALUE

On success, **mincore**() returns zero. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EAGAIN kernel is temporarily out of resources.

EFAULT
vec points to an invalid address.

EINVAL
addr is not a multiple of the page size.

ENOMEM
length is greater than (*TASK_SIZE − addr*). (This could occur if a negative value is specified for *length*, since that value will be interpreted as a large unsigned integer.) In Linux 2.6.11 and earlier, the error **EINVAL** was returned for this condition.

ENOMEM
addr to *addr* + *length* contained unmapped memory.

STANDARDS

None.

HISTORY

Linux 2.3.99pre1, glibc 2.2.

First appeared in 4.4BSD.

NetBSD, FreeBSD, OpenBSD, Solaris 8, AIX 5.1, SunOS 4.1.

BUGS

Before Linux 2.6.21, **mincore**() did not return correct information for **MAP_PRIVATE** mappings, or for nonlinear mappings (established using *remap_file_pages*(2)).

fincore(1), *madvise*(2), *mlock*(2), *mmap*(2), *posix_fadvise*(2), *posix_madvise*(3)

NAME

mkdir, mkdirat − create a directory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/stat.h>

int mkdir(const char *pathname, mode_t mode);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <sys/stat.h>

int mkdirat(int dirfd, const char *pathname, mode_t mode);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

mkdirat():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_ATFILE_SOURCE

DESCRIPTION

mkdir() attempts to create a directory named *pathname*.

The argument *mode* specifies the mode for the new directory (see *inode*(7)). It is modified by the process's *umask* in the usual way: in the absence of a default ACL, the mode of the created directory is (*mode* & ~*umask* & 0777). Whether other *mode* bits are honored for the created directory depends on the operating system. For Linux, see NOTES below.

The newly created directory will be owned by the effective user ID of the process. If the directory containing the file has the set-group-ID bit set, or if the filesystem is mounted with BSD group semantics (*mount −o bsdgroups* or, synonymously *mount −o grpid*), the new directory will inherit the group ownership from its parent; otherwise it will be owned by the effective group ID of the process.

If the parent directory has the set-group-ID bit set, then so will the newly created directory.

mkdirat()

The **mkdirat**() system call operates in exactly the same way as **mkdir**(), except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **mkdir**() for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *mkdir*())

If *pathname* is absolute, then *dirfd* is ignored.

See *openat*(2) for an explanation of the need for **mkdirat**().

RETURN VALUE

mkdir() and **mkdirat**() return zero on success. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
The parent directory does not allow write permission to the process, or one of the directories in *pathname* did not allow search permission. (See also *path_resolution*(7).)

EBADF
(**mkdirat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EDQUOT
The user's quota of disk blocks or inodes on the filesystem has been exhausted.

EEXIST
pathname already exists (not necessarily as a directory). This includes the case where *pathname* is a symbolic link, dangling or not.

EFAULT
pathname points outside your accessible address space.

EINVAL
The final component ("basename") of the new directory's *pathname* is invalid (e.g., it contains characters not permitted by the underlying filesystem).

ELOOP
Too many symbolic links were encountered in resolving *pathname*.

EMLINK
The number of links to the parent directory would exceed **LINK_MAX**.

ENAMETOOLONG
pathname was too long.

ENOENT
A directory component in *pathname* does not exist or is a dangling symbolic link.

ENOMEM
Insufficient kernel memory was available.

ENOSPC
The device containing *pathname* has no room for the new directory.

ENOSPC
The new directory cannot be created because the user's disk quota is exhausted.

ENOTDIR
A component used as a directory in *pathname* is not, in fact, a directory.

ENOTDIR
(**mkdirat**()) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EPERM
The filesystem containing *pathname* does not support the creation of directories.

EROFS
pathname refers to a file on a read-only filesystem.

VERSIONS

Under Linux, apart from the permission bits, the **S_ISVTX** *mode* bit is also honored.

glibc notes

On older kernels where **mkdirat**() is unavailable, the glibc wrapper function falls back to the use of **mkdir**(). When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

STANDARDS

POSIX.1-2008.

HISTORY

mkdir()
SVr4, BSD, POSIX.1-2001.

mkdirat()
Linux 2.6.16, glibc 2.4.

NOTES

There are many infelicities in the protocol underlying NFS. Some of these affect **mkdir**().

SEE ALSO

NAME

mknod, mknodat − create a special or ordinary file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/stat.h>

int mknod(const char *pathname, mode_t mode, dev_t dev);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <sys/stat.h>

int mknodat(int dirfd, const char *pathname, mode_t mode, dev_t dev);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

mknod():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _BSD_SOURCE || _SVID_SOURCE

DESCRIPTION

The system call **mknod**() creates a filesystem node (file, device special file, or named pipe) named *pathname*, with attributes specified by *mode* and *dev*.

The *mode* argument specifies both the file mode to use and the type of node to be created. It should be a combination (using bitwise OR) of one of the file types listed below and zero or more of the file mode bits listed in *inode*(7).

The file mode is modified by the process's *umask* in the usual way: in the absence of a default ACL, the permissions of the created node are (*mode* & *~umask*).

The file type must be one of **S_IFREG**, **S_IFCHR**, **S_IFBLK**, **S_IFIFO**, or **S_IFSOCK** to specify a regular file (which will be created empty), character special file, block special file, FIFO (named pipe), or UNIX domain socket, respectively. (Zero file type is equivalent to type **S_IFREG**.)

If the file type is **S_IFCHR** or **S_IFBLK**, then *dev* specifies the major and minor numbers of the newly created device special file (**makedev**(3) may be useful to build the value for *dev*); otherwise it is ignored.

If *pathname* already exists, or is a symbolic link, this call fails with an **EEXIST** error.

The newly created node will be owned by the effective user ID of the process. If the directory containing the node has the set-group-ID bit set, or if the filesystem is mounted with BSD group semantics, the new node will inherit the group ownership from its parent directory; otherwise it will be owned by the effective group ID of the process.

mknodat()

The **mknodat**() system call operates in exactly the same way as **mknod**(), except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **mknod**() for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *mknod*())

If *pathname* is absolute, then *dirfd* is ignored.

See *openat*(2) for an explanation of the need for **mknodat**().

RETURN VALUE

mknod() and **mknodat**() return zero on success. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
The parent directory does not allow write permission to the process, or one of the directories in the path prefix of *pathname* did not allow search permission. (See also *path_resolution*(7).)

EBADF
(**mknodat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EDQUOT
The user's quota of disk blocks or inodes on the filesystem has been exhausted.

EEXIST
pathname already exists. This includes the case where *pathname* is a symbolic link, dangling or not.

EFAULT
pathname points outside your accessible address space.

EINVAL
mode requested creation of something other than a regular file, device special file, FIFO or socket.

ELOOP
Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG
pathname was too long.

ENOENT
A directory component in *pathname* does not exist or is a dangling symbolic link.

ENOMEM
Insufficient kernel memory was available.

ENOSPC
The device containing *pathname* has no room for the new node.

ENOTDIR
A component used as a directory in *pathname* is not, in fact, a directory.

ENOTDIR
(**mknodat**()) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EPERM
mode requested creation of something other than a regular file, FIFO (named pipe), or UNIX domain socket, and the caller is not privileged (Linux: does not have the **CAP_MKNOD** capability); also returned if the filesystem containing *pathname* does not support the type of node requested.

EROFS
pathname refers to a file on a read-only filesystem.

VERSIONS

POSIX.1-2001 says: "The only portable use of **mknod**() is to create a FIFO-special file. If *mode* is not **S_IFIFO** or *dev* is not 0, the behavior of **mknod**() is unspecified." However, nowadays one should never use **mknod**() for this purpose; one should use *mkfifo*(3), a function especially defined for this purpose.

Under Linux, **mknod**() cannot be used to create directories. One should make directories with *mkdir*(2).

STANDARDS

POSIX.1-2008.

HISTORY

mknod()
SVr4, 4.4BSD, POSIX.1-2001 (but see VERSIONS).

mknodat()
Linux 2.6.16, glibc 2.4. POSIX.1-2008.

NOTES

There are many infelicities in the protocol underlying NFS. Some of these affect **mknod**() and **mknodat**().

NAME

mlock, mlock2, munlock, mlockall, munlockall − lock and unlock memory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/mman.h>

int mlock(const void addr[.len], size_t len);
int mlock2(const void addr[.len], size_t len, unsigned int flags);
int munlock(const void addr[.len], size_t len);

int mlockall(int flags);
int munlockall(void);
```

DESCRIPTION

mlock(), **mlock2**(), and **mlockall**() lock part or all of the calling process's virtual address space into RAM, preventing that memory from being paged to the swap area.

munlock() and **munlockall**() perform the converse operation, unlocking part or all of the calling process's virtual address space, so that pages in the specified virtual address range can be swapped out again if required by the kernel memory manager.

Memory locking and unlocking are performed in units of whole pages.

mlock(), mlock2(), and munlock()

mlock() locks pages in the address range starting at *addr* and continuing for *len* bytes. All pages that contain a part of the specified address range are guaranteed to be resident in RAM when the call returns successfully; the pages are guaranteed to stay in RAM until later unlocked.

mlock2() also locks pages in the specified range starting at *addr* and continuing for *len* bytes. However, the state of the pages contained in that range after the call returns successfully will depend on the value in the *flags* argument.

The *flags* argument can be either 0 or the following constant:

MLOCK_ONFAULT
: Lock pages that are currently resident and mark the entire range so that the remaining nonresident pages are locked when they are populated by a page fault.

If *flags* is 0, **mlock2**() behaves exactly the same as **mlock**().

munlock() unlocks pages in the address range starting at *addr* and continuing for *len* bytes. After this call, all pages that contain a part of the specified memory range can be moved to external swap space again by the kernel.

mlockall() and munlockall()

mlockall() locks all pages mapped into the address space of the calling process. This includes the pages of the code, data, and stack segment, as well as shared libraries, user space kernel data, shared memory, and memory-mapped files. All mapped pages are guaranteed to be resident in RAM when the call returns successfully; the pages are guaranteed to stay in RAM until later unlocked.

The *flags* argument is constructed as the bitwise OR of one or more of the following constants:

MCL_CURRENT
: Lock all pages which are currently mapped into the address space of the process.

MCL_FUTURE
: Lock all pages which will become mapped into the address space of the process in the future. These could be, for instance, new pages required by a growing heap and stack as well as new memory-mapped files or shared memory regions.

MCL_ONFAULT (since Linux 4.4)
: Used together with **MCL_CURRENT**, **MCL_FUTURE**, or both. Mark all current (with **MCL_CURRENT**) or future (with **MCL_FUTURE**) mappings to lock pages when they are faulted in. When used with **MCL_CURRENT**, all present pages are locked, but **mlockall**() will not fault in non-present pages. When used with **MCL_FUTURE**, all future mappings will be marked to lock pages when they are faulted in, but they will not be populated by the

lock when the mapping is created. **MCL_ONFAULT** must be used with either **MCL_CURRENT** or **MCL_FUTURE** or both.

If **MCL_FUTURE** has been specified, then a later system call (e.g., *mmap*(2), *sbrk*(2), *malloc*(3)), may fail if it would cause the number of locked bytes to exceed the permitted maximum (see below). In the same circumstances, stack growth may likewise fail: the kernel will deny stack expansion and deliver a **SIGSEGV** signal to the process.

munlockall() unlocks all pages mapped into the address space of the calling process.

RETURN VALUE

On success, these system calls return 0. On error, −1 is returned, *errno* is set to indicate the error, and no changes are made to any locks in the address space of the process.

ERRORS

EAGAIN
(**mlock**(), **mlock2**(), and *munlock*()) Some or all of the specified address range could not be locked.

EINVAL
(**mlock**(), **mlock2**(), and *munlock*()) The result of the addition *addr+len* was less than *addr* (e.g., the addition may have resulted in an overflow).

EINVAL
(**mlock2**()) Unknown *flags* were specified.

EINVAL
(**mlockall**()) Unknown *flags* were specified or **MCL_ONFAULT** was specified without either **MCL_FUTURE** or **MCL_CURRENT**.

EINVAL
(Not on Linux) *addr* was not a multiple of the page size.

ENOMEM
(**mlock**(), **mlock2**(), and *munlock*()) Some of the specified address range does not correspond to mapped pages in the address space of the process.

ENOMEM
(**mlock**(), **mlock2**(), and *munlock*()) Locking or unlocking a region would result in the total number of mappings with distinct attributes (e.g., locked versus unlocked) exceeding the allowed maximum. (For example, unlocking a range in the middle of a currently locked mapping would result in three mappings: two locked mappings at each end and an unlocked mapping in the middle.)

ENOMEM
(Linux 2.6.9 and later) the caller had a nonzero **RLIMIT_MEMLOCK** soft resource limit, but tried to lock more memory than the limit permitted. This limit is not enforced if the process is privileged (**CAP_IPC_LOCK**).

ENOMEM
(Linux 2.4 and earlier) the calling process tried to lock more than half of RAM.

EPERM
The caller is not privileged, but needs privilege (**CAP_IPC_LOCK**) to perform the requested operation.

EPERM
(**munlockall**()) (Linux 2.6.8 and earlier) The caller was not privileged (**CAP_IPC_LOCK**).

VERSIONS

Linux

Under Linux, **mlock**(), **mlock2**(), and **munlock**() automatically round *addr* down to the nearest page boundary. However, the POSIX.1 specification of **mlock**() and **munlock**() allows an implementation to require that *addr* is page aligned, so portable applications should ensure this.

The *VmLck* field of the Linux-specific */proc/*pid*/status* file shows how many kilobytes of memory the process with ID *PID* has locked using **mlock**(), **mlock2**(), **mlockall**(), and *mmap*(2) **MAP_LOCKED**.

STANDARDS

mlock()
munlock()
mlockall()
munlockall()
POSIX.1-2008.

mlock2()
Linux.

On POSIX systems on which **mlock**() and **munlock**() are available, **_POSIX_MEMLOCK_RANGE** is defined in <*unistd.h*> and the number of bytes in a page can be determined from the constant **PAGESIZE** (if defined) in <*limits.h*> or by calling *sysconf(_SC_PAGESIZE)*.

On POSIX systems on which **mlockall**() and **munlockall**() are available, **_POSIX_MEMLOCK** is defined in <*unistd.h*> to a value greater than 0. (See also *sysconf*(3).)

HISTORY

mlock()
munlock()
mlockall()
munlockall()
POSIX.1-2001, POSIX.1-2008, SVr4.

mlock2()
Linux 4.4, glibc 2.27.

NOTES

Memory locking has two main applications: real-time algorithms and high-security data processing. Real-time applications require deterministic timing, and, like scheduling, paging is one major cause of unexpected program execution delays. Real-time applications will usually also switch to a real-time scheduler with *sched_setscheduler*(2). Cryptographic security software often handles critical bytes like passwords or secret keys as data structures. As a result of paging, these secrets could be transferred onto a persistent swap store medium, where they might be accessible to the enemy long after the security software has erased the secrets in RAM and terminated. (But be aware that the suspend mode on laptops and some desktop computers will save a copy of the system's RAM to disk, regardless of memory locks.)

Real-time processes that are using **mlockall**() to prevent delays on page faults should reserve enough locked stack pages before entering the time-critical section, so that no page fault can be caused by function calls. This can be achieved by calling a function that allocates a sufficiently large automatic variable (an array) and writes to the memory occupied by this array in order to touch these stack pages. This way, enough pages will be mapped for the stack and can be locked into RAM. The dummy writes ensure that not even copy-on-write page faults can occur in the critical section.

Memory locks are not inherited by a child created via *fork*(2) and are automatically removed (unlocked) during an *execve*(2) or when the process terminates. The **mlockall**() **MCL_FUTURE** and **MCL_FUTURE | MCL_ONFAULT** settings are not inherited by a child created via *fork*(2) and are cleared during an *execve*(2).

Note that *fork*(2) will prepare the address space for a copy-on-write operation. The consequence is that any write access that follows will cause a page fault that in turn may cause high latencies for a real-time process. Therefore, it is crucial not to invoke *fork*(2) after an **mlockall**() or **mlock**() operation—not even from a thread which runs at a low priority within a process which also has a thread running at elevated priority.

The memory lock on an address range is automatically removed if the address range is unmapped via *munmap*(2).

Memory locks do not stack, that is, pages which have been locked several times by calls to **mlock**(), **mlock2**(), or **mlockall**() will be unlocked by a single call to **munlock**() for the corresponding range or by **munlockall**(). Pages which are mapped to several locations or by several processes stay locked into RAM as long as they are locked at least at one location or by at least one process.

If a call to **mlockall**() which uses the **MCL_FUTURE** flag is followed by another call that does not specify this flag, the changes made by the **MCL_FUTURE** call will be lost.

The **mlock2**() **MLOCK_ONFAULT** flag and the **mlockall**() **MCL_ONFAULT** flag allow efficient memory locking for applications that deal with large mappings where only a (small) portion of pages in the mapping are touched. In such cases, locking all of the pages in a mapping would incur a significant penalty for memory locking.

Limits and permissions

In Linux 2.6.8 and earlier, a process must be privileged (**CAP_IPC_LOCK**) in order to lock memory and the **RLIMIT_MEMLOCK** soft resource limit defines a limit on how much memory the process may lock.

Since Linux 2.6.9, no limits are placed on the amount of memory that a privileged process can lock and the **RLIMIT_MEMLOCK** soft resource limit instead defines a limit on how much memory an unprivileged process may lock.

BUGS

In Linux 4.8 and earlier, a bug in the kernel's accounting of locked memory for unprivileged processes (i.e., without **CAP_IPC_LOCK**) meant that if the region specified by *addr* and *len* overlapped an existing lock, then the already locked bytes in the overlapping region were counted twice when checking against the limit. Such double accounting could incorrectly calculate a "total locked memory" value for the process that exceeded the **RLIMIT_MEMLOCK** limit, with the result that **mlock**() and **mlock2**() would fail on requests that should have succeeded. This bug was fixed in Linux 4.9.

In Linux 2.4 series of kernels up to and including Linux 2.4.17, a bug caused the **mlockall**() **MCL_FUTURE** flag to be inherited across a *fork*(2). This was rectified in Linux 2.4.18.

Since Linux 2.6.9, if a privileged process calls *mlockall(MCL_FUTURE)* and later drops privileges (loses the **CAP_IPC_LOCK** capability by, for example, setting its effective UID to a nonzero value), then subsequent memory allocations (e.g., *mmap*(2), *brk*(2)) will fail if the **RLIMIT_MEMLOCK** resource limit is encountered.

NAME

mmap, munmap − map or unmap files or devices into memory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/mman.h>

void *mmap(void addr[.length], size_t length, int prot, int flags,
           int fd, off_t offset);
int munmap(void addr[.length], size_t length);
```

See NOTES for information on feature test macro requirements.

DESCRIPTION

mmap() creates a new mapping in the virtual address space of the calling process. The starting address for the new mapping is specified in *addr*. The *length* argument specifies the length of the mapping (which must be greater than 0).

If *addr* is NULL, then the kernel chooses the (page-aligned) address at which to create the mapping; this is the most portable method of creating a new mapping. If *addr* is not NULL, then the kernel takes it as a hint about where to place the mapping; on Linux, the kernel will pick a nearby page boundary (but always above or equal to the value specified by */proc/sys/vm/mmap_min_addr*) and attempt to create the mapping there. If another mapping already exists there, the kernel picks a new address that may or may not depend on the hint. The address of the new mapping is returned as the result of the call.

The contents of a file mapping (as opposed to an anonymous mapping; see **MAP_ANONYMOUS** below), are initialized using *length* bytes starting at offset *offset* in the file (or other object) referred to by the file descriptor *fd*. *offset* must be a multiple of the page size as returned by *sysconf(_SC_PAGE_SIZE)*.

After the **mmap**() call has returned, the file descriptor, *fd*, can be closed immediately without invalidating the mapping.

The *prot* argument describes the desired memory protection of the mapping (and must not conflict with the open mode of the file). It is either **PROT_NONE** or the bitwise OR of one or more of the following flags:

PROT_EXEC Pages may be executed.

PROT_READ Pages may be read.

PROT_WRITE Pages may be written.

PROT_NONE Pages may not be accessed.

The flags argument

The *flags* argument determines whether updates to the mapping are visible to other processes mapping the same region, and whether updates are carried through to the underlying file. This behavior is determined by including exactly one of the following values in *flags*:

MAP_SHARED
: Share this mapping. Updates to the mapping are visible to other processes mapping the same region, and (in the case of file-backed mappings) are carried through to the underlying file. (To precisely control when updates are carried through to the underlying file requires the use of *msync*(2).)

MAP_SHARED_VALIDATE (since Linux 4.15)
: This flag provides the same behavior as **MAP_SHARED** except that **MAP_SHARED** mappings ignore unknown flags in *flags*. By contrast, when creating a mapping using **MAP_SHARED_VALIDATE**, the kernel verifies all passed flags are known and fails the mapping with the error **EOPNOTSUPP** for unknown flags. This mapping type is also required to be able to use some mapping flags (e.g., **MAP_SYNC**).

MAP_PRIVATE
: Create a private copy-on-write mapping. Updates to the mapping are not visible to other processes mapping the same file, and are not carried through to the underlying file. It is unspecified whether changes made to the file after the **mmap**() call are visible in the mapped

region.

Both **MAP_SHARED** and **MAP_PRIVATE** are described in POSIX.1-2001 and POSIX.1-2008. **MAP_SHARED_VALIDATE** is a Linux extension.

In addition, zero or more of the following values can be ORed in *flags*:

MAP_32BIT (since Linux 2.4.20, 2.6)
Put the mapping into the first 2 Gigabytes of the process address space. This flag is supported only on x86-64, for 64-bit programs. It was added to allow thread stacks to be allocated somewhere in the first 2 GB of memory, so as to improve context-switch performance on some early 64-bit processors. Modern x86-64 processors no longer have this performance problem, so use of this flag is not required on those systems. The **MAP_32BIT** flag is ignored when **MAP_FIXED** is set.

MAP_ANON
Synonym for **MAP_ANONYMOUS**; provided for compatibility with other implementations.

MAP_ANONYMOUS
The mapping is not backed by any file; its contents are initialized to zero. The *fd* argument is ignored; however, some implementations require *fd* to be −1 if **MAP_ANONYMOUS** (or **MAP_ANON**) is specified, and portable applications should ensure this. The *offset* argument should be zero. Support for **MAP_ANONYMOUS** in conjunction with **MAP_SHARED** was added in Linux 2.4.

MAP_DENYWRITE
This flag is ignored. (Long ago—Linux 2.0 and earlier—it signaled that attempts to write to the underlying file should fail with **ETXTBSY**. But this was a source of denial-of-service attacks.)

MAP_EXECUTABLE
This flag is ignored.

MAP_FILE
Compatibility flag. Ignored.

MAP_FIXED
Don't interpret *addr* as a hint: place the mapping at exactly that address. *addr* must be suitably aligned: for most architectures a multiple of the page size is sufficient; however, some architectures may impose additional restrictions. If the memory region specified by *addr* and *length* overlaps pages of any existing mapping(s), then the overlapped part of the existing mapping(s) will be discarded. If the specified address cannot be used, **mmap**() will fail.

Software that aspires to be portable should use the **MAP_FIXED** flag with care, keeping in mind that the exact layout of a process's memory mappings is allowed to change significantly between Linux versions, C library versions, and operating system releases. *Carefully read the discussion of this flag in NOTES!*

MAP_FIXED_NOREPLACE (since Linux 4.17)
This flag provides behavior that is similar to **MAP_FIXED** with respect to the *addr* enforcement, but differs in that **MAP_FIXED_NOREPLACE** never clobbers a preexisting mapped range. If the requested range would collide with an existing mapping, then this call fails with the error **EEXIST.** This flag can therefore be used as a way to atomically (with respect to other threads) attempt to map an address range: one thread will succeed; all others will report failure.

Note that older kernels which do not recognize the **MAP_FIXED_NOREPLACE** flag will typically (upon detecting a collision with a preexisting mapping) fall back to a "non-**MAP_FIXED**" type of behavior: they will return an address that is different from the requested address. Therefore, backward-compatible software should check the returned address against the requested address.

MAP_GROWSDOWN
This flag is used for stacks. It indicates to the kernel virtual memory system that the mapping should extend downward in memory. The return address is one page lower than the memory area that is actually created in the process's virtual address space. Touching an address in the

"guard" page below the mapping will cause the mapping to grow by a page. This growth can be repeated until the mapping grows to within a page of the high end of the next lower mapping, at which point touching the "guard" page will result in a **SIGSEGV** signal.

MAP_HUGETLB (since Linux 2.6.32)
Allocate the mapping using "huge" pages. See the Linux kernel source file *Documentation/admin−guide/mm/hugetlbpage.rst* for further information, as well as NOTES, below.

MAP_HUGE_2MB
MAP_HUGE_1GB (since Linux 3.8)
Used in conjunction with **MAP_HUGETLB** to select alternative hugetlb page sizes (respectively, 2 MB and 1 GB) on systems that support multiple hugetlb page sizes.

More generally, the desired huge page size can be configured by encoding the base-2 logarithm of the desired page size in the six bits at the offset **MAP_HUGE_SHIFT**. (A value of zero in this bit field provides the default huge page size; the default huge page size can be discovered via the *Hugepagesize* field exposed by */proc/meminfo*.) Thus, the above two constants are defined as:

```
#define MAP_HUGE_2MB    (21 << MAP_HUGE_SHIFT)
#define MAP_HUGE_1GB    (30 << MAP_HUGE_SHIFT)
```

The range of huge page sizes that are supported by the system can be discovered by listing the subdirectories in */sys/kernel/mm/hugepages*.

MAP_LOCKED (since Linux 2.5.37)
Mark the mapped region to be locked in the same way as *mlock*(2). This implementation will try to populate (prefault) the whole range but the **mmap**() call doesn't fail with **ENOMEM** if this fails. Therefore major faults might happen later on. So the semantic is not as strong as *mlock*(2). One should use **mmap**() plus *mlock*(2) when major faults are not acceptable after the initialization of the mapping. The **MAP_LOCKED** flag is ignored in older kernels.

MAP_NONBLOCK (since Linux 2.5.46)
This flag is meaningful only in conjunction with **MAP_POPULATE**. Don't perform read-ahead: create page tables entries only for pages that are already present in RAM. Since Linux 2.6.23, this flag causes **MAP_POPULATE** to do nothing. One day, the combination of **MAP_POPULATE** and **MAP_NONBLOCK** may be reimplemented.

MAP_NORESERVE
Do not reserve swap space for this mapping. When swap space is reserved, one has the guarantee that it is possible to modify the mapping. When swap space is not reserved one might get **SIGSEGV** upon a write if no physical memory is available. See also the discussion of the file */proc/sys/vm/overcommit_memory* in *proc*(5). Before Linux 2.6, this flag had effect only for private writable mappings.

MAP_POPULATE (since Linux 2.5.46)
Populate (prefault) page tables for a mapping. For a file mapping, this causes read-ahead on the file. This will help to reduce blocking on page faults later. The **mmap**() call doesn't fail if the mapping cannot be populated (for example, due to limitations on the number of mapped huge pages when using **MAP_HUGETLB**). Support for **MAP_POPULATE** in conjunction with private mappings was added in Linux 2.6.23.

MAP_STACK (since Linux 2.6.27)
Allocate the mapping at an address suitable for a process or thread stack.

This flag is currently a no-op on Linux. However, by employing this flag, applications can ensure that they transparently obtain support if the flag is implemented in the future. Thus, it is used in the glibc threading implementation to allow for the fact that some architectures may (later) require special treatment for stack allocations. A further reason to employ this flag is portability: **MAP_STACK** exists (and has an effect) on some other systems (e.g., some of the BSDs).

MAP_SYNC (since Linux 4.15)
This flag is available only with the **MAP_SHARED_VALIDATE** mapping type; mappings of type **MAP_SHARED** will silently ignore this flag. This flag is supported only for files supporting DAX (direct mapping of persistent memory). For other files, creating a mapping with

this flag results in an **EOPNOTSUPP** error.

Shared file mappings with this flag provide the guarantee that while some memory is mapped writable in the address space of the process, it will be visible in the same file at the same offset even after the system crashes or is rebooted. In conjunction with the use of appropriate CPU instructions, this provides users of such mappings with a more efficient way of making data modifications persistent.

MAP_UNINITIALIZED (since Linux 2.6.33)
Don't clear anonymous pages. This flag is intended to improve performance on embedded devices. This flag is honored only if the kernel was configured with the **CONFIG_MMAP_ALLOW_UNINITIALIZED** option. Because of the security implications, that option is normally enabled only on embedded devices (i.e., devices where one has complete control of the contents of user memory).

Of the above flags, only **MAP_FIXED** is specified in POSIX.1-2001 and POSIX.1-2008. However, most systems also support **MAP_ANONYMOUS** (or its synonym **MAP_ANON**).

munmap()
The **munmap**() system call deletes the mappings for the specified address range, and causes further references to addresses within the range to generate invalid memory references. The region is also automatically unmapped when the process is terminated. On the other hand, closing the file descriptor does not unmap the region.

The address *addr* must be a multiple of the page size (but *length* need not be). All pages containing a part of the indicated range are unmapped, and subsequent references to these pages will generate **SIGSEGV**. It is not an error if the indicated range does not contain any mapped pages.

RETURN VALUE

On success, **mmap**() returns a pointer to the mapped area. On error, the value **MAP_FAILED** (that is, *(void *) −1*) is returned, and *errno* is set to indicate the error.

On success, **munmap**() returns 0. On failure, it returns −1, and *errno* is set to indicate the error (probably to **EINVAL**).

ERRORS

EACCES
A file descriptor refers to a non-regular file. Or a file mapping was requested, but *fd* is not open for reading. Or **MAP_SHARED** was requested and **PROT_WRITE** is set, but *fd* is not open in read/write (**O_RDWR**) mode. Or **PROT_WRITE** is set, but the file is append-only.

EAGAIN
The file has been locked, or too much memory has been locked (see *setrlimit*(2)).

EBADF
fd is not a valid file descriptor (and **MAP_ANONYMOUS** was not set).

EEXIST
MAP_FIXED_NOREPLACE was specified in *flags*, and the range covered by *addr* and *length* clashes with an existing mapping.

EINVAL
We don't like *addr*, *length*, or *offset* (e.g., they are too large, or not aligned on a page boundary).

EINVAL
(since Linux 2.6.12) *length* was 0.

EINVAL
flags contained none of **MAP_PRIVATE**, **MAP_SHARED**, or **MAP_SHARED_VALIDATE**.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENODEV
The underlying filesystem of the specified file does not support memory mapping.

ENOMEM
No memory is available.

ENOMEM
The process's maximum number of mappings would have been exceeded. This error can also occur for **munmap**(), when unmapping a region in the middle of an existing mapping, since this results in two smaller mappings on either side of the region being unmapped.

ENOMEM
(since Linux 4.7) The process's **RLIMIT_DATA** limit, described in *getrlimit*(2), would have been exceeded.

ENOMEM
We don't like *addr*, because it exceeds the virtual address space of the CPU.

EOVERFLOW
On 32-bit architecture together with the large file extension (i.e., using 64-bit *off_t*): the number of pages used for *length* plus number of pages used for *offset* would overflow *unsigned long* (32 bits).

EPERM
The *prot* argument asks for **PROT_EXEC** but the mapped area belongs to a file on a filesystem that was mounted no-exec.

EPERM
The operation was prevented by a file seal; see *fcntl*(2).

EPERM
The **MAP_HUGETLB** flag was specified, but the caller was not privileged (did not have the **CAP_IPC_LOCK** capability) and is not a member of the *sysctl_hugetlb_shm_group* group; see the description of */proc/sys/vm/sysctl_hugetlb_shm_group* in *proc_sys*(5).

ETXTBSY
MAP_DENYWRITE was set but the object specified by *fd* is open for writing.

Use of a mapped region can result in these signals:

SIGSEGV
Attempted write into a region mapped as read-only.

SIGBUS
Attempted access to a page of the buffer that lies beyond the end of the mapped file. For an explanation of the treatment of the bytes in the page that corresponds to the end of a mapped file that is not a multiple of the page size, see NOTES.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
mmap(), **munmap**()	Thread safety	MT-Safe

VERSIONS

On some hardware architectures (e.g., i386), **PROT_WRITE** implies **PROT_READ**. It is architecture dependent whether **PROT_READ** implies **PROT_EXEC** or not. Portable programs should always set **PROT_EXEC** if they intend to execute code in the new mapping.

The portable way to create a mapping is to specify *addr* as 0 (NULL), and omit **MAP_FIXED** from *flags*. In this case, the system chooses the address for the mapping; the address is chosen so as not to conflict with any existing mapping, and will not be 0. If the **MAP_FIXED** flag is specified, and *addr* is 0 (NULL), then the mapped address will be 0 (NULL).

Certain *flags* constants are defined only if suitable feature test macros are defined (possibly by default): **_DEFAULT_SOURCE** with glibc 2.19 or later; or **_BSD_SOURCE** or **_SVID_SOURCE** in glibc 2.19 and earlier. (Employing **_GNU_SOURCE** also suffices, and requiring that macro specifically would have been more logical, since these flags are all Linux-specific.) The relevant flags are: **MAP_32BIT**, **MAP_ANONYMOUS** (and the synonym **MAP_ANON**), **MAP_DENYWRITE**, **MAP_EXECUTABLE**, **MAP_FILE**, **MAP_GROWSDOWN**, **MAP_HUGETLB**, **MAP_LOCKED**, **MAP_NONBLOCK**, **MAP_NORESERVE**, **MAP_POPULATE**, and **MAP_STACK**.

C library/kernel differences

This page describes the interface provided by the glibc **mmap**() wrapper function. Originally, this function invoked a system call of the same name. Since Linux 2.4, that system call has been superseded by *mmap2*(2), and nowadays the glibc **mmap**() wrapper function invokes *mmap2*(2) with a suitably adjusted value for *offset*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.4BSD.

On POSIX systems on which **mmap**(), *msync*(2), and **munmap**() are available, **_POSIX_MAPPED_FILES** is defined in *<unistd.h>* to a value greater than 0. (See also *sysconf*(3).)

NOTES

Memory mapped by **mmap**() is preserved across *fork*(2), with the same attributes.

A file is mapped in multiples of the page size. For a file that is not a multiple of the page size, the remaining bytes in the partial page at the end of the mapping are zeroed when mapped, and modifications to that region are not written out to the file. The effect of changing the size of the underlying file of a mapping on the pages that correspond to added or removed regions of the file is unspecified.

An application can determine which pages of a mapping are currently resident in the buffer/page cache using *mincore*(2).

Using MAP_FIXED safely

The only safe use for **MAP_FIXED** is where the address range specified by *addr* and *length* was previously reserved using another mapping; otherwise, the use of **MAP_FIXED** is hazardous because it forcibly removes preexisting mappings, making it easy for a multithreaded process to corrupt its own address space.

For example, suppose that thread A looks through */proc/*pid*/maps* in order to locate an unused address range that it can map using **MAP_FIXED**, while thread B simultaneously acquires part or all of that same address range. When thread A subsequently employs **mmap(MAP_FIXED)**, it will effectively clobber the mapping that thread B created. In this scenario, thread B need not create a mapping directly; simply making a library call that, internally, uses *dlopen*(3) to load some other shared library, will suffice. The *dlopen*(3) call will map the library into the process's address space. Furthermore, almost any library call may be implemented in a way that adds memory mappings to the address space, either with this technique, or by simply allocating memory. Examples include *brk*(2), *malloc*(3), *pthread_create*(3), and the PAM libraries .

Since Linux 4.17, a multithreaded program can use the **MAP_FIXED_NOREPLACE** flag to avoid the hazard described above when attempting to create a mapping at a fixed address that has not been reserved by a preexisting mapping.

Timestamps changes for file-backed mappings

For file-backed mappings, the *st_atime* field for the mapped file may be updated at any time between the **mmap**() and the corresponding unmapping; the first reference to a mapped page will update the field if it has not been already.

The *st_ctime* and *st_mtime* field for a file mapped with **PROT_WRITE** and **MAP_SHARED** will be updated after a write to the mapped region, and before a subsequent *msync*(2) with the **MS_SYNC** or **MS_ASYNC** flag, if one occurs.

Huge page (Huge TLB) mappings

For mappings that employ huge pages, the requirements for the arguments of **mmap**() and **munmap**() differ somewhat from the requirements for mappings that use the native system page size.

For **mmap**(), *offset* must be a multiple of the underlying huge page size. The system automatically aligns *length* to be a multiple of the underlying huge page size.

For **munmap**(), *addr*, and *length* must both be a multiple of the underlying huge page size.

BUGS

On Linux, there are no guarantees like those suggested above under **MAP_NORESERVE**. By default, any process can be killed at any moment when the system runs out of memory.

Before Linux 2.6.7, the **MAP_POPULATE** flag has effect only if *prot* is specified as **PROT_NONE**.

SUSv3 specifies that **mmap**() should fail if *length* is 0. However, before Linux 2.6.12, **mmap**() succeeded in this case: no mapping was created and the call returned *addr*. Since Linux 2.6.12, **mmap**() fails with the error **EINVAL** for this case.

POSIX specifies that the system shall always zero fill any partial page at the end of the object and that system will never write any modification of the object beyond its end. On Linux, when you write data to such partial page after the end of the object, the data stays in the page cache even after the file is closed and unmapped and even though the data is never written to the file itself, subsequent mappings may see the modified content. In some cases, this could be fixed by calling *msync*(2) before the unmap takes place; however, this doesn't work on *tmpfs*(5) (for example, when using the POSIX shared memory interface documented in *shm_overview*(7)).

EXAMPLES

The following program prints part of the file specified in its first command-line argument to standard output. The range of bytes to be printed is specified via offset and length values in the second and third command-line arguments. The program creates a memory mapping of the required pages of the file and then uses *write*(2) to output the desired bytes.

Program source

```
#include <fcntl.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/mman.h>
#include <sys/stat.h>
#include <unistd.h>

#define handle_error(msg) \
    do { perror(msg); exit(EXIT_FAILURE); } while (0)

int
main(int argc, char *argv[])
{
    int          fd;
    char         *addr;
    off_t        offset, pa_offset;
    size_t       length;
    ssize_t      s;
    struct stat  sb;

    if (argc < 3 || argc > 4) {
        fprintf(stderr, "%s file offset [length]\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    fd = open(argv[1], O_RDONLY);
    if (fd == -1)
        handle_error("open");

    if (fstat(fd, &sb) == -1)           /* To obtain file size */
        handle_error("fstat");

    offset = atoi(argv[2]);
    pa_offset = offset & ~(sysconf(_SC_PAGE_SIZE) - 1);
        /* offset for mmap() must be page aligned */

    if (offset >= sb.st_size) {
        fprintf(stderr, "offset is past end of file\n");
        exit(EXIT_FAILURE);
    }
```

```
        if (argc == 4) {
            length = atoi(argv[3]);
            if (offset + length > sb.st_size)
                length = sb.st_size - offset;
                    /* Can't display bytes past end of file */

        } else {    /* No length arg ==> display to end of file */
            length = sb.st_size - offset;
        }

        addr = mmap(NULL, length + offset - pa_offset, PROT_READ,
                    MAP_PRIVATE, fd, pa_offset);
        if (addr == MAP_FAILED)
            handle_error("mmap");

        s = write(STDOUT_FILENO, addr + offset - pa_offset, length);
        if (s != length) {
            if (s == -1)
                handle_error("write");

            fprintf(stderr, "partial write");
            exit(EXIT_FAILURE);
        }

        munmap(addr, length + offset - pa_offset);
        close(fd);

        exit(EXIT_SUCCESS);
    }

NAME

mmap2 − map files or devices into memory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/mman.h>    /* Definition of MAP_* and PROT_* constants */
#include <sys/syscall.h> /* Definition of SYS_* constants */
#include <unistd.h>

void *syscall(SYS_mmap2, unsigned long addr, unsigned long length,
              unsigned long prot, unsigned long flags,
              unsigned long fd, unsigned long pgoffset);
```

DESCRIPTION

This is probably not the system call that you are interested in; instead, see *mmap*(2), which describes the glibc wrapper function that invokes this system call.

The **mmap2**() system call provides the same interface as *mmap*(2), except that the final argument specifies the offset into the file in 4096-byte units (instead of bytes, as is done by *mmap*(2)). This enables applications that use a 32-bit *off_t* to map large files (up to 2^44 bytes).

RETURN VALUE

On success, **mmap2**() returns a pointer to the mapped area. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
: Problem with getting the data from user space.

EINVAL
: (Various platforms where the page size is not 4096 bytes.) *offset * 4096* is not a multiple of the system page size.

mmap2() can also return any of the errors described in *mmap*(2).

VERSIONS

On architectures where this system call is present, the glibc **mmap**() wrapper function invokes this system call rather than the *mmap*(2) system call.

This system call does not exist on x86-64.

On ia64, the unit for *offset* is actually the system page size, rather than 4096 bytes.

STANDARDS

Linux.

HISTORY

Linux 2.3.31.

NAME

modify_ldt − get or set a per-process LDT entry

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <asm/ldt.h>      /* Definition of struct user_desc */
#include <sys/syscall.h>  /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_modify_ldt, int  func, void ptr[.bytecount],
        unsigned long bytecount);
```

Note: glibc provides no wrapper for **modify_ldt**(), necessitating the use of *syscall*(2).

DESCRIPTION

modify_ldt() reads or writes the local descriptor table (LDT) for a process. The LDT is an array of segment descriptors that can be referenced by user code. Linux allows processes to configure a per-process (actually per-mm) LDT. For more information about the LDT, see the Intel Software Developer's Manual or the AMD Architecture Programming Manual.

When *func* is 0, **modify_ldt**() reads the LDT into the memory pointed to by *ptr*. The number of bytes read is the smaller of *bytecount* and the actual size of the LDT, although the kernel may act as though the LDT is padded with additional trailing zero bytes. On success, **modify_ldt**() will return the number of bytes read.

When *func* is 1 or 0x11, **modify_ldt**() modifies the LDT entry indicated by *ptr−>entry_number*. *ptr* points to a *user_desc* structure and *bytecount* must equal the size of this structure.

The *user_desc* structure is defined in <*asm/ldt.h*> as:

```
struct user_desc {
    unsigned int  entry_number;
    unsigned int  base_addr;
    unsigned int  limit;
    unsigned int  seg_32bit:1;
    unsigned int  contents:2;
    unsigned int  read_exec_only:1;
    unsigned int  limit_in_pages:1;
    unsigned int  seg_not_present:1;
    unsigned int  useable:1;
};
```

In Linux 2.4 and earlier, this structure was named *modify_ldt_ldt_s*.

The *contents* field is the segment type (data, expand-down data, non-conforming code, or conforming code). The other fields match their descriptions in the CPU manual, although **modify_ldt**() cannot set the hardware-defined "accessed" bit described in the CPU manual.

A *user_desc* is considered "empty" if *read_exec_only* and *seg_not_present* are set to 1 and all of the other fields are 0. An LDT entry can be cleared by setting it to an "empty" *user_desc* or, if *func* is 1, by setting both *base* and *limit* to 0.

A conforming code segment (i.e., one with *contents==3*) will be rejected if *func* is 1 or if *seg_not_present* is 0.

When *func* is 2, **modify_ldt**() will read zeros. This appears to be a leftover from Linux 2.4.

RETURN VALUE

On success, **modify_ldt**() returns either the actual number of bytes read (for reading) or 0 (for writing). On failure, **modify_ldt**() returns −1 and sets *errno* to indicate the error.

ERRORS

EFAULT

ptr points outside the address space.

EINVAL
ptr is 0, or *func* is 1 and *bytecount* is not equal to the size of the structure *user_desc*, or *func* is 1 or 0x11 and the new LDT entry has invalid values.

ENOSYS
func is neither 0, 1, 2, nor 0x11.

STANDARDS
Linux.

NOTES
modify_ldt() should not be used for thread-local storage, as it slows down context switches and only supports a limited number of threads. Threading libraries should use *set_thread_area*(2) or *arch_prctl*(2) instead, except on extremely old kernels that do not support those system calls.

The normal use for **modify_ldt**() is to run legacy 16-bit or segmented 32-bit code. Not all kernels allow 16-bit segments to be installed, however.

Even on 64-bit kernels, **modify_ldt**() cannot be used to create a long mode (i.e., 64-bit) code segment. The undocumented field "lm" in *user_desc* is not useful, and, despite its name, does not result in a long mode segment.

BUGS
On 64-bit kernels before Linux 3.19, setting the "lm" bit in *user_desc* prevents the descriptor from being considered empty. Keep in mind that the "lm" bit does not exist in the 32-bit headers, but these buggy kernels will still notice the bit even when set in a 32-bit process.

NAME

mount − mount filesystem

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/mount.h>

int mount(const char *source, const char *target,
          const char * filesystemtype, unsigned long mountflags,
          const void *_Nullable data);
```

DESCRIPTION

mount() attaches the filesystem specified by *source* (which is often a pathname referring to a device, but can also be the pathname of a directory or file, or a dummy string) to the location (a directory or file) specified by the pathname in *target*.

Appropriate privilege (Linux: the **CAP_SYS_ADMIN** capability) is required to mount filesystems.

Values for the *filesystemtype* argument supported by the kernel are listed in */proc/filesystems* (e.g., "btrfs", "ext4", "jfs", "xfs", "vfat", "fuse", "tmpfs", "cgroup", "proc", "mqueue", "nfs", "cifs", "iso9660"). Further types may become available when the appropriate modules are loaded.

The *data* argument is interpreted by the different filesystems. Typically it is a string of comma-separated options understood by this filesystem. See *mount*(8) for details of the options available for each filesystem type. This argument may be specified as NULL, if there are no options.

A call to **mount**() performs one of a number of general types of operation, depending on the bits specified in *mountflags*. The choice of which operation to perform is determined by testing the bits set in *mountflags*, with the tests being conducted in the order listed here:

- Remount an existing mount: *mountflags* includes **MS_REMOUNT**.
- Create a bind mount: *mountflags* includes **MS_BIND**.
- Change the propagation type of an existing mount: *mountflags* includes one of **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE**.
- Move an existing mount to a new location: *mountflags* includes **MS_MOVE**.
- Create a new mount: *mountflags* includes none of the above flags.

Each of these operations is detailed later in this page. Further flags may be specified in *mountflags* to modify the behavior of **mount**(), as described below.

Additional mount flags

The list below describes the additional flags that can be specified in *mountflags*. Note that some operation types ignore some or all of these flags, as described later in this page.

MS_DIRSYNC (since Linux 2.5.19)
: Make directory changes on this filesystem synchronous. (This property can be obtained for individual directories or subtrees using *chattr*(1)

MS_LAZYTIME (since Linux 4.0)
: Reduce on-disk updates of inode timestamps (atime, mtime, ctime) by maintaining these changes only in memory. The on-disk timestamps are updated only when:

  - the inode needs to be updated for some change unrelated to file timestamps;
  - the application employs *fsync*(2), *syncfs*(2), or *sync*(2);
  - an undeleted inode is evicted from memory; or
  - more than 24 hours have passed since the inode was written to disk.

  This mount option significantly reduces writes needed to update the inode's timestamps, especially mtime and atime. However, in the event of a system crash, the atime and mtime fields on disk might be out of date by up to 24 hours.

  Examples of workloads where this option could be of significant benefit include frequent random writes to preallocated files, as well as cases where the **MS_STRICTATIME** mount

option is also enabled. (The advantage of combining **MS_STRICTATIME** and **MS_LAZYTIME** is that *stat*(2) will return the correctly updated atime, but the atime updates will be flushed to disk only in the cases listed above.)

MS_MANDLOCK
Permit mandatory locking on files in this filesystem. (Mandatory locking must still be enabled on a per-file basis, as described in *fcntl*(2).) Since Linux 4.5, this mount option requires the **CAP_SYS_ADMIN** capability and a kernel configured with the **CONFIG_MANDATORY_FILE_LOCKING** option. Mandatory locking has been fully deprecated in Linux 5.15, so this flag should be considered deprecated.

MS_NOATIME
Do not update access times for (all types of) files on this filesystem.

MS_NODEV
Do not allow access to devices (special files) on this filesystem.

MS_NODIRATIME
Do not update access times for directories on this filesystem. This flag provides a subset of the functionality provided by **MS_NOATIME**; that is, **MS_NOATIME** implies **MS_NODIRATIME**.

MS_NOEXEC
Do not allow programs to be executed from this filesystem.

MS_NOSUID
Do not honor set-user-ID and set-group-ID bits or file capabilities when executing programs from this filesystem. In addition, SELinux domain transitions require the permission *nosuid_transition*, which in turn needs also the policy capability *nnp_nosuid_transition*.

MS_RDONLY
Mount filesystem read-only.

MS_REC (since Linux 2.4.11)
Used in conjunction with **MS_BIND** to create a recursive bind mount, and in conjunction with the propagation type flags to recursively change the propagation type of all of the mounts in a subtree. See below for further details.

MS_RELATIME (since Linux 2.6.20)
When a file on this filesystem is accessed, update the file's last access time (atime) only if the current value of atime is less than or equal to the file's last modification time (mtime) or last status change time (ctime). This option is useful for programs, such as *mutt*(1), that need to know when a file has been read since it was last modified. Since Linux 2.6.30, the kernel defaults to the behavior provided by this flag (unless **MS_NOATIME** was specified), and the **MS_STRICTATIME** flag is required to obtain traditional semantics. In addition, since Linux 2.6.30, the file's last access time is always updated if it is more than 1 day old.

MS_SILENT (since Linux 2.6.17)
Suppress the display of certain (*printk*()) warning messages in the kernel log. This flag supersedes the misnamed and obsolete **MS_VERBOSE** flag (available since Linux 2.4.12), which has the same meaning.

MS_STRICTATIME (since Linux 2.6.30)
Always update the last access time (atime) when files on this filesystem are accessed. (This was the default behavior before Linux 2.6.30.) Specifying this flag overrides the effect of setting the **MS_NOATIME** and **MS_RELATIME** flags.

MS_SYNCHRONOUS
Make writes on this filesystem synchronous (as though the **O_SYNC** flag to *open*(2) was specified for all file opens to this filesystem).

MS_NOSYMFOLLOW (since Linux 5.10)
Do not follow symbolic links when resolving paths. Symbolic links can still be created, and *readlink*(1), *readlink*(2), *realpath*(1), and *realpath*(3) all still work properly.

From Linux 2.4 onward, some of the above flags are settable on a per-mount basis, while others apply to the superblock of the mounted filesystem, meaning that all mounts of the same filesystem share those

flags. (Previously, all of the flags were per-superblock.)

The per-mount-point flags are as follows:

- Since Linux 2.4: **MS_NODEV**, **MS_NOEXEC**, and **MS_NOSUID** flags are settable on a per-mount-point basis.
- Additionally, since Linux 2.6.16: **MS_NOATIME** and **MS_NODIRATIME**.
- Additionally, since Linux 2.6.20: **MS_RELATIME**.

The following flags are per-superblock: **MS_DIRSYNC**, **MS_LAZYTIME**, **MS_MANDLOCK**, **MS_SILENT**, and **MS_SYNCHRONOUS**. The initial settings of these flags are determined on the first mount of the filesystem, and will be shared by all subsequent mounts of the same filesystem. Subsequently, the settings of the flags can be changed via a remount operation (see below). Such changes will be visible via all mounts associated with the filesystem.

Since Linux 2.6.16, **MS_RDONLY** can be set or cleared on a per-mount-point basis as well as on the underlying filesystem superblock. The mounted filesystem will be writable only if neither the filesystem nor the mountpoint are flagged as read-only.

Remounting an existing mount

An existing mount may be remounted by specifying **MS_REMOUNT** in *mountflags*. This allows you to change the *mountflags* and *data* of an existing mount without having to unmount and remount the filesystem. *target* should be the same value specified in the initial **mount**() call.

The *source* and *filesystemtype* arguments are ignored.

The *mountflags* and *data* arguments should match the values used in the original **mount**() call, except for those parameters that are being deliberately changed.

The following *mountflags* can be changed: **MS_LAZYTIME**, **MS_MANDLOCK**, **MS_NOATIME**, **MS_NODEV**, **MS_NODIRATIME**, **MS_NOEXEC**, **MS_NOSUID**, **MS_RELATIME**, **MS_RDONLY**, **MS_STRICTATIME** (whose effect is to clear the **MS_NOATIME** and **MS_RELATIME** flags), and **MS_SYNCHRONOUS**. Attempts to change the setting of the **MS_DIRSYNC** and **MS_SILENT** flags during a remount are silently ignored. Note that changes to per-superblock flags are visible via all mounts of the associated filesystem (because the per-superblock flags are shared by all mounts).

Since Linux 3.17, if none of **MS_NOATIME**, **MS_NODIRATIME**, **MS_RELATIME**, or **MS_STRICTATIME** is specified in *mountflags*, then the remount operation preserves the existing values of these flags (rather than defaulting to **MS_RELATIME**).

Since Linux 2.6.26, the **MS_REMOUNT** flag can be used with **MS_BIND** to modify only the per-mount-point flags. This is particularly useful for setting or clearing the "read-only" flag on a mount without changing the underlying filesystem. Specifying *mountflags* as:

```
MS_REMOUNT | MS_BIND | MS_RDONLY
```

will make access through this mountpoint read-only, without affecting other mounts.

Creating a bind mount

If *mountflags* includes **MS_BIND** (available since Linux 2.4), then perform a bind mount. A bind mount makes a file or a directory subtree visible at another point within the single directory hierarchy. Bind mounts may cross filesystem boundaries and span *chroot*(2) jails.

The *filesystemtype* and *data* arguments are ignored.

The remaining bits (other than **MS_REC**, described below) in the *mountflags* argument are also ignored. (The bind mount has the same mount options as the underlying mount.) However, see the discussion of remounting above, for a method of making an existing bind mount read-only.

By default, when a directory is bind mounted, only that directory is mounted; if there are any submounts under the directory tree, they are not bind mounted. If the **MS_REC** flag is also specified, then a recursive bind mount operation is performed: all submounts under the *source* subtree (other than unbindable mounts) are also bind mounted at the corresponding location in the *target* subtree.

Changing the propagation type of an existing mount

If *mountflags* includes one of **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE** (all available since Linux 2.6.15), then the propagation type of an existing mount is changed. If more

than one of these flags is specified, an error results.

The only other flags that can be specified while changing the propagation type are **MS_REC** (described below) and **MS_SILENT** (which is ignored).

The *source*, *filesystemtype*, and *data* arguments are ignored.

The meanings of the propagation type flags are as follows:

MS_SHARED
: Make this mount shared. Mount and unmount events immediately under this mount will propagate to the other mounts that are members of this mount's peer group. Propagation here means that the same mount or unmount will automatically occur under all of the other mounts in the peer group. Conversely, mount and unmount events that take place under peer mounts will propagate to this mount.

MS_PRIVATE
: Make this mount private. Mount and unmount events do not propagate into or out of this mount.

MS_SLAVE
: If this is a shared mount that is a member of a peer group that contains other members, convert it to a slave mount. If this is a shared mount that is a member of a peer group that contains no other members, convert it to a private mount. Otherwise, the propagation type of the mount is left unchanged.

  When a mount is a slave, mount and unmount events propagate into this mount from the (master) shared peer group of which it was formerly a member. Mount and unmount events under this mount do not propagate to any peer.

  A mount can be the slave of another peer group while at the same time sharing mount and unmount events with a peer group of which it is a member.

MS_UNBINDABLE
: Make this mount unbindable. This is like a private mount, and in addition this mount can't be bind mounted. When a recursive bind mount (**mount**() with the **MS_BIND** and **MS_REC** flags) is performed on a directory subtree, any unbindable mounts within the subtree are automatically pruned (i.e., not replicated) when replicating that subtree to produce the target subtree.

By default, changing the propagation type affects only the *target* mount. If the **MS_REC** flag is also specified in *mountflags*, then the propagation type of all mounts under *target* is also changed.

For further details regarding mount propagation types (including the default propagation type assigned to new mounts), see *mount_namespaces*(7).

Moving a mount
: If *mountflags* contains the flag **MS_MOVE** (available since Linux 2.4.18), then move a subtree: *source* specifies an existing mount and *target* specifies the new location to which that mount is to be relocated. The move is atomic: at no point is the subtree unmounted.

  The remaining bits in the *mountflags* argument are ignored, as are the *filesystemtype* and *data* arguments.

Creating a new mount
: If none of **MS_REMOUNT**, **MS_BIND**, **MS_MOVE**, **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE** is specified in *mountflags*, then **mount**() performs its default action: creating a new mount. *source* specifies the source for the new mount, and *target* specifies the directory at which to create the mount point.

  The *filesystemtype* and *data* arguments are employed, and further bits may be specified in *mountflags* to modify the behavior of the call.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

The error values given below result from filesystem type independent errors. Each filesystem type may have its own special errors and its own special behavior. See the Linux kernel source code for details.

EACCES
A component of a path was not searchable. (See also *path_resolution*(7).)

EACCES
Mounting a read-only filesystem was attempted without giving the **MS_RDONLY** flag.

The filesystem may be read-only for various reasons, including: it resides on a read-only optical disk; it is resides on a device with a physical switch that has been set to mark the device read-only; the filesystem implementation was compiled with read-only support; or errors were detected when initially mounting the filesystem, so that it was marked read-only and can't be remounted as read-write (until the errors are fixed).

Some filesystems instead return the error **EROFS** on an attempt to mount a read-only filesystem.

EACCES
The block device *source* is located on a filesystem mounted with the **MS_NODEV** option.

EBUSY
An attempt was made to stack a new mount directly on top of an existing mount point that was created in this mount namespace with the same *source* and *target*.

EBUSY
source cannot be remounted read-only, because it still holds files open for writing.

EFAULT
One of the pointer arguments points outside the user address space.

EINVAL
source had an invalid superblock.

EINVAL
A remount operation (**MS_REMOUNT**) was attempted, but *source* was not already mounted on *target*.

EINVAL
A move operation (**MS_MOVE**) was attempted, but the mount tree under *source* includes unbindable mounts and *target* is a mount that has propagation type **MS_SHARED**.

EINVAL
A move operation (**MS_MOVE**) was attempted, but the parent mount of *source* mount has propagation type **MS_SHARED**.

EINVAL
A move operation (**MS_MOVE**) was attempted, but *source* was not a mount, or was '/'.

EINVAL
A bind operation (**MS_BIND**) was requested where *source* referred a mount namespace magic link (i.e., a */proc/*pid*/ns/mnt* magic link or a bind mount to such a link) and the propagation type of the parent mount of *target* was **MS_SHARED**, but propagation of the requested bind mount could lead to a circular dependency that might prevent the mount namespace from ever being freed.

EINVAL
mountflags includes more than one of **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE**.

EINVAL
mountflags includes **MS_SHARED**, **MS_PRIVATE**, **MS_SLAVE**, or **MS_UNBINDABLE** and also includes a flag other than **MS_REC** or **MS_SILENT**.

EINVAL
An attempt was made to bind mount an unbindable mount.

EINVAL
In an unprivileged mount namespace (i.e., a mount namespace owned by a user namespace that was created by an unprivileged user), a bind mount operation (**MS_BIND**) was attempted without specifying (**MS_REC**), which would have revealed the filesystem tree underneath one of the submounts of the directory being bound.

ELOOP
Too many links encountered during pathname resolution.

ELOOP
A move operation was attempted, and *target* is a descendant of *source*.

EMFILE
(In case no block device is required:) Table of dummy devices is full.

ENAMETOOLONG
A pathname was longer than **MAXPATHLEN**.

ENODEV
filesystemtype not configured in the kernel.

ENOENT
A pathname was empty or had a nonexistent component.

ENOMEM
The kernel could not allocate a free page to copy filenames or data into.

ENOTBLK
source is not a block device (and a device was required).

ENOTDIR
target, or a prefix of *source*, is not a directory.

ENXIO
The major number of the block device *source* is out of range.

EPERM
The caller does not have the required privileges.

EPERM
An attempt was made to modify (**MS_REMOUNT**) the **MS_RDONLY**, **MS_NOSUID**, or **MS_NOEXEC** flag, or one of the "atime" flags (**MS_NOATIME**, **MS_NODIRATIME**, **MS_RELATIME**) of an existing mount, but the mount is locked; see *mount_namespaces*(7).

EROFS
Mounting a read-only filesystem was attempted without giving the **MS_RDONLY** flag. See **EACCES**, above.

STANDARDS
Linux.

HISTORY
The definitions of **MS_DIRSYNC**, **MS_MOVE**, **MS_PRIVATE**, **MS_REC**, **MS_RELATIME**, **MS_SHARED**, **MS_SLAVE**, **MS_STRICTATIME**, and **MS_UNBINDABLE** were added to glibc headers in glibc 2.12.

Since Linux 2.4 a single filesystem can be mounted at multiple mount points, and multiple mounts can be stacked on the same mount point.

The *mountflags* argument may have the magic number 0xC0ED (**MS_MGC_VAL**) in the top 16 bits. (All of the other flags discussed in DESCRIPTION occupy the low order 16 bits of *mountflags*.) Specifying **MS_MGC_VAL** was required before Linux 2.4, but since Linux 2.4 is no longer required and is ignored if specified.

The original **MS_SYNC** flag was renamed **MS_SYNCHRONOUS** in 1.1.69 when a different **MS_SYNC** was added to <*mman.h*>.

Before Linux 2.4 an attempt to execute a set-user-ID or set-group-ID program on a filesystem mounted with **MS_NOSUID** would fail with **EPERM**. Since Linux 2.4 the set-user-ID and set-group-ID bits are just silently ignored in this case.

NOTES
Mount namespaces
Starting with Linux 2.4.19, Linux provides mount namespaces. A mount namespace is the set of filesystem mounts that are visible to a process. Mount namespaces can be (and usually are) shared between multiple processes, and changes to the namespace (i.e., mounts and unmounts) by one process

are visible to all other processes sharing the same namespace. (The pre-2.4.19 Linux situation can be considered as one in which a single namespace was shared by every process on the system.)

A child process created by *fork*(2) shares its parent's mount namespace; the mount namespace is preserved across an *execve*(2).

A process can obtain a private mount namespace if: it was created using the *clone*(2) **CLONE_NEWNS** flag, in which case its new namespace is initialized to be a *copy* of the namespace of the process that called *clone*(2); or it calls *unshare*(2) with the **CLONE_NEWNS** flag, which causes the caller's mount namespace to obtain a private copy of the namespace that it was previously sharing with other processes, so that future mounts and unmounts by the caller are invisible to other processes (except child processes that the caller subsequently creates) and vice versa.

For further details on mount namespaces, see *mount_namespaces*(7).

Parental relationship between mounts

Each mount has a parent mount. The overall parental relationship of all mounts defines the single directory hierarchy seen by the processes within a mount namespace.

The parent of a new mount is defined when the mount is created. In the usual case, the parent of a new mount is the mount of the filesystem containing the directory or file at which the new mount is attached. In the case where a new mount is stacked on top of an existing mount, the parent of the new mount is the previous mount that was stacked at that location.

The parental relationship between mounts can be discovered via the */proc/*pid*/mountinfo* file (see below).

/proc/*pid*/mounts* and */proc/*pid*/mountinfo

The Linux-specific */proc/*pid*/mounts* file exposes the list of mounts in the mount namespace of the process with the specified ID. The */proc/*pid*/mountinfo* file exposes even more information about mounts, including the propagation type and mount ID information that makes it possible to discover the parental relationship between mounts. See *proc*(5) and *mount_namespaces*(7) for details of this file.

NAME

mount_setattr − change properties of a mount or mount tree

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/fcntl.h> /* Definition of **AT_*** constants */
#include <linux/mount.h> /* Definition of **MOUNT_ATTR_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_mount_setattr, int *dirfd***, const char *** *pathname***,**
unsigned int *flags***, struct mount_attr *** *attr***, size_t** *size***);**

Note: glibc provides no wrapper for **mount_setattr**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **mount_setattr**() system call changes the mount properties of a mount or an entire mount tree. If *pathname* is a relative pathname, then it is interpreted relative to the directory referred to by the file descriptor *dirfd*. If *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process. If *pathname* is the empty string and **AT_EMPTY_PATH** is specified in *flags*, then the mount properties of the mount identified by *dirfd* are changed. (See *openat*(2) for an explanation of why the *dirfd* argument is useful.)

The **mount_setattr**() system call uses an extensible structure (*struct mount_attr*) to allow for future extensions. Any non-flag extensions to **mount_setattr**() will be implemented as new fields appended to the this structure, with a zero value in a new field resulting in the kernel behaving as though that extension field was not present. Therefore, the caller *must* zero-fill this structure on initialization. See the "Extensibility" subsection under **NOTES** for more details.

The *size* argument should usually be specified as *sizeof(struct mount_attr)*. However, if the caller is using a kernel that supports an extended *struct mount_attr*, but the caller does not intend to make use of these features, it is possible to pass the size of an earlier version of the structure together with the extended structure. This allows the kernel to not copy later parts of the structure that aren't used anyway. With each extension that changes the size of *struct mount_attr*, the kernel will expose a definition of the form **MOUNT_ATTR_SIZE_VER***number*. For example, the macro for the size of the initial version of *struct mount_attr* is **MOUNT_ATTR_SIZE_VER0**.

The *flags* argument can be used to alter the pathname resolution behavior. The supported values are:

AT_EMPTY_PATH
If *pathname* is the empty string, change the mount properties on *dirfd* itself.

AT_RECURSIVE
Change the mount properties of the entire mount tree.

AT_SYMLINK_NOFOLLOW
Don't follow trailing symbolic links.

AT_NO_AUTOMOUNT
Don't trigger automounts.

The *attr* argument of **mount_setattr**() is a structure of the following form:

```
struct mount_attr {
    __u64 attr_set;     /* Mount properties to set */
    __u64 attr_clr;     /* Mount properties to clear */
    __u64 propagation;  /* Mount propagation type */
    __u64 userns_fd;    /* User namespace file descriptor */
};
```

The *attr_set* and *attr_clr* members are used to specify the mount properties that are supposed to be set or cleared for a mount or mount tree. Flags set in *attr_set* enable a property on a mount or mount tree, and flags set in *attr_clr* remove a property from a mount or mount tree.

When changing mount properties, the kernel will first clear the flags specified in the *attr_clr* field, and then set the flags specified in the *attr_set* field. For example, these settings:

```
struct mount_attr attr = {
    .attr_clr = MOUNT_ATTR_NOEXEC | MOUNT_ATTR_NODEV,
    .attr_set = MOUNT_ATTR_RDONLY | MOUNT_ATTR_NOSUID,
};
```

are equivalent to the following steps:

```
unsigned int current_mnt_flags = mnt->mnt_flags;

/*
 * Clear all flags set in .attr_clr,
 * clearing MOUNT_ATTR_NOEXEC and MOUNT_ATTR_NODEV.
 */
current_mnt_flags &= ~attr->attr_clr;

/*
 * Now set all flags set in .attr_set,
 * applying MOUNT_ATTR_RDONLY and MOUNT_ATTR_NOSUID.
 */
current_mnt_flags |= attr->attr_set;

mnt->mnt_flags = current_mnt_flags;
```

As a result of this change, the mount or mount tree (a) is read-only; (b) blocks the execution of set-user-ID and set-group-ID programs; (c) allows execution of programs; and (d) allows access to devices.

Multiple changes with the same set of flags requested in *attr_clr* and *attr_set* are guaranteed to be idempotent after the changes have been applied.

The following mount attributes can be specified in the *attr_set* or *attr_clr* fields:

MOUNT_ATTR_RDONLY
: If set in *attr_set*, makes the mount read-only. If set in *attr_clr*, removes the read-only setting if set on the mount.

MOUNT_ATTR_NOSUID
: If set in *attr_set*, causes the mount not to honor the set-user-ID and set-group-ID mode bits and file capabilities when executing programs. If set in *attr_clr*, clears the set-user-ID, set-group-ID, and file capability restriction if set on this mount.

MOUNT_ATTR_NODEV
: If set in *attr_set*, prevents access to devices on this mount. If set in *attr_clr*, removes the restriction that prevented accessing devices on this mount.

MOUNT_ATTR_NOEXEC
: If set in *attr_set*, prevents executing programs on this mount. If set in *attr_clr*, removes the restriction that prevented executing programs on this mount.

MOUNT_ATTR_NOSYMFOLLOW
: If set in *attr_set*, prevents following symbolic links on this mount. If set in *attr_clr*, removes the restriction that prevented following symbolic links on this mount.

MOUNT_ATTR_NODIRATIME
: If set in *attr_set*, prevents updating access time for directories on this mount. If set in *attr_clr*, removes the restriction that prevented updating access time for directories. Note that **MOUNT_ATTR_NODIRATIME** can be combined with other access-time settings and is implied by the noatime setting. All other access-time settings are mutually exclusive.

MOUNT_ATTR__ATIME - changing access-time settings
: The access-time values listed below are an enumeration that includes the value zero, expressed in the bits defined by the mask **MOUNT_ATTR__ATIME**. Even though these bits are an enumeration (in contrast to the other mount flags such as **MOUNT_ATTR_NOEXEC**), they are nonetheless passed in *attr_set* and *attr_clr* for consistency with *fsmount*(2), which introduced this behavior.

Note that, since the access-time values are an enumeration rather than bit values, a caller wanting to transition to a different access-time setting cannot simply specify the access-time setting in *attr_set*, but must also include **MOUNT_ATTR__ATIME** in the *attr_clr* field. The kernel will verify that **MOUNT_ATTR__ATIME** isn't partially set in *attr_clr* (i.e., either all bits in the **MOUNT_ATTR__ATIME** bit field are either set or clear), and that *attr_set* doesn't have any access-time bits set if **MOUNT_ATTR__ATIME** isn't set in *attr_clr*.

MOUNT_ATTR_RELATIME
When a file is accessed via this mount, update the file's last access time (atime) only if the current value of atime is less than or equal to the file's last modification time (mtime) or last status change time (ctime).

To enable this access-time setting on a mount or mount tree, **MOUNT_ATTR_RELATIME** must be set in *attr_set* and **MOUNT_ATTR__ATIME** must be set in the *attr_clr* field.

MOUNT_ATTR_NOATIME
Do not update access times for (all types of) files on this mount.

To enable this access-time setting on a mount or mount tree, **MOUNT_ATTR_NOATIME** must be set in *attr_set* and **MOUNT_ATTR__ATIME** must be set in the *attr_clr* field.

MOUNT_ATTR_STRICTATIME
Always update the last access time (atime) when files are accessed on this mount.

To enable this access-time setting on a mount or mount tree, **MOUNT_ATTR_STRICTATIME** must be set in *attr_set* and **MOUNT_ATTR__ATIME** must be set in the *attr_clr* field.

MOUNT_ATTR_IDMAP
If set in *attr_set*, creates an ID-mapped mount. The ID mapping is taken from the user namespace specified in *userns_fd* and attached to the mount.

Since it is not supported to change the ID mapping of a mount after it has been ID mapped, it is invalid to specify **MOUNT_ATTR_IDMAP** in *attr_clr*.

For further details, see the subsection "ID-mapped mounts" under NOTES.

The *propagation* field is used to specify the propagation type of the mount or mount tree. This field either has the value zero, meaning leave the propagation type unchanged, or it has one of the following values:

MS_PRIVATE
Turn all mounts into private mounts.

MS_SHARED
Turn all mounts into shared mounts.

MS_SLAVE
Turn all mounts into dependent mounts.

MS_UNBINDABLE
Turn all mounts into unbindable mounts.

For further details on the above propagation types, see *mount_namespaces*(7).

RETURN VALUE

On success, **mount_setattr**() returns zero. On error, −1 is returned and *errno* is set to indicate the cause of the error.

ERRORS

EBADF
pathname is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EBADF
userns_fd is not a valid file descriptor.

EBUSY
The caller tried to change the mount to **MOUNT_ATTR_RDONLY**, but the mount still holds files open for writing.

EBUSY
The caller tried to create an ID-mapped mount raising **MOUNT_ATTR_IDMAP** and specifying *userns_fd* but the mount still holds files open for writing.

EINVAL
The pathname specified via the *dirfd* and *pathname* arguments to **mount_setattr**() isn't a mount point.

EINVAL
An unsupported value was set in *flags*.

EINVAL
An unsupported value was specified in the *attr_set* field of *mount_attr*.

EINVAL
An unsupported value was specified in the *attr_clr* field of *mount_attr*.

EINVAL
An unsupported value was specified in the *propagation* field of *mount_attr*.

EINVAL
More than one of **MS_SHARED**, **MS_SLAVE**, **MS_PRIVATE**, or **MS_UNBINDABLE** was set in the *propagation* field of *mount_attr*.

EINVAL
An access-time setting was specified in the *attr_set* field without **MOUNT_ATTR__ATIME** being set in the *attr_clr* field.

EINVAL
MOUNT_ATTR_IDMAP was specified in *attr_clr*.

EINVAL
A file descriptor value was specified in *userns_fd* which exceeds **INT_MAX**.

EINVAL
A valid file descriptor value was specified in *userns_fd*, but the file descriptor did not refer to a user namespace.

EINVAL
The underlying filesystem does not support ID-mapped mounts.

EINVAL
The mount that is to be ID mapped is not a detached mount; that is, the mount has not previously been visible in a mount namespace.

EINVAL
A partial access-time setting was specified in *attr_clr* instead of **MOUNT_ATTR__ATIME** being set.

EINVAL
The mount is located outside the caller's mount namespace.

EINVAL
The underlying filesystem has been mounted in a mount namespace that is owned by a noninitial user namespace

ENOENT
A pathname was empty or had a nonexistent component.

ENOMEM
When changing mount propagation to **MS_SHARED**, a new peer group ID needs to be allocated for all mounts without a peer group ID set. This allocation failed because there was not enough memory to allocate the relevant internal structures.

ENOSPC
When changing mount propagation to **MS_SHARED**, a new peer group ID needs to be allocated for all mounts without a peer group ID set. This allocation failed because the kernel has run out of IDs.

EPERM
One of the mounts had at least one of **MOUNT_ATTR_NOATIME**, **MOUNT_ATTR_NODEV**, **MOUNT_ATTR_NODIRATIME**, **MOUNT_ATTR_NOEXEC**, **MOUNT_ATTR_NOSUID**, or **MOUNT_ATTR_RDONLY** set and the flag is locked. Mount attributes become locked on a mount if:

- A new mount or mount tree is created causing mount propagation across user namespaces (i.e., propagation to a mount namespace owned by a different user namespace). The kernel will lock the aforementioned flags to prevent these sensitive properties from being altered.
- A new mount and user namespace pair is created. This happens for example when specifying **CLONE_NEWUSER | CLONE_NEWNS** in *unshare*(2), *clone*(2), or *clone3*(2). The aforementioned flags become locked in the new mount namespace to prevent sensitive mount properties from being altered. Since the newly created mount namespace will be owned by the newly created user namespace, a calling process that is privileged in the new user namespace would—in the absence of such locking—be able to alter sensitive mount properties (e.g., to remount a mount that was marked read-only as read-write in the new mount namespace).

EPERM
A valid file descriptor value was specified in *userns_fd*, but the file descriptor refers to the initial user namespace.

EPERM
An attempt was made to add an ID mapping to a mount that is already ID mapped.

EPERM
The caller does not have **CAP_SYS_ADMIN** in the initial user namespace.

STANDARDS
Linux.

HISTORY
Linux 5.12.

NOTES
ID-mapped mounts
Creating an ID-mapped mount makes it possible to change the ownership of all files located under a mount. Thus, ID-mapped mounts make it possible to change ownership in a temporary and localized way. It is a localized change because the ownership changes are visible only via a specific mount. All other users and locations where the filesystem is exposed are unaffected. It is a temporary change because the ownership changes are tied to the lifetime of the mount.

Whenever callers interact with the filesystem through an ID-mapped mount, the ID mapping of the mount will be applied to user and group IDs associated with filesystem objects. This encompasses the user and group IDs associated with inodes and also the following *xattr*(7) keys:

- *security.capability*, whenever filesystem capabilities are stored or returned in the **VFS_CAP_REVISION_3** format, which stores a root user ID alongside the capabilities (see *capabilities*(7)).
- *system.posix_acl_access* and *system.posix_acl_default*, whenever user IDs or group IDs are stored in **ACL_USER** or **ACL_GROUP** entries.

The following conditions must be met in order to create an ID-mapped mount:

- The caller must have the **CAP_SYS_ADMIN** capability in the user namespace the filesystem was mounted in.
- The underlying filesystem must support ID-mapped mounts. Currently, the following filesystems support ID-mapped mounts:

  - *xfs*(5) (since Linux 5.12)
  - *ext4*(5) (since Linux 5.12)
  - **FAT** (since Linux 5.12)
  - *btrfs*(5) (since Linux 5.15)
  - **ntfs3** (since Linux 5.15)
  - **f2fs** (since Linux 5.18)
  - **erofs** (since Linux 5.19)
  - **overlayfs** (ID-mapped lower and upper layers supported since Linux 5.19)
- The mount must not already be ID-mapped. This also implies that the ID mapping of a mount cannot be altered.
- The mount must not have any writers.
- The mount must be a detached mount; that is, it must have been created by calling *open_tree*(2) with the **OPEN_TREE_CLONE** flag and it must not already have been visible in a mount namespace. (To put things another way: the mount must not have been attached to the filesystem hierarchy with a system call such as *move_mount*(2)

ID mappings can be created for user IDs, group IDs, and project IDs. An ID mapping is essentially a mapping of a range of user or group IDs into another or the same range of user or group IDs. ID mappings are written to map files as three numbers separated by white space. The first two numbers specify the starting user or group ID in each of the two user namespaces. The third number specifies the range of the ID mapping. For example, a mapping for user IDs such as "1000 1001 1" would indicate that user ID 1000 in the caller's user namespace is mapped to user ID 1001 in its ancestor user namespace. Since the map range is 1, only user ID 1000 is mapped.

It is possible to specify up to 340 ID mappings for each ID mapping type. If any user IDs or group IDs are not mapped, all files owned by that unmapped user or group ID will appear as being owned by the overflow user ID or overflow group ID respectively.

Further details on setting up ID mappings can be found in *user_namespaces*(7).

In the common case, the user namespace passed in *userns_fd* (together with **MOUNT_ATTR_IDMAP** in *attr_set*) to create an ID-mapped mount will be the user namespace of a container. In other scenarios it will be a dedicated user namespace associated with a user's login session as is the case for portable home directories in *systemd-homed.service*(8)). It is also perfectly fine to create a dedicated user namespace for the sake of ID mapping a mount.

ID-mapped mounts can be useful in the following and a variety of other scenarios:

- Sharing files or filesystems between multiple users or multiple machines, especially in complex scenarios. For example, ID-mapped mounts are used to implement portable home directories in *systemd-homed.service*(8), where they allow users to move their home directory to an external storage device and use it on multiple computers where they are assigned different user IDs and group IDs. This effectively makes it possible to assign random user IDs and group IDs at login time.
- Sharing files or filesystems from the host with unprivileged containers. This allows a user to avoid having to change ownership permanently through *chown*(2).
- ID mapping a container's root filesystem. Users don't need to change ownership permanently through *chown*(2). Especially for large root filesystems, using *chown*(2) can be prohibitively expensive.
- Sharing files or filesystems between containers with non-overlapping ID mappings.
- Implementing discretionary access (DAC) permission checking for filesystems lacking a concept of ownership.
- Efficiently changing ownership on a per-mount basis. In contrast to *chown*(2), changing ownership of large sets of files is instantaneous with ID-mapped mounts. This is especially useful when ownership of an entire root filesystem of a virtual machine or container is to be changed as mentioned above. With ID-mapped mounts, a single **mount_setattr**() system call will be sufficient to change the ownership of all files.
- Taking the current ownership into account. ID mappings specify precisely what a user or group ID is supposed to be mapped to. This contrasts with the *chown*(2) system call which cannot by itself take the current ownership of the files it changes into account. It simply changes the ownership to

the specified user ID and group ID.

- Locally and temporarily restricted ownership changes. ID-mapped mounts make it possible to change ownership locally, restricting the ownership changes to specific mounts, and temporarily as the ownership changes only apply as long as the mount exists. By contrast, changing ownership via the *chown*(2) system call changes the ownership globally and permanently.

Extensibility

In order to allow for future extensibility, **mount_setattr**() requires the user-space application to specify the size of the *mount_attr* structure that it is passing. By providing this information, it is possible for **mount_setattr**() to provide both forwards- and backwards-compatibility, with *size* acting as an implicit version number. (Because new extension fields will always be appended, the structure size will always increase.) This extensibility design is very similar to other system calls such as *perf_setattr*(2), *perf_event_open*(2), *clone3*(2) and *openat2*(2).

Let *usize* be the size of the structure as specified by the user-space application, and let *ksize* be the size of the structure which the kernel supports, then there are three cases to consider:

- If *ksize* equals *usize*, then there is no version mismatch and *attr* can be used verbatim.
- If *ksize* is larger than *usize*, then there are some extension fields that the kernel supports which the user-space application is unaware of. Because a zero value in any added extension field signifies a no-op, the kernel treats all of the extension fields not provided by the user-space application as having zero values. This provides backwards-compatibility.
- If *ksize* is smaller than *usize*, then there are some extension fields which the user-space application is aware of but which the kernel does not support. Because any extension field must have its zero values signify a no-op, the kernel can safely ignore the unsupported extension fields if they are all zero. If any unsupported extension fields are non-zero, then −1 is returned and *errno* is set to **E2BIG**. This provides forwards-compatibility.

Because the definition of *struct mount_attr* may change in the future (with new fields being added when system headers are updated), user-space applications should zero-fill *struct mount_attr* to ensure that recompiling the program with new headers will not result in spurious errors at run time. The simplest way is to use a designated initializer:

```
struct mount_attr attr = {
    .attr_set = MOUNT_ATTR_RDONLY,
    .attr_clr = MOUNT_ATTR_NODEV
};
```

Alternatively, the structure can be zero-filled using *memset*(3) or similar functions:

```
struct mount_attr attr;
memset(&attr, 0, sizeof(attr));
attr.attr_set = MOUNT_ATTR_RDONLY;
attr.attr_clr = MOUNT_ATTR_NODEV;
```

A user-space application that wishes to determine which extensions the running kernel supports can do so by conducting a binary search on *size* with a structure which has every byte nonzero (to find the largest value which doesn't produce an error of **E2BIG**).

EXAMPLES

```
/*
 * This program allows the caller to create a new detached mount
 * and set various properties on it.
 */
#define _GNU_SOURCE
#include <err.h>
#include <fcntl.h>
#include <getopt.h>
#include <linux/mount.h>
#include <linux/types.h>
#include <stdbool.h>
#include <stdio.h>
#include <stdlib.h>
```

```
#include <string.h>
#include <sys/syscall.h>
#include <unistd.h>

static inline int
mount_setattr(int dirfd, const char *pathname, unsigned int flags,
              struct mount_attr *attr, size_t size)
{
    return syscall(SYS_mount_setattr, dirfd, pathname, flags,
                   attr, size);
}

static inline int
open_tree(int dirfd, const char *filename, unsigned int flags)
{
    return syscall(SYS_open_tree, dirfd, filename, flags);
}

static inline int
move_mount(int from_dirfd, const char *from_pathname,
           int to_dirfd, const char *to_pathname, unsigned int flags)
{
    return syscall(SYS_move_mount, from_dirfd, from_pathname,
                   to_dirfd, to_pathname, flags);
}

static const struct option longopts[] = {
    {"map-mount",       required_argument,  NULL,  'a'},
    {"recursive",       no_argument,        NULL,  'b'},
    {"read-only",       no_argument,        NULL,  'c'},
    {"block-setid",     no_argument,        NULL,  'd'},
    {"block-devices",   no_argument,        NULL,  'e'},
    {"block-exec",      no_argument,        NULL,  'f'},
    {"no-access-time",  no_argument,        NULL,  'g'},
    { NULL,             0,                  NULL,   0 },
};

NAME

move_pages − move individual pages of a process to another node

LIBRARY

NUMA (Non-Uniform Memory Access) policy library (*libnuma*, −*lnuma*)

SYNOPSIS

#include <numaif.h>

long move_pages(int *pid***, unsigned long** *count***, void *** *pages***[.***count***],**
const int *nodes***[.***count***], int** *status***[.***count***], int** *flags***);**

DESCRIPTION

move_pages() moves the specified *pages* of the process *pid* to the memory nodes specified by *nodes*. The result of the move is reflected in *status*. The *flags* indicate constraints on the pages to be moved.

pid is the ID of the process in which pages are to be moved. If *pid* is 0, then **move_pages**() moves pages of the calling process.

To move pages in another process requires the following privileges:

- Up to and including Linux 4.12: the caller must be privileged (**CAP_SYS_NICE**) or the real or effective user ID of the calling process must match the real or saved-set user ID of the target process.
- The older rules allowed the caller to discover various virtual address choices made by the kernel that could lead to the defeat of address-space-layout randomization for a process owned by the same UID as the caller, the rules were changed starting with Linux 4.13. Since Linux 4.13, permission is governed by a ptrace access mode **PTRACE_MODE_READ_REALCREDS** check with respect to the target process; see *ptrace*(2).

count is the number of pages to move. It defines the size of the three arrays *pages*, *nodes*, and *status*.

pages is an array of pointers to the pages that should be moved. These are pointers that should be aligned to page boundaries. Addresses are specified as seen by the process specified by *pid*.

nodes is an array of integers that specify the desired location for each page. Each element in the array is a node number. *nodes* can also be NULL, in which case **move_pages**() does not move any pages but instead will return the node where each page currently resides, in the *status* array. Obtaining the status of each page may be necessary to determine pages that need to be moved.

status is an array of integers that return the status of each page. The array contains valid values only if **move_pages**() did not return an error. Preinitialization of the array to a value which cannot represent a real numa node or valid error of status array could help to identify pages that have been migrated.

flags specify what types of pages to move. **MPOL_MF_MOVE** means that only pages that are in exclusive use by the process are to be moved. **MPOL_MF_MOVE_ALL** means that pages shared between multiple processes can also be moved. The process must be privileged (**CAP_SYS_NICE**) to use **MPOL_MF_MOVE_ALL**.

Page states in the status array

The following values can be returned in each element of the *status* array.

0..MAX_NUMNODES
: Identifies the node on which the page resides.

−EACCES
: The page is mapped by multiple processes and can be moved only if **MPOL_MF_MOVE_ALL** is specified.

−EBUSY
: The page is currently busy and cannot be moved. Try again later. This occurs if a page is undergoing I/O or another kernel subsystem is holding a reference to the page.

−EFAULT
: This is a zero page or the memory area is not mapped by the process.

−EIO Unable to write back a page. The page has to be written back in order to move it since the page is dirty and the filesystem does not provide a migration function that would allow the move of dirty pages.

−EINVAL
A dirty page cannot be moved. The filesystem does not provide a migration function and has no ability to write back pages.

−ENOENT
The page is not present.

−ENOMEM
Unable to allocate memory on target node.

RETURN VALUE

On success **move_pages**() returns zero. On error, it returns −1, and sets *errno* to indicate the error. If positive value is returned, it is the number of nonmigrated pages.

ERRORS

Positive value
The number of nonmigrated pages if they were the result of nonfatal reasons (since Linux 4.17).

E2BIG Too many pages to move. Since Linux 2.6.29, the kernel no longer generates this error.

EACCES
One of the target nodes is not allowed by the current cpuset.

EFAULT
Parameter array could not be accessed.

EINVAL
Flags other than **MPOL_MF_MOVE** and **MPOL_MF_MOVE_ALL** was specified or an attempt was made to migrate pages of a kernel thread.

ENODEV
One of the target nodes is not online.

EPERM
The caller specified **MPOL_MF_MOVE_ALL** without sufficient privileges (**CAP_SYS_NICE**). Or, the caller attempted to move pages of a process belonging to another user but did not have privilege to do so (**CAP_SYS_NICE**).

ESRCH
Process does not exist.

STANDARDS

Linux.

HISTORY

Linux 2.6.18.

NOTES

For information on library support, see *numa*(7).

Use *get_mempolicy*(2) with the **MPOL_F_MEMS_ALLOWED** flag to obtain the set of nodes that are allowed by the current cpuset. Note that this information is subject to change at any time by manual or automatic reconfiguration of the cpuset.

Use of this function may result in pages whose location (node) violates the memory policy established for the specified addresses (See *mbind*(2)) and/or the specified process (See *set_mempolicy*(2)). That is, memory policy does not constrain the destination nodes used by **move_pages**().

The <*numaif.h*> header is not included with glibc, but requires installing *libnuma−devel* or a similar package.

NAME

mprotect, pkey_mprotect − set protection on a region of memory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/mman.h>

int mprotect(void *addr***[.***len***], size_t** *len***, int** *prot***);**

#define _GNU_SOURCE /* See feature_test_macros(7) */
#include <sys/mman.h>

int pkey_mprotect(void *addr***[.***len***], size_t** *len***, int** *prot***, int** *pkey***);**

DESCRIPTION

mprotect() changes the access protections for the calling process's memory pages containing any part of the address range in the interval [*addr*, *addr*+*len*−1]. *addr* must be aligned to a page boundary.

If the calling process tries to access memory in a manner that violates the protections, then the kernel generates a **SIGSEGV** signal for the process.

prot is a combination of the following access flags: **PROT_NONE** or a bitwise OR of the other values in the following list:

PROT_NONE
The memory cannot be accessed at all.

PROT_READ
The memory can be read.

PROT_WRITE
The memory can be modified.

PROT_EXEC
The memory can be executed.

PROT_SEM (since Linux 2.5.7)
The memory can be used for atomic operations. This flag was introduced as part of the *futex*(2) implementation (in order to guarantee the ability to perform atomic operations required by commands such as **FUTEX_WAIT**), but is not currently used in on any architecture.

PROT_SAO (since Linux 2.6.26)
The memory should have strong access ordering. This feature is specific to the PowerPC architecture (version 2.06 of the architecture specification adds the SAO CPU feature, and it is available on POWER 7 or PowerPC A2, for example).

Additionally (since Linux 2.6.0), *prot* can have one of the following flags set:

PROT_GROWSUP
Apply the protection mode up to the end of a mapping that grows upwards. (Such mappings are created for the stack area on architectures—for example, HP-PARISC—that have an upwardly growing stack.)

PROT_GROWSDOWN
Apply the protection mode down to the beginning of a mapping that grows downward (which should be a stack segment or a segment mapped with the **MAP_GROWSDOWN** flag set).

Like **mprotect**(), **pkey_mprotect**() changes the protection on the pages specified by *addr* and *len*. The *pkey* argument specifies the protection key (see *pkeys*(7)) to assign to the memory. The protection key must be allocated with *pkey_alloc*(2) before it is passed to **pkey_mprotect**(). For an example of the use of this system call, see *pkeys*(7).

RETURN VALUE

On success, **mprotect**() and **pkey_mprotect**() return zero. On error, these system calls return −1, and *errno* is set to indicate the error.

ERRORS

EACCES
The memory cannot be given the specified access. This can happen, for example, if you *mmap*(2) a file to which you have read-only access, then ask **mprotect**() to mark it **PROT_WRITE**.

EINVAL
addr is not a valid pointer, or not a multiple of the system page size.

EINVAL
(**pkey_mprotect**()) *pkey* has not been allocated with *pkey_alloc*(2)

EINVAL
Both **PROT_GROWSUP** and **PROT_GROWSDOWN** were specified in *prot*.

EINVAL
Invalid flags specified in *prot*.

EINVAL
(PowerPC architecture) **PROT_SAO** was specified in *prot*, but SAO hardware feature is not available.

ENOMEM
Internal kernel structures could not be allocated.

ENOMEM
Addresses in the range [*addr*, *addr*+*len*−1] are invalid for the address space of the process, or specify one or more pages that are not mapped. (Before Linux 2.4.19, the error **EFAULT** was incorrectly produced for these cases.)

ENOMEM
Changing the protection of a memory region would result in the total number of mappings with distinct attributes (e.g., read versus read/write protection) exceeding the allowed maximum. (For example, making the protection of a range **PROT_READ** in the middle of a region currently protected as **PROT_READ|PROT_WRITE** would result in three mappings: two read/write mappings at each end and a read-only mapping in the middle.)

VERSIONS

POSIX says that the behavior of **mprotect**() is unspecified if it is applied to a region of memory that was not obtained via *mmap*(2).

On Linux, it is always permissible to call **mprotect**() on any address in a process's address space (except for the kernel vsyscall area). In particular, it can be used to change existing code mappings to be writable.

Whether **PROT_EXEC** has any effect different from **PROT_READ** depends on processor architecture, kernel version, and process state. If **READ_IMPLIES_EXEC** is set in the process's personality flags (see *personality*(2)), specifying **PROT_READ** will implicitly add **PROT_EXEC**.

On some hardware architectures (e.g., i386), **PROT_WRITE** implies **PROT_READ**.

POSIX.1 says that an implementation may permit access other than that specified in *prot*, but at a minimum can allow write access only if **PROT_WRITE** has been set, and must not allow any access if **PROT_NONE** has been set.

Applications should be careful when mixing use of **mprotect**() and **pkey_mprotect**(). On x86, when **mprotect**() is used with *prot* set to **PROT_EXEC** a pkey may be allocated and set on the memory implicitly by the kernel, but only when the pkey was 0 previously.

On systems that do not support protection keys in hardware, **pkey_mprotect**() may still be used, but *pkey* must be set to −1. When called this way, the operation of **pkey_mprotect**() is equivalent to **mprotect**().

STANDARDS

mprotect()
POSIX.1-2008.

pkey_mprotect()
Linux.

HISTORY

mprotect()
POSIX.1-2001, SVr4.

pkey_mprotect()
Linux 4.9, glibc 2.27.

NOTES

EXAMPLES

The program below demonstrates the use of **mprotect**(). The program allocates four pages of memory, makes the third of these pages read-only, and then executes a loop that walks upward through the allocated region modifying bytes.

An example of what we might see when running the program is the following:

```
$ ./a.out
Start of region:        0x804c000
Got SIGSEGV at address: 0x804e000
```

Program source

```
#include <malloc.h>
#include <signal.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/mman.h>
#include <unistd.h>

#define handle_error(msg) \
    do { perror(msg); exit(EXIT_FAILURE); } while (0)

static char *buffer;

static void
handler(int sig, siginfo_t *si, void *unused)
{
    /* Note: calling printf() from a signal handler is not safe
       (and should not be done in production programs), since
       printf() is not async-signal-safe; see signal-safety(7).
       Nevertheless, we use printf() here as a simple way of
       showing that the handler was called. */

    printf("Got SIGSEGV at address: %p\n", si->si_addr);
    exit(EXIT_FAILURE);
}

int
main(void)
{
    int               pagesize;
    struct sigaction  sa;

    sa.sa_flags = SA_SIGINFO;
    sigemptyset(&sa.sa_mask);
    sa.sa_sigaction = handler;
    if (sigaction(SIGSEGV, &sa, NULL) == -1)
        handle_error("sigaction");

    pagesize = sysconf(_SC_PAGE_SIZE);
    if (pagesize == -1)
        handle_error("sysconf");
```

```
        /* Allocate a buffer aligned on a page boundary;
           initial protection is PROT_READ | PROT_WRITE. */

        buffer = memalign(pagesize, 4 * pagesize);
        if (buffer == NULL)
            handle_error("memalign");

        printf("Start of region:        %p\n", buffer);

        if (mprotect(buffer + pagesize * 2, pagesize,
                     PROT_READ) == -1)
            handle_error("mprotect");

        for (char *p = buffer ; ; )
            *(p++) = 'a';

        printf("Loop completed\n");     /* Should never happen */
        exit(EXIT_SUCCESS);
    }
```

NAME

mq_getsetattr − get/set message queue attributes

SYNOPSIS

#include <mqueue.h> /* Definition of **struct mq_attr** */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_mq_getsetattr, mqd_t *mqdes***,**
const struct mq_attr *****newattr*, struct mq_attr *****oldattr***);**

DESCRIPTION

Do not use this system call.

This is the low-level system call used to implement *mq_getattr*(3) and *mq_setattr*(3). For an explanation of how this system call operates, see the description of *mq_setattr*(3).

STANDARDS

None.

NOTES

Never call it unless you are writing a C library!

NAME

mremap − remap a virtual memory address

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sys/mman.h>

void *mremap(void old_address[.old_size], size_t old_size,
             size_t new_size, int flags, ... /* void *new_address */);
```

DESCRIPTION

mremap() expands (or shrinks) an existing memory mapping, potentially moving it at the same time (controlled by the *flags* argument and the available virtual address space).

old_address is the old address of the virtual memory block that you want to expand (or shrink). Note that *old_address* has to be page aligned. *old_size* is the old size of the virtual memory block. *new_size* is the requested size of the virtual memory block after the resize. An optional fifth argument, *new_address*, may be provided; see the description of **MREMAP_FIXED** below.

If the value of *old_size* is zero, and *old_address* refers to a shareable mapping (see the description of **MAP_SHARED** in *mmap*(2)), then **mremap**() will create a new mapping of the same pages. *new_size* will be the size of the new mapping and the location of the new mapping may be specified with *new_address*; see the description of **MREMAP_FIXED** below. If a new mapping is requested via this method, then the **MREMAP_MAYMOVE** flag must also be specified.

The *flags* bit-mask argument may be 0, or include the following flags:

MREMAP_MAYMOVE
: By default, if there is not sufficient space to expand a mapping at its current location, then **mremap**() fails. If this flag is specified, then the kernel is permitted to relocate the mapping to a new virtual address, if necessary. If the mapping is relocated, then absolute pointers into the old mapping location become invalid (offsets relative to the starting address of the mapping should be employed).

MREMAP_FIXED (since Linux 2.3.31)
: This flag serves a similar purpose to the **MAP_FIXED** flag of *mmap*(2). If this flag is specified, then **mremap**() accepts a fifth argument, *void *new_address*, which specifies a page-aligned address to which the mapping must be moved. Any previous mapping at the address range specified by *new_address* and *new_size* is unmapped.

  If **MREMAP_FIXED** is specified, then **MREMAP_MAYMOVE** must also be specified.

MREMAP_DONTUNMAP (since Linux 5.7)
: This flag, which must be used in conjunction with **MREMAP_MAYMOVE**, remaps a mapping to a new address but does not unmap the mapping at *old_address*.

  The **MREMAP_DONTUNMAP** flag can be used only with private anonymous mappings (see the description of **MAP_PRIVATE** and **MAP_ANONYMOUS** in *mmap*(2)).

  After completion, any access to the range specified by *old_address* and *old_size* will result in a page fault. The page fault will be handled by a *userfaultfd*(2) handler if the address is in a range previously registered with *userfaultfd*(2). Otherwise, the kernel allocates a zero-filled page to handle the fault.

  The **MREMAP_DONTUNMAP** flag may be used to atomically move a mapping while leaving the source mapped. See NOTES for some possible applications of **MREMAP_DONTUNMAP**.

If the memory segment specified by *old_address* and *old_size* is locked (using *mlock*(2) or similar), then this lock is maintained when the segment is resized and/or relocated. As a consequence, the amount of memory locked by the process may change.

RETURN VALUE

On success **mremap**() returns a pointer to the new virtual memory area. On error, the value **MAP_FAILED** (that is, *(void *) −1*) is returned, and *errno* is set to indicate the error.

ERRORS

EAGAIN
The caller tried to expand a memory segment that is locked, but this was not possible without exceeding the **RLIMIT_MEMLOCK** resource limit.

EFAULT
Some address in the range *old_address* to *old_address*+*old_size* is an invalid virtual memory address for this process. You can also get **EFAULT** even if there exist mappings that cover the whole address space requested, but those mappings are of different types.

EINVAL
An invalid argument was given. Possible causes are:

- *old_address* was not page aligned;
- a value other than **MREMAP_MAYMOVE** or **MREMAP_FIXED** or **MREMAP_DONTUNMAP** was specified in *flags*;
- *new_size* was zero;
- *new_size* or *new_address* was invalid;
- the new address range specified by *new_address* and *new_size* overlapped the old address range specified by *old_address* and *old_size*;
- **MREMAP_FIXED** or **MREMAP_DONTUNMAP** was specified without also specifying **MREMAP_MAYMOVE**;
- **MREMAP_DONTUNMAP** was specified, but one or more pages in the range specified by *old_address* and *old_size* were not private anonymous;
- **MREMAP_DONTUNMAP** was specified and *old_size* was not equal to *new_size*;
- *old_size* was zero and *old_address* does not refer to a shareable mapping (but see BUGS);
- *old_size* was zero and the **MREMAP_MAYMOVE** flag was not specified.

ENOMEM
Not enough memory was available to complete the operation. Possible causes are:

- The memory area cannot be expanded at the current virtual address, and the **MREMAP_MAYMOVE** flag is not set in *flags*. Or, there is not enough (virtual) memory available.
- **MREMAP_DONTUNMAP** was used causing a new mapping to be created that would exceed the (virtual) memory available. Or, it would exceed the maximum number of allowed mappings.

STANDARDS
Linux.

HISTORY
Prior to glibc 2.4, glibc did not expose the definition of **MREMAP_FIXED**, and the prototype for **mremap**() did not allow for the *new_address* argument.

NOTES
mremap() changes the mapping between virtual addresses and memory pages. This can be used to implement a very efficient *realloc*(3).

In Linux, memory is divided into pages. A process has (one or) several linear virtual memory segments. Each virtual memory segment has one or more mappings to real memory pages (in the page table). Each virtual memory segment has its own protection (access rights), which may cause a segmentation violation (**SIGSEGV**) if the memory is accessed incorrectly (e.g., writing to a read-only segment). Accessing virtual memory outside of the segments will also cause a segmentation violation.

If **mremap**() is used to move or expand an area locked with *mlock*(2) or equivalent, the **mremap**() call will make a best effort to populate the new area but will not fail with **ENOMEM** if the area cannot be populated.

MREMAP_DONTUNMAP use cases

Possible applications for **MREMAP_DONTUNMAP** include:

- Non-cooperative *userfaultfd*(2): an application can yank out a virtual address range using **MREMAP_DONTUNMAP** and then employ a *userfaultfd*(2) handler to handle the page faults that subsequently occur as other threads in the process touch pages in the yanked range.
- Garbage collection: **MREMAP_DONTUNMAP** can be used in conjunction with *userfaultfd*(2) to implement garbage collection algorithms (e.g., in a Java virtual machine). Such an implementation can be cheaper (and simpler) than conventional garbage collection techniques that involve marking pages with protection **PROT_NONE** in conjunction with the use of a **SIGSEGV** handler to catch accesses to those pages.

BUGS

Before Linux 4.14, if *old_size* was zero and the mapping referred to by *old_address* was a private mapping (see the description of **MAP_PRIVATE** in *mmap*(2)), **mremap**() created a new private mapping unrelated to the original mapping. This behavior was unintended and probably unexpected in user-space applications (since the intention of **mremap**() is to create a new mapping based on the original mapping). Since Linux 4.14, **mremap**() fails with the error **EINVAL** in this scenario.

NAME

msgctl − System V message control operations

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/msg.h>

int msgctl(int *msqid***, int** *op***, struct msqid_ds *****buf***);**

DESCRIPTION

msgctl() performs the control operation specified by *op* on the System V message queue with identifier *msqid*.

The *msqid_ds* data structure is defined in <*sys/msg.h*> as follows:

```
struct msqid_ds {
    struct ipc_perm msg_perm;   /* Ownership and permissions */
    time_t          msg_stime;  /* Time of last msgsnd(2) */
    time_t          msg_rtime;  /* Time of last msgrcv(2) */
    time_t          msg_ctime;  /* Time of creation or last
                                   modification by msgctl() */
    unsigned long   msg_cbytes; /* # of bytes in queue */
    msgqnum_t       msg_qnum;   /* # number of messages in queue */
    msglen_t        msg_qbytes; /* Maximum # of bytes in queue */
    pid_t           msg_lspid;  /* PID of last msgsnd(2) */
    pid_t           msg_lrpid;  /* PID of last msgrcv(2) */
};
```

The fields of the *msqid_ds* structure are as follows:

msg_perm This is an *ipc_perm* structure (see below) that specifies the access permissions on the message queue.

msg_stime Time of the last *msgsnd*(2) system call.

msg_rtime Time of the last *msgrcv*(2) system call.

msg_ctime Time of creation of queue or time of last **msgctl**() **IPC_SET** operation.

msg_cbytes Number of bytes in all messages currently on the message queue. This is a nonstandard Linux extension that is not specified in POSIX.

msg_qnum Number of messages currently on the message queue.

msg_qbytes Maximum number of bytes of message text allowed on the message queue.

msg_lspid ID of the process that performed the last *msgsnd*(2) system call.

msg_lrpid ID of the process that performed the last *msgrcv*(2) system call.

The *ipc_perm* structure is defined as follows (the highlighted fields are settable using **IPC_SET**):

```
struct ipc_perm {
    key_t          __key;       /* Key supplied to msgget(2) */
    uid_t          uid;         /* Effective UID of owner */
    gid_t          gid;         /* Effective GID of owner */
    uid_t          cuid;        /* Effective UID of creator */
    gid_t          cgid;        /* Effective GID of creator */
    unsigned short mode;        /* Permissions */
    unsigned short __seq;       /* Sequence number */
};
```

The least significant 9 bits of the *mode* field of the *ipc_perm* structure define the access permissions for the message queue. The permission bits are as follows:

0400 Read by user
0200 Write by user
0040 Read by group

0020 Write by group
0004 Read by others
0002 Write by others

Bits 0100, 0010, and 0001 (the execute bits) are unused by the system.

Valid values for *op* are:

IPC_STAT
Copy information from the kernel data structure associated with *msqid* into the *msqid_ds* structure pointed to by *buf*. The caller must have read permission on the message queue.

IPC_SET
Write the values of some members of the *msqid_ds* structure pointed to by *buf* to the kernel data structure associated with this message queue, updating also its *msg_ctime* member.

The following members of the structure are updated: *msg_qbytes*, *msg_perm.uid*, *msg_perm.gid*, and (the least significant 9 bits of) *msg_perm.mode*.

The effective UID of the calling process must match the owner (*msg_perm.uid*) or creator (*msg_perm.cuid*) of the message queue, or the caller must be privileged. Appropriate privilege (Linux: the **CAP_SYS_RESOURCE** capability) is required to raise the *msg_qbytes* value beyond the system parameter **MSGMNB**.

IPC_RMID
Immediately remove the message queue, awakening all waiting reader and writer processes (with an error return and *errno* set to **EIDRM**). The calling process must have appropriate privileges or its effective user ID must be either that of the creator or owner of the message queue. The third argument to **msgctl**() is ignored in this case.

IPC_INFO (Linux-specific)
Return information about system-wide message queue limits and parameters in the structure pointed to by *buf*. This structure is of type *msginfo* (thus, a cast is required), defined in <*sys/msg.h*> if the **_GNU_SOURCE** feature test macro is defined:

```
struct msginfo {
    int msgpool; /* Size in kibibytes of buffer pool
                    used to hold message data;
                    unused within kernel */
    int msgmap;  /* Maximum number of entries in message
                    map; unused within kernel */
    int msgmax;  /* Maximum number of bytes that can be
                    written in a single message */
    int msgmnb;  /* Maximum number of bytes that can be
                    written to queue; used to initialize
                    msg_qbytes during queue creation
                    (msgget(2)) */
    int msgmni;  /* Maximum number of message queues */
    int msgssz;  /* Message segment size;
                    unused within kernel */
    int msgtql;  /* Maximum number of messages on all queues
                    in system; unused within kernel */
    unsigned short msgseg;
                 /* Maximum number of segments;
                    unused within kernel */
};
```

The *msgmni*, *msgmax*, and *msgmnb* settings can be changed via */proc* files of the same name; see *proc*(5) for details.

MSG_INFO (Linux-specific)
Return a *msginfo* structure containing the same information as for **IPC_INFO**, except that the following fields are returned with information about system resources consumed by message queues: the *msgpool* field returns the number of message queues that currently exist on the system; the *msgmap* field returns the total number of messages in all queues on the system;

and the *msgtql* field returns the total number of bytes in all messages in all queues on the system.

MSG_STAT (Linux-specific)
Return a *msqid_ds* structure as for **IPC_STAT**. However, the *msqid* argument is not a queue identifier, but instead an index into the kernel's internal array that maintains information about all message queues on the system.

MSG_STAT_ANY (Linux-specific, since Linux 4.17)
Return a *msqid_ds* structure as for **MSG_STAT**. However, *msg_perm.mode* is not checked for read access for *msqid* meaning that any user can employ this operation (just as any user may read */proc/sysvipc/msg* to obtain the same information).

RETURN VALUE

On success, **IPC_STAT**, **IPC_SET**, and **IPC_RMID** return 0. A successful **IPC_INFO** or **MSG_INFO** operation returns the index of the highest used entry in the kernel's internal array recording information about all message queues. (This information can be used with repeated **MSG_STAT** or **MSG_STAT_ANY** operations to obtain information about all queues on the system.) A successful **MSG_STAT** or **MSG_STAT_ANY** operation returns the identifier of the queue whose index was given in *msqid*.

On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
The argument *op* is equal to **IPC_STAT** or **MSG_STAT**, but the calling process does not have read permission on the message queue *msqid*, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EFAULT
The argument *op* has the value **IPC_SET** or **IPC_STAT**, but the address pointed to by *buf* isn't accessible.

EIDRM
The message queue was removed.

EINVAL
Invalid value for *op* or *msqid*. Or: for a **MSG_STAT** operation, the index value specified in *msqid* referred to an array slot that is currently unused.

EPERM
The argument *op* has the value **IPC_SET** or **IPC_RMID**, but the effective user ID of the calling process is not the creator (as found in *msg_perm.cuid*) or the owner (as found in *msg_perm.uid*) of the message queue, and the caller is not privileged (Linux: does not have the **CAP_SYS_ADMIN** capability).

EPERM
An attempt (**IPC_SET**) was made to increase *msg_qbytes* beyond the system parameter **MSGMNB**, but the caller is not privileged (Linux: does not have the **CAP_SYS_RESOURCE** capability).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

Various fields in the *struct msqid_ds* were typed as *short* under Linux 2.2 and have become *long* under Linux 2.4. To take advantage of this, a recompilation under glibc-2.1.91 or later should suffice. (The kernel distinguishes old and new calls by an **IPC_64** flag in *op*.)

NOTES

The **IPC_INFO**, **MSG_STAT**, and **MSG_INFO** operations are used by the *ipcs*(1) program to provide information on allocated resources. In the future these may modified or moved to a */proc* filesystem interface.

NAME

msgget − get a System V message queue identifier

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/msg.h>

int msgget(key_t *key***, int** *msgflg***);**

DESCRIPTION

The **msgget**() system call returns the System V message queue identifier associated with the value of the *key* argument. It may be used either to obtain the identifier of a previously created message queue (when *msgflg* is zero and *key* does not have the value **IPC_PRIVATE**), or to create a new set.

A new message queue is created if *key* has the value **IPC_PRIVATE** or *key* isn't **IPC_PRIVATE**, no message queue with the given key *key* exists, and **IPC_CREAT** is specified in *msgflg*.

If *msgflg* specifies both **IPC_CREAT** and **IPC_EXCL** and a message queue already exists for *key*, then **msgget**() fails with *errno* set to **EEXIST**. (This is analogous to the effect of the combination **O_CREAT | O_EXCL** for *open*(2).)

Upon creation, the least significant bits of the argument *msgflg* define the permissions of the message queue. These permission bits have the same format and semantics as the permissions specified for the *mode* argument of *open*(2). (The execute permissions are not used.)

If a new message queue is created, then its associated data structure *msqid_ds* (see *msgctl*(2)) is initialized as follows:

- *msg_perm.cuid* and *msg_perm.uid* are set to the effective user ID of the calling process.
- *msg_perm.cgid* and *msg_perm.gid* are set to the effective group ID of the calling process.
- The least significant 9 bits of *msg_perm.mode* are set to the least significant 9 bits of *msgflg*.
- *msg_qnum*, *msg_lspid*, *msg_lrpid*, *msg_stime*, and *msg_rtime* are set to 0.
- *msg_ctime* is set to the current time.
- *msg_qbytes* is set to the system limit **MSGMNB**.

If the message queue already exists the permissions are verified, and a check is made to see if it is marked for destruction.

RETURN VALUE

On success, **msgget**() returns the message queue identifier (a nonnegative integer). On failure, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
A message queue exists for *key*, but the calling process does not have permission to access the queue, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EEXIST
IPC_CREAT and **IPC_EXCL** were specified in *msgflg*, but a message queue already exists for *key*.

ENOENT
No message queue exists for *key* and *msgflg* did not specify **IPC_CREAT**.

ENOMEM
A message queue has to be created but the system does not have enough memory for the new data structure.

ENOSPC
A message queue has to be created but the system limit for the maximum number of message queues (**MSGMNI**) would be exceeded.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

Linux

Until Linux 2.3.20, Linux would return **EIDRM** for a **msgget**() on a message queue scheduled for deletion.

NOTES

IPC_PRIVATE isn't a flag field but a *key_t* type. If this special value is used for *key*, the system call ignores everything but the least significant 9 bits of *msgflg* and creates a new message queue (on success).

The following is a system limit on message queue resources affecting a **msgget**() call:

MSGMNI

System-wide limit on the number of message queues. Before Linux 3.19, the default value for this limit was calculated using a formula based on available system memory. Since Linux 3.19, the default value is 32,000. On Linux, this limit can be read and modified via */proc/sys/kernel/msgmni*.

BUGS

The name choice **IPC_PRIVATE** was perhaps unfortunate, **IPC_NEW** would more clearly show its function.

NAME

msgrcv, msgsnd − System V message queue operations

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/msg.h>

int msgsnd(int *msqid***, const void** *msgp***[.***msgsz***], size_t** *msgsz***,**
int *msgflg***);**

ssize_t msgrcv(int *msqid***, void** *msgp***[.***msgsz***], size_t** *msgsz***, long** *msgtyp***,**
int *msgflg***);**

DESCRIPTION

The **msgsnd**() and **msgrcv**() system calls are used to send messages to, and receive messages from, a System V message queue. The calling process must have write permission on the message queue in order to send a message, and read permission to receive a message.

The *msgp* argument is a pointer to a caller-defined structure of the following general form:

```
struct msgbuf {
    long mtype;       /* message type, must be > 0 */
    char mtext[1];    /* message data */
};
```

The *mtext* field is an array (or other structure) whose size is specified by *msgsz*, a nonnegative integer value. Messages of zero length (i.e., no *mtext* field) are permitted. The *mtype* field must have a strictly positive integer value. This value can be used by the receiving process for message selection (see the description of **msgrcv**() below).

msgsnd()

The **msgsnd**() system call appends a copy of the message pointed to by *msgp* to the message queue whose identifier is specified by *msqid*.

If sufficient space is available in the queue, **msgsnd**() succeeds immediately. The queue capacity is governed by the *msg_qbytes* field in the associated data structure for the message queue. During queue creation this field is initialized to **MSGMNB** bytes, but this limit can be modified using *msgctl*(2). A message queue is considered to be full if either of the following conditions is true:

- Adding a new message to the queue would cause the total number of bytes in the queue to exceed the queue's maximum size (the *msg_qbytes* field).
- Adding another message to the queue would cause the total number of messages in the queue to exceed the queue's maximum size (the *msg_qbytes* field). This check is necessary to prevent an unlimited number of zero-length messages being placed on the queue. Although such messages contain no data, they nevertheless consume (locked) kernel memory.

If insufficient space is available in the queue, then the default behavior of **msgsnd**() is to block until space becomes available. If **IPC_NOWAIT** is specified in *msgflg*, then the call instead fails with the error **EAGAIN**.

A blocked **msgsnd**() call may also fail if:

- the queue is removed, in which case the system call fails with *errno* set to **EIDRM**; or
- a signal is caught, in which case the system call fails with *errno* set to **EINTR**;**see** *signal*(7). (**msgsnd**() is never automatically restarted after being interrupted by a signal handler, regardless of the setting of the **SA_RESTART** flag when establishing a signal handler.)

Upon successful completion the message queue data structure is updated as follows:

- *msg_lspid* is set to the process ID of the calling process.
- *msg_qnum* is incremented by 1.
- *msg_stime* is set to the current time.

msgrcv()

The **msgrcv**() system call removes a message from the queue specified by *msqid* and places it in the buffer pointed to by *msgp*.

The argument *msgsz* specifies the maximum size in bytes for the member *mtext* of the structure pointed to by the *msgp* argument. If the message text has length greater than *msgsz*, then the behavior depends on whether **MSG_NOERROR** is specified in *msgflg*. If **MSG_NOERROR** is specified, then the message text will be truncated (and the truncated part will be lost); if **MSG_NOERROR** is not specified, then the message isn't removed from the queue and the system call fails returning −1 with *errno* set to **E2BIG**.

Unless **MSG_COPY** is specified in *msgflg* (see below), the *msgtyp* argument specifies the type of message requested, as follows:

- If *msgtyp* is 0, then the first message in the queue is read.
- If *msgtyp* is greater than 0, then the first message in the queue of type *msgtyp* is read, unless **MSG_EXCEPT** was specified in *msgflg*, in which case the first message in the queue of type not equal to *msgtyp* will be read.
- If *msgtyp* is less than 0, then the first message in the queue with the lowest type less than or equal to the absolute value of *msgtyp* will be read.

The *msgflg* argument is a bit mask constructed by ORing together zero or more of the following flags:

IPC_NOWAIT
: Return immediately if no message of the requested type is in the queue. The system call fails with *errno* set to **ENOMSG**.

MSG_COPY (since Linux 3.8)
: Nondestructively fetch a copy of the message at the ordinal position in the queue specified by *msgtyp* (messages are considered to be numbered starting at 0).

  This flag must be specified in conjunction with **IPC_NOWAIT**, with the result that, if there is no message available at the given position, the call fails immediately with the error **ENOMSG**. Because they alter the meaning of *msgtyp* in orthogonal ways, **MSG_COPY** and **MSG_EXCEPT** may not both be specified in *msgflg*.

  The **MSG_COPY** flag was added for the implementation of the kernel checkpoint-restore facility and is available only if the kernel was built with the **CONFIG_CHECKPOINT_RESTORE** option.

MSG_EXCEPT
: Used with *msgtyp* greater than 0 to read the first message in the queue with message type that differs from *msgtyp*.

MSG_NOERROR
: To truncate the message text if longer than *msgsz* bytes.

If no message of the requested type is available and **IPC_NOWAIT** isn't specified in *msgflg*, the calling process is blocked until one of the following conditions occurs:

- A message of the desired type is placed in the queue.
- The message queue is removed from the system. In this case, the system call fails with *errno* set to **EIDRM**.
- The calling process catches a signal. In this case, the system call fails with *errno* set to **EINTR**. (**msgrcv**() is never automatically restarted after being interrupted by a signal handler, regardless of the setting of the **SA_RESTART** flag when establishing a signal handler.)

Upon successful completion the message queue data structure is updated as follows:

msg_lrpid is set to the process ID of the calling process.

msg_qnum is decremented by 1.

msg_rtime is set to the current time.

RETURN VALUE

On success, **msgsnd**() returns 0 and **msgrcv**() returns the number of bytes actually copied into the *mtext* array. On failure, both functions return −1, and set *errno* to indicate the error.

ERRORS

msgsnd() can fail with the following errors:

EACCES
The calling process does not have write permission on the message queue, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EAGAIN
The message can't be sent due to the *msg_qbytes* limit for the queue and **IPC_NOWAIT** was specified in *msgflg*.

EFAULT
The address pointed to by *msgp* isn't accessible.

EIDRM
The message queue was removed.

EINTR
Sleeping on a full message queue condition, the process caught a signal.

EINVAL
Invalid *msqid* value, or nonpositive *mtype* value, or invalid *msgsz* value (less than 0 or greater than the system value **MSGMAX**).

ENOMEM
The system does not have enough memory to make a copy of the message pointed to by *msgp*.

msgrcv() can fail with the following errors:

E2BIG The message text length is greater than *msgsz* and **MSG_NOERROR** isn't specified in *msgflg*.

EACCES
The calling process does not have read permission on the message queue, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EFAULT
The address pointed to by *msgp* isn't accessible.

EIDRM
While the process was sleeping to receive a message, the message queue was removed.

EINTR
While the process was sleeping to receive a message, the process caught a signal; see *signal*(7).

EINVAL
msqid was invalid, or *msgsz* was less than 0.

EINVAL (since Linux 3.14)
msgflg specified **MSG_COPY**, but not **IPC_NOWAIT**.

EINVAL (since Linux 3.14)
msgflg specified both **MSG_COPY** and **MSG_EXCEPT**.

ENOMSG
IPC_NOWAIT was specified in *msgflg* and no message of the requested type existed on the message queue.

ENOMSG
IPC_NOWAIT and **MSG_COPY** were specified in *msgflg* and the queue contains less than *msgtyp* messages.

ENOSYS (since Linux 3.8)
Both **MSG_COPY** and **IPC_NOWAIT** were specified in *msgflg*, and this kernel was configured without **CONFIG_CHECKPOINT_RESTORE**.

STANDARDS

POSIX.1-2008.

The **MSG_EXCEPT** and **MSG_COPY** flags are Linux-specific; their definitions can be obtained by defining the **_GNU_SOURCE** feature test macro.

HISTORY

POSIX.1-2001, SVr4.

The *msgp* argument is declared as *struct msgbuf* * in glibc 2.0 and 2.1. It is declared as *void* * in glibc 2.2 and later, as required by SUSv2 and SUSv3.

NOTES

The following limits on message queue resources affect the **msgsnd**() call:

MSGMAX
: Maximum size of a message text, in bytes (default value: 8192 bytes). On Linux, this limit can be read and modified via */proc/sys/kernel/msgmax*.

MSGMNB
: Maximum number of bytes that can be held in a message queue (default value: 16384 bytes). On Linux, this limit can be read and modified via */proc/sys/kernel/msgmnb*. A privileged process (Linux: a process with the **CAP_SYS_RESOURCE** capability) can increase the size of a message queue beyond **MSGMNB** using the *msgctl*(2) **IPC_SET** operation.

The implementation has no intrinsic system-wide limits on the number of message headers (**MSGTQL**) and the number of bytes in the message pool (**MSGPOOL**).

BUGS

In Linux 3.13 and earlier, if **msgrcv**() was called with the **MSG_COPY** flag, but without **IPC_NOWAIT**, and the message queue contained less than *msgtyp* messages, then the call would block until the next message is written to the queue. At that point, the call would return a copy of the message, *regardless* of whether that message was at the ordinal position *msgtyp*. This bug is fixed in Linux 3.14.

Specifying both **MSG_COPY** and **MSC_EXCEPT** in *msgflg* is a logical error (since these flags impose different interpretations on *msgtyp*). In Linux 3.13 and earlier, this error was not diagnosed by **msgrcv**(). This bug is fixed in Linux 3.14.

EXAMPLES

The program below demonstrates the use of **msgsnd**() and **msgrcv**().

The example program is first run with the **−s** option to send a message and then run again with the **−r** option to receive a message.

The following shell session shows a sample run of the program:

```
$ ./a.out -s
sent: a message at Wed Mar  4 16:25:45 2015

$ ./a.out -r
message received: a message at Wed Mar  4 16:25:45 2015
```

Program source

```
#include <errno.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/ipc.h>
#include <sys/msg.h>
#include <time.h>
#include <unistd.h>

struct msgbuf {
    long mtype;
    char mtext[80];
};
```

```

NAME

msync − synchronize a file with a memory map

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/mman.h>

int msync(void *addr***[.***length***], size_t** *length***, int** *flags***);**

DESCRIPTION

msync() flushes changes made to the in-core copy of a file that was mapped into memory using *mmap*(2) back to the filesystem. Without use of this call, there is no guarantee that changes are written back before *munmap*(2) is called. To be more precise, the part of the file that corresponds to the memory area starting at *addr* and having length *length* is updated.

The *flags* argument should specify exactly one of **MS_ASYNC** and **MS_SYNC**, and may additionally include the **MS_INVALIDATE** bit. These bits have the following meanings:

MS_ASYNC
Specifies that an update be scheduled, but the call returns immediately.

MS_SYNC
Requests an update and waits for it to complete.

MS_INVALIDATE
Asks to invalidate other mappings of the same file (so that they can be updated with the fresh values just written).

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBUSY
MS_INVALIDATE was specified in *flags*, and a memory lock exists for the specified address range.

EINVAL
addr is not a multiple of PAGESIZE; or any bit other than **MS_ASYNC** | **MS_INVALIDATE** | **MS_SYNC** is set in *flags*; or both **MS_SYNC** and **MS_ASYNC** are set in *flags*.

ENOMEM
The indicated memory (or part of it) was not mapped.

VERSIONS

According to POSIX, either **MS_SYNC** or **MS_ASYNC** must be specified in *flags*, and indeed failure to include one of these flags will cause **msync**() to fail on some systems. However, Linux permits a call to **msync**() that specifies neither of these flags, with semantics that are (currently) equivalent to specifying **MS_ASYNC**. (Since Linux 2.6.19, **MS_ASYNC** is in fact a no-op, since the kernel properly tracks dirty pages and flushes them to storage as necessary.) Notwithstanding the Linux behavior, portable, future-proof applications should ensure that they specify either **MS_SYNC** or **MS_ASYNC** in *flags*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

This call was introduced in Linux 1.3.21, and then used **EFAULT** instead of **ENOMEM**. In Linux 2.4.19, this was changed to the POSIX value **ENOMEM**.

On POSIX systems on which **msync**() is available, both **_POSIX_MAPPED_FILES** and **_POSIX_SYNCHRONIZED_IO** are defined in <*unistd.h*> to a value greater than 0. (See also *sysconf*(3).)

NAME

nanosleep − high-resolution sleep

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <time.h>

int nanosleep(const struct timespec *duration,
              struct timespec *_Nullable rem);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

nanosleep():
_POSIX_C_SOURCE >= 199309L

DESCRIPTION

nanosleep() suspends the execution of the calling thread until either at least the time specified in **duration* has elapsed, or the delivery of a signal that triggers the invocation of a handler in the calling thread or that terminates the process.

If the call is interrupted by a signal handler, **nanosleep**() returns −1, sets *errno* to **EINTR**, and writes the remaining time into the structure pointed to by *rem* unless *rem* is NULL. The value of **rem* can then be used to call **nanosleep**() again and complete the specified pause (but see NOTES).

The *timespec*(3) structure is used to specify intervals of time with nanosecond precision.

The value of the nanoseconds field must be in the range [0, 999999999].

Compared to *sleep*(3) and *usleep*(3), **nanosleep**() has the following advantages: it provides a higher resolution for specifying the sleep interval; POSIX.1 explicitly specifies that it does not interact with signals; and it makes the task of resuming a sleep that has been interrupted by a signal handler easier.

RETURN VALUE

On successfully sleeping for the requested duration, **nanosleep**() returns 0. If the call is interrupted by a signal handler or encounters an error, then it returns −1, with *errno* set to indicate the error.

ERRORS

EFAULT
: Problem with copying information from user space.

EINTR
: The pause has been interrupted by a signal that was delivered to the thread (see *signal*(7)). The remaining sleep time has been written into **rem* so that the thread can easily call **nanosleep**() again and continue with the pause.

EINVAL
: The value in the *tv_nsec* field was not in the range [0, 999999999] or *tv_sec* was negative.

VERSIONS

POSIX.1 specifies that **nanosleep**() should measure time against the **CLOCK_REALTIME** clock. However, Linux measures the time using the **CLOCK_MONOTONIC** clock. This probably does not matter, since the POSIX.1 specification for *clock_settime*(2) says that discontinuous changes in **CLOCK_REALTIME** should not affect **nanosleep**():

> Setting the value of the **CLOCK_REALTIME** clock via *clock_settime*(2) shall have no effect on threads that are blocked waiting for a relative time service based upon this clock, including the **nanosleep**() function; ... Consequently, these time services shall expire when the requested duration elapses, independently of the new or old value of the clock.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

In order to support applications requiring much more precise pauses (e.g., in order to control some time-critical hardware), **nanosleep**() would handle pauses of up to 2 milliseconds by busy waiting with microsecond precision when called from a thread scheduled under a real-time policy like

SCHED_FIFO or **SCHED_RR**. This special extension was removed in Linux 2.5.39, and is thus not available in Linux 2.6.0 and later kernels.

NOTES

If the *duration* is not an exact multiple of the granularity underlying clock (see *time*(7)), then the interval will be rounded up to the next multiple. Furthermore, after the sleep completes, there may still be a delay before the CPU becomes free to once again execute the calling thread.

The fact that **nanosleep**() sleeps for a relative interval can be problematic if the call is repeatedly restarted after being interrupted by signals, since the time between the interruptions and restarts of the call will lead to drift in the time when the sleep finally completes. This problem can be avoided by using *clock_nanosleep*(2) with an absolute time value.

BUGS

If a program that catches signals and uses **nanosleep**() receives signals at a very high rate, then scheduling delays and rounding errors in the kernel's calculation of the sleep interval and the returned *remain* value mean that the *remain* value may steadily *increase* on successive restarts of the **nanosleep**() call. To avoid such problems, use *clock_nanosleep*(2) with the **TIMER_ABSTIME** flag to sleep to an absolute deadline.

In Linux 2.4, if **nanosleep**() is stopped by a signal (e.g., **SIGTSTP**), then the call fails with the error **EINTR** after the thread is resumed by a **SIGCONT** signal. If the system call is subsequently restarted, then the time that the thread spent in the stopped state is *not* counted against the sleep interval. This problem is fixed in Linux 2.6.0 and later kernels.

NAME

nfsservctl − syscall interface to kernel nfs daemon

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <linux/nfsd/syscall.h>

long nfsservctl(int *cmd***, struct nfsctl_arg ***_argp_**,**
union nfsctl_res ***_resp_);**

DESCRIPTION

Note: Since Linux 3.1, this system call no longer exists. It has been replaced by a set of files in the *nfsd* filesystem; see *nfsd*(7)

```
/*
 * These are the commands understood by nfsctl().
 */
#define NFSCTL_SVC        0  /* This is a server process. */
#define NFSCTL_ADDCLIENT  1  /* Add an NFS client. */
#define NFSCTL_DELCLIENT  2  /* Remove an NFS client. */
#define NFSCTL_EXPORT     3  /* Export a filesystem. */
#define NFSCTL_UNEXPORT   4  /* Unexport a filesystem. */
#define NFSCTL_UGIDUPDATE 5  /* Update a client's UID/GID map
                                (only in Linux 2.4.x and earlier). */
#define NFSCTL_GETFH      6  /* Get a file handle (used by mountd(8))
                                (only in Linux 2.4.x and earlier). */

struct nfsctl_arg {
    int                     ca_version;     /* safeguard */
    union {
        struct nfsctl_svc     u_svc;
        struct nfsctl_client  u_client;
        struct nfsctl_export  u_export;
        struct nfsctl_uidmap  u_umap;
        struct nfsctl_fhparm  u_getfh;
        unsigned int          u_debug;
    } u;
}

union nfsctl_res {
        struct knfs_fh          cr_getfh;
        unsigned int            cr_debug;
};
```

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

STANDARDS

Linux.

HISTORY

Removed in Linux 3.1. Removed in glibc 2.28.

SEE ALSO

nfsd(7)

NAME

nice − change process priority

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int nice(int inc);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

nice():
_XOPEN_SOURCE
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _BSD_SOURCE || _SVID_SOURCE

DESCRIPTION

nice() adds *inc* to the nice value for the calling thread. (A higher nice value means a lower priority.)

The range of the nice value is +19 (low priority) to −20 (high priority). Attempts to set a nice value outside the range are clamped to the range.

Traditionally, only a privileged process could lower the nice value (i.e., set a higher priority). However, since Linux 2.6.12, an unprivileged process can decrease the nice value of a target process that has a suitable **RLIMIT_NICE** soft limit; see *getrlimit*(2) for details.

RETURN VALUE

On success, the new nice value is returned (but see NOTES below). On error, −1 is returned, and *errno* is set to indicate the error.

A successful call can legitimately return −1. To detect an error, set *errno* to 0 before the call, and check whether it is nonzero after **nice**() returns −1.

ERRORS

EPERM
The calling process attempted to increase its priority by supplying a negative *inc* but has insufficient privileges. Under Linux, the **CAP_SYS_NICE** capability is required. (But see the discussion of the **RLIMIT_NICE** resource limit in *setrlimit*(2).)

VERSIONS

C library/kernel differences

POSIX.1 specifies that **nice**() should return the new nice value. However, the raw Linux system call returns 0 on success. Likewise, the **nice**() wrapper function provided in glibc 2.2.3 and earlier returns 0 on success.

Since glibc 2.2.4, the **nice**() wrapper function provided by glibc provides conformance to POSIX.1 by calling *getpriority*(2) to obtain the new nice value, which is then returned to the caller.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

NOTES

For further details on the nice value, see *sched*(7).

Note: the addition of the "autogroup" feature in Linux 2.6.38 means that the nice value no longer has its traditional effect in many circumstances. For details, see *sched*(7).

NAME

open, openat, creat − open and possibly create a file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <fcntl.h>

int open(const char *pathname, int flags, ...
        /* mode_t mode */ );

int creat(const char *pathname, mode_t mode);

int openat(int dirfd, const char *pathname, int flags, ...
        /* mode_t mode */ );

/* Documented separately, in openat2(2): */
int openat2(int dirfd, const char *pathname,
        const struct open_how *how, size_t size);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

openat():
  Since glibc 2.10:
    _POSIX_C_SOURCE >= 200809L
  Before glibc 2.10:
    _ATFILE_SOURCE

DESCRIPTION

The **open**() system call opens the file specified by *pathname*. If the specified file does not exist, it may optionally (if **O_CREAT** is specified in *flags*) be created by **open**().

The return value of **open**() is a file descriptor, a small, nonnegative integer that is an index to an entry in the process's table of open file descriptors. The file descriptor is used in subsequent system calls (*read*(2), *write*(2), *lseek*(2), *fcntl*(2), etc.) to refer to the open file. The file descriptor returned by a successful call will be the lowest-numbered file descriptor not currently open for the process.

By default, the new file descriptor is set to remain open across an *execve*(2) (i.e., the **FD_CLOEXEC** file descriptor flag described in *fcntl*(2) is initially disabled); the **O_CLOEXEC** flag, described below, can be used to change this default. The file offset is set to the beginning of the file (see *lseek*(2)).

A call to **open**() creates a new *open file description*, an entry in the system-wide table of open files. The open file description records the file offset and the file status flags (see below). A file descriptor is a reference to an open file description; this reference is unaffected if *pathname* is subsequently removed or modified to refer to a different file. For further details on open file descriptions, see NOTES.

The argument *flags* must include one of the following *access modes*: **O_RDONLY**, **O_WRONLY**, or **O_RDWR**. These request opening the file read-only, write-only, or read/write, respectively.

In addition, zero or more file creation flags and file status flags can be bitwise ORed in *flags*. The *file creation flags* are **O_CLOEXEC**, **O_CREAT**, **O_DIRECTORY**, **O_EXCL**, **O_NOCTTY**, **O_NOFOLLOW**, **O_TMPFILE**, and **O_TRUNC**. The *file status flags* are all of the remaining flags listed below. The distinction between these two groups of flags is that the file creation flags affect the semantics of the open operation itself, while the file status flags affect the semantics of subsequent I/O operations. The file status flags can be retrieved and (in some cases) modified; see *fcntl*(2) for details.

The full list of file creation flags and file status flags is as follows:

O_APPEND

The file is opened in append mode. Before each *write*(2), the file offset is positioned at the end of the file, as if with *lseek*(2). The modification of the file offset and the write operation are performed as a single atomic step.

O_APPEND may lead to corrupted files on NFS filesystems if more than one process appends data to a file at once. This is because NFS does not support appending to a file, so the client kernel has to simulate it, which can't be done without a race condition.

O_ASYNC
Enable signal-driven I/O: generate a signal (**SIGIO** by default, but this can be changed via *fcntl*(2)) when input or output becomes possible on this file descriptor. This feature is available only for terminals, pseudoterminals, sockets, and (since Linux 2.6) pipes and FIFOs. See *fcntl*(2) for further details. See also BUGS, below.

O_CLOEXEC (since Linux 2.6.23)
Enable the close-on-exec flag for the new file descriptor. Specifying this flag permits a program to avoid additional *fcntl*(2) **F_SETFD** operations to set the **FD_CLOEXEC** flag.

Note that the use of this flag is essential in some multithreaded programs, because using a separate *fcntl*(2) **F_SETFD** operation to set the **FD_CLOEXEC** flag does not suffice to avoid race conditions where one thread opens a file descriptor and attempts to set its close-on-exec flag using *fcntl*(2) at the same time as another thread does a *fork*(2) plus *execve*(2). Depending on the order of execution, the race may lead to the file descriptor returned by **open**() being unintentionally leaked to the program executed by the child process created by *fork*(2). (This kind of race is in principle possible for any system call that creates a file descriptor whose close-on-exec flag should be set, and various other Linux system calls provide an equivalent of the **O_CLOEXEC** flag to deal with this problem.)

O_CREAT
If *pathname* does not exist, create it as a regular file.

The owner (user ID) of the new file is set to the effective user ID of the process.

The group ownership (group ID) of the new file is set either to the effective group ID of the process (System V semantics) or to the group ID of the parent directory (BSD semantics). On Linux, the behavior depends on whether the set-group-ID mode bit is set on the parent directory: if that bit is set, then BSD semantics apply; otherwise, System V semantics apply. For some filesystems, the behavior also depends on the *bsdgroups* and *sysvgroups* mount options described in *mount*(8)

The *mode* argument specifies the file mode bits to be applied when a new file is created. If neither **O_CREAT** nor **O_TMPFILE** is specified in *flags*, then *mode* is ignored (and can thus be specified as 0, or simply omitted). The *mode* argument **must** be supplied if **O_CREAT** or **O_TMPFILE** is specified in *flags*; if it is not supplied, some arbitrary bytes from the stack will be applied as the file mode.

The effective mode is modified by the process's *umask* in the usual way: in the absence of a default ACL, the mode of the created file is *(mode & ~umask)*.

Note that *mode* applies only to future accesses of the newly created file; the **open**() call that creates a read-only file may well return a read/write file descriptor.

The following symbolic constants are provided for *mode*:

S_IRWXU
00700 user (file owner) has read, write, and execute permission

S_IRUSR
00400 user has read permission

S_IWUSR
00200 user has write permission

S_IXUSR
00100 user has execute permission

S_IRWXG
00070 group has read, write, and execute permission

S_IRGRP
00040 group has read permission

S_IWGRP
00020 group has write permission

S_IXGRP
00010 group has execute permission

S_IRWXO
00007 others have read, write, and execute permission

S_IROTH
00004 others have read permission

S_IWOTH
00002 others have write permission

S_IXOTH
00001 others have execute permission

According to POSIX, the effect when other bits are set in *mode* is unspecified. On Linux, the following bits are also honored in *mode*:

S_ISUID 0004000 set-user-ID bit

S_ISGID 0002000 set-group-ID bit (see *inode*(7)).

S_ISVTX
0001000 sticky bit (see *inode*(7)).

O_DIRECT (since Linux 2.4.10)
Try to minimize cache effects of the I/O to and from this file. In general this will degrade performance, but it is useful in special situations, such as when applications do their own caching. File I/O is done directly to/from user-space buffers. The **O_DIRECT** flag on its own makes an effort to transfer data synchronously, but does not give the guarantees of the **O_SYNC** flag that data and necessary metadata are transferred. To guarantee synchronous I/O, **O_SYNC** must be used in addition to **O_DIRECT**. See NOTES below for further discussion.

A semantically similar (but deprecated) interface for block devices is described in *raw*(8)

O_DIRECTORY
If *pathname* is not a directory, cause the open to fail. This flag was added in Linux 2.1.126, to avoid denial-of-service problems if *opendir*(3) is called on a FIFO or tape device.

O_DSYNC
Write operations on the file will complete according to the requirements of synchronized I/O *data* integrity completion.

By the time *write*(2) (and similar) return, the output data has been transferred to the underlying hardware, along with any file metadata that would be required to retrieve that data (i.e., as though each *write*(2) was followed by a call to *fdatasync*(2)). *See NOTES below*.

O_EXCL
Ensure that this call creates the file: if this flag is specified in conjunction with **O_CREAT**, and *pathname* already exists, then **open**() fails with the error **EEXIST**.

When these two flags are specified, symbolic links are not followed: if *pathname* is a symbolic link, then **open**() fails regardless of where the symbolic link points.

In general, the behavior of **O_EXCL** is undefined if it is used without **O_CREAT**. There is one exception: on Linux 2.6 and later, **O_EXCL** can be used without **O_CREAT** if *pathname* refers to a block device. If the block device is in use by the system (e.g., mounted), **open**() fails with the error **EBUSY**.

On NFS, **O_EXCL** is supported only when using NFSv3 or later on kernel 2.6 or later. In NFS environments where **O_EXCL** support is not provided, programs that rely on it for performing locking tasks will contain a race condition. Portable programs that want to perform atomic file locking using a lockfile, and need to avoid reliance on NFS support for **O_EXCL**, can create a unique file on the same filesystem (e.g., incorporating hostname and PID), and use *link*(2) to make a link to the lockfile. If *link*(2) returns 0, the lock is successful. Otherwise, use *stat*(2) on the unique file to check if its link count has increased to 2, in which case the lock is also successful.

O_LARGEFILE
(LFS) Allow files whose sizes cannot be represented in an *off_t* (but can be represented in an *off64_t*) to be opened. The **_LARGEFILE64_SOURCE** macro must be defined (before including *any* header files) in order to obtain this definition. Setting the **_FILE_OFFSET_BITS** feature test macro to 64 (rather than using **O_LARGEFILE**) is the preferred method of accessing large files on 32-bit systems (see *feature_test_macros*(7)).

O_NOATIME (since Linux 2.6.8)
Do not update the file last access time (*st_atime* in the inode) when the file is *read*(2).

This flag can be employed only if one of the following conditions is true:

- The effective UID of the process matches the owner UID of the file.
- The calling process has the **CAP_FOWNER** capability in its user namespace and the owner UID of the file has a mapping in the namespace.

This flag is intended for use by indexing or backup programs, where its use can significantly reduce the amount of disk activity. This flag may not be effective on all filesystems. One example is NFS, where the server maintains the access time.

O_NOCTTY
If *pathname* refers to a terminal device—see *tty*(4)—it will not become the process's controlling terminal even if the process does not have one.

O_NOFOLLOW
If the trailing component (i.e., basename) of *pathname* is a symbolic link, then the open fails, with the error **ELOOP**. Symbolic links in earlier components of the pathname will still be followed. (Note that the **ELOOP** error that can occur in this case is indistinguishable from the case where an open fails because there are too many symbolic links found while resolving components in the prefix part of the pathname.)

This flag is a FreeBSD extension, which was added in Linux 2.1.126, and has subsequently been standardized in POSIX.1-2008.

See also **O_PATH** below.

O_NONBLOCK or **O_NDELAY**
When possible, the file is opened in nonblocking mode. Neither the **open**() nor any subsequent I/O operations on the file descriptor which is returned will cause the calling process to wait.

Note that the setting of this flag has no effect on the operation of *poll*(2), *select*(2), *epoll*(7), and similar, since those interfaces merely inform the caller about whether a file descriptor is "ready", meaning that an I/O operation performed on the file descriptor with the **O_NONBLOCK** flag *clear* would not block.

Note that this flag has no effect for regular files and block devices; that is, I/O operations will (briefly) block when device activity is required, regardless of whether **O_NONBLOCK** is set. Since **O_NONBLOCK** semantics might eventually be implemented, applications should not depend upon blocking behavior when specifying this flag for regular files and block devices.

For the handling of FIFOs (named pipes), see also *fifo*(7). For a discussion of the effect of **O_NONBLOCK** in conjunction with mandatory file locks and with file leases, see *fcntl*(2).

O_PATH (since Linux 2.6.39)
Obtain a file descriptor that can be used for two purposes: to indicate a location in the filesystem tree and to perform operations that act purely at the file descriptor level. The file itself is not opened, and other file operations (e.g., *read*(2), *write*(2), *fchmod*(2), *fchown*(2), *fgetxattr*(2), *ioctl*(2), *mmap*(2)) fail with the error **EBADF**.

The following operations *can* be performed on the resulting file descriptor:

- *close*(2).
- *fchdir*(2), if the file descriptor refers to a directory (since Linux 3.5).

- *fstat*(2) (since Linux 3.6).
- *fstatfs*(2) (since Linux 3.12).
- Duplicating the file descriptor (**dup**(2), *fcntl*(2) **F_DUPFD**, etc.).
- Getting and setting file descriptor flags (**fcntl**(2) **F_GETFD** and **F_SETFD**).
- Retrieving open file status flags using the *fcntl*(2) **F_GETFL** operation: the returned flags will include the bit **O_PATH**.
- Passing the file descriptor as the *dirfd* argument of **openat**() and the other "*at()" system calls. This includes *linkat*(2) with **AT_EMPTY_PATH** (or via procfs using **AT_SYMLINK_FOLLOW**) even if the file is not a directory.
- Passing the file descriptor to another process via a UNIX domain socket (see **SCM_RIGHTS** in *unix*(7)).

When **O_PATH** is specified in *flags*, flag bits other than **O_CLOEXEC**, **O_DIRECTORY**, and **O_NOFOLLOW** are ignored.

Opening a file or directory with the **O_PATH** flag requires no permissions on the object itself (but does require execute permission on the directories in the path prefix). Depending on the subsequent operation, a check for suitable file permissions may be performed (e.g., *fchdir*(2) requires execute permission on the directory referred to by its file descriptor argument). By contrast, obtaining a reference to a filesystem object by opening it with the **O_RDONLY** flag requires that the caller have read permission on the object, even when the subsequent operation (e.g., *fchdir*(2), *fstat*(2)) does not require read permission on the object.

If *pathname* is a symbolic link and the **O_NOFOLLOW** flag is also specified, then the call returns a file descriptor referring to the symbolic link. This file descriptor can be used as the *dirfd* argument in calls to *fchownat*(2), *fstatat*(2), *linkat*(2), and *readlinkat*(2) with an empty pathname to have the calls operate on the symbolic link.

If *pathname* refers to an automount point that has not yet been triggered, so no other filesystem is mounted on it, then the call returns a file descriptor referring to the automount directory without triggering a mount. *fstatfs*(2) can then be used to determine if it is, in fact, an untriggered automount point (**.f_type == AUTOFS_SUPER_MAGIC**).

One use of **O_PATH** for regular files is to provide the equivalent of POSIX.1's **O_EXEC** functionality. This permits us to open a file for which we have execute permission but not read permission, and then execute that file, with steps something like the following:

```
char buf[PATH_MAX];
fd = open("some_prog", O_PATH);
snprintf(buf, PATH_MAX, "/proc/self/fd/%d", fd);
execl(buf, "some_prog", (char *) NULL);
```

An **O_PATH** file descriptor can also be passed as the argument of *fexecve*(3).

O_SYNC

Write operations on the file will complete according to the requirements of synchronized I/O *file* integrity completion (by contrast with the synchronized I/O *data* integrity completion provided by **O_DSYNC**.)

By the time *write*(2) (or similar) returns, the output data and associated file metadata have been transferred to the underlying hardware (i.e., as though each *write*(2) was followed by a call to *fsync*(2)). *See NOTES below*.

O_TMPFILE (since Linux 3.11)

Create an unnamed temporary regular file. The *pathname* argument specifies a directory; an unnamed inode will be created in that directory's filesystem. Anything written to the resulting file will be lost when the last file descriptor is closed, unless the file is given a name.

O_TMPFILE must be specified with one of **O_RDWR** or **O_WRONLY** and, optionally, **O_EXCL**. If **O_EXCL** is not specified, then *linkat*(2) can be used to link the temporary file into the filesystem, making it permanent, using code like the following:

```
char path[PATH_MAX];
fd = open("/path/to/dir", O_TMPFILE | O_RDWR,
                          S_IRUSR | S_IWUSR);

/* File I/O on 'fd'... */

linkat(fd, "", AT_FDCWD, "/path/for/file", AT_EMPTY_PATH);

/* If the caller doesn't have the CAP_DAC_READ_SEARCH
   capability (needed to use AT_EMPTY_PATH with linkat(2)),
   and there is a proc(5) filesystem mounted, then the
   linkat(2) call above can be replaced with:

snprintf(path, PATH_MAX,  "/proc/self/fd/%d", fd);
linkat(AT_FDCWD, path, AT_FDCWD, "/path/for/file",
                          AT_SYMLINK_FOLLOW);
*/
```

In this case, the **open**() *mode* argument determines the file permission mode, as with **O_CREAT**.

Specifying **O_EXCL** in conjunction with **O_TMPFILE** prevents a temporary file from being linked into the filesystem in the above manner. (Note that the meaning of **O_EXCL** in this case is different from the meaning of **O_EXCL** otherwise.)

There are two main use cases for **O_TMPFILE**:

- Improved *tmpfile*(3) functionality: race-free creation of temporary files that (1) are automatically deleted when closed; (2) can never be reached via any pathname; (3) are not subject to symlink attacks; and (4) do not require the caller to devise unique names.
- Creating a file that is initially invisible, which is then populated with data and adjusted to have appropriate filesystem attributes (**fchown**(2), *fchmod*(2), *fsetxattr*(2), etc.) before being atomically linked into the filesystem in a fully formed state (using *linkat*(2) as described above).

O_TMPFILE requires support by the underlying filesystem; only a subset of Linux filesystems provide that support. In the initial implementation, support was provided in the ext2, ext3, ext4, UDF, Minix, and tmpfs filesystems. Support for other filesystems has subsequently been added as follows: XFS (Linux 3.15); Btrfs (Linux 3.16); F2FS (Linux 3.16); and ubifs (Linux 4.9)

O_TRUNC
If the file already exists and is a regular file and the access mode allows writing (i.e., is **O_RDWR** or **O_WRONLY**) it will be truncated to length 0. If the file is a FIFO or terminal device file, the **O_TRUNC** flag is ignored. Otherwise, the effect of **O_TRUNC** is unspecified.

creat()
A call to **creat**() is equivalent to calling **open**() with *flags* equal to **O_CREAT|O_WRONLY|O_TRUNC**.

openat()
The **openat**() system call operates in exactly the same way as **open**(), except for the differences described here.

The *dirfd* argument is used in conjunction with the *pathname* argument as follows:

- If the pathname given in *pathname* is absolute, then *dirfd* is ignored.
- If the pathname given in *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *open*())
- If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **open**() for a relative pathname). In this case, *dirfd* must be a directory that

was opened for reading (**O_RDONLY**) or using the **O_PATH** flag.

If the pathname given in *pathname* is relative, and *dirfd* is not a valid file descriptor, an error (**EBADF**) results. (Specifying an invalid file descriptor number in *dirfd* can be used as a means to ensure that *pathname* is absolute.)

openat2(2)

The *openat2*(2) system call is an extension of **openat**(), and provides a superset of the features of **openat**(). It is documented separately, in *openat2*(2).

RETURN VALUE

On success, **open**(), **openat**(), and **creat**() return the new file descriptor (a nonnegative integer). On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

open(), **openat**(), and **creat**() can fail with the following errors:

EACCES

The requested access to the file is not allowed, or search permission is denied for one of the directories in the path prefix of *pathname*, or the file did not exist yet and write access to the parent directory is not allowed. (See also *path_resolution*(7).)

EACCES

Where **O_CREAT** is specified, the *protected_fifos* or *protected_regular* sysctl is enabled, the file already exists and is a FIFO or regular file, the owner of the file is neither the current user nor the owner of the containing directory, and the containing directory is both world- or group-writable and sticky. For details, see the descriptions of */proc/sys/fs/protected_fifos* and */proc/sys/fs/protected_regular* in *proc*(5).

EBADF

(**openat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EBUSY

O_EXCL was specified in *flags* and *pathname* refers to a block device that is in use by the system (e.g., it is mounted).

EDQUOT

Where **O_CREAT** is specified, the file does not exist, and the user's quota of disk blocks or inodes on the filesystem has been exhausted.

EEXIST

pathname already exists and **O_CREAT** and **O_EXCL** were used.

EFAULT

pathname points outside your accessible address space.

EFBIG

See **EOVERFLOW**.

EINTR

While blocked waiting to complete an open of a slow device (e.g., a FIFO; see *fifo*(7)), the call was interrupted by a signal handler; see *signal*(7).

EINVAL

The filesystem does not support the **O_DIRECT** flag. See **NOTES** for more information.

EINVAL

Invalid value in *flags*.

EINVAL

O_TMPFILE was specified in *flags*, but neither **O_WRONLY** nor **O_RDWR** was specified.

EINVAL

O_CREAT was specified in *flags* and the final component ("basename") of the new file's *pathname* is invalid (e.g., it contains characters not permitted by the underlying filesystem).

EINVAL

The final component ("basename") of *pathname* is invalid (e.g., it contains characters not permitted by the underlying filesystem).

EISDIR
pathname refers to a directory and the access requested involved writing (that is, **O_WRONLY** or **O_RDWR** is set).

EISDIR
pathname refers to an existing directory, **O_TMPFILE** and one of **O_WRONLY** or **O_RDWR** were specified in *flags*, but this kernel version does not provide the **O_TMPFILE** functionality.

ELOOP
Too many symbolic links were encountered in resolving *pathname*.

ELOOP
pathname was a symbolic link, and *flags* specified **O_NOFOLLOW** but not **O_PATH**.

EMFILE
The per-process limit on the number of open file descriptors has been reached (see the description of **RLIMIT_NOFILE** in *getrlimit*(2)).

ENAMETOOLONG
pathname was too long.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENODEV
pathname refers to a device special file and no corresponding device exists. (This is a Linux kernel bug; in this situation **ENXIO** must be returned.)

ENOENT
O_CREAT is not set and the named file does not exist.

ENOENT
A directory component in *pathname* does not exist or is a dangling symbolic link.

ENOENT
pathname refers to a nonexistent directory, **O_TMPFILE** and one of **O_WRONLY** or **O_RDWR** were specified in *flags*, but this kernel version does not provide the **O_TMPFILE** functionality.

ENOMEM
The named file is a FIFO, but memory for the FIFO buffer can't be allocated because the per-user hard limit on memory allocation for pipes has been reached and the caller is not privileged; see *pipe*(7).

ENOMEM
Insufficient kernel memory was available.

ENOSPC
pathname was to be created but the device containing *pathname* has no room for the new file.

ENOTDIR
A component used as a directory in *pathname* is not, in fact, a directory, or **O_DIRECTORY** was specified and *pathname* was not a directory.

ENOTDIR
(**openat**()) *pathname* is a relative pathname and *dirfd* is a file descriptor referring to a file other than a directory.

ENXIO
O_NONBLOCK | **O_WRONLY** is set, the named file is a FIFO, and no process has the FIFO open for reading.

ENXIO
The file is a device special file and no corresponding device exists.

ENXIO
The file is a UNIX domain socket.

EOPNOTSUPP
The filesystem containing *pathname* does not support **O_TMPFILE**.

EOVERFLOW
pathname refers to a regular file that is too large to be opened. The usual scenario here is that an application compiled on a 32-bit platform without *−D_FILE_OFFSET_BITS=64* tried to open a file whose size exceeds *(1<<31)−1* bytes; see also **O_LARGEFILE** above. This is the error specified by POSIX.1; before Linux 2.6.24, Linux gave the error **EFBIG** for this case.

EPERM
The **O_NOATIME** flag was specified, but the effective user ID of the caller did not match the owner of the file and the caller was not privileged.

EPERM
The operation was prevented by a file seal; see *fcntl*(2).

EROFS
pathname refers to a file on a read-only filesystem and write access was requested.

ETXTBSY
pathname refers to an executable image which is currently being executed and write access was requested.

ETXTBSY
pathname refers to a file that is currently in use as a swap file, and the **O_TRUNC** flag was specified.

ETXTBSY
pathname refers to a file that is currently being read by the kernel (e.g., for module/firmware loading), and write access was requested.

EWOULDBLOCK
The **O_NONBLOCK** flag was specified, and an incompatible lease was held on the file (see *fcntl*(2)).

VERSIONS

The (undefined) effect of **O_RDONLY | O_TRUNC** varies among implementations. On many systems the file is actually truncated.

Synchronized I/O

The POSIX.1-2008 "synchronized I/O" option specifies different variants of synchronized I/O, and specifies the **open**() flags **O_SYNC**, **O_DSYNC**, and **O_RSYNC** for controlling the behavior. Regardless of whether an implementation supports this option, it must at least support the use of **O_SYNC** for regular files.

Linux implements **O_SYNC** and **O_DSYNC**, but not **O_RSYNC**. Somewhat incorrectly, glibc defines **O_RSYNC** to have the same value as **O_SYNC**. (**O_RSYNC** is defined in the Linux header file *<asm/fcntl.h>* on HP PA-RISC, but it is not used.)

O_SYNC provides synchronized I/O *file* integrity completion, meaning write operations will flush data and all associated metadata to the underlying hardware. **O_DSYNC** provides synchronized I/O *data* integrity completion, meaning write operations will flush data to the underlying hardware, but will only flush metadata updates that are required to allow a subsequent read operation to complete successfully. Data integrity completion can reduce the number of disk operations that are required for applications that don’t need the guarantees of file integrity completion.

To understand the difference between the two types of completion, consider two pieces of file metadata: the file last modification timestamp (*st_mtime*) and the file length. All write operations will update the last file modification timestamp, but only writes that add data to the end of the file will change the file length. The last modification timestamp is not needed to ensure that a read completes successfully, but the file length is. Thus, **O_DSYNC** would only guarantee to flush updates to the file length metadata (whereas **O_SYNC** would also always flush the last modification timestamp metadata).

Before Linux 2.6.33, Linux implemented only the **O_SYNC** flag for **open**(). However, when that flag was specified, most filesystems actually provided the equivalent of synchronized I/O *data* integrity completion (i.e., **O_SYNC** was actually implemented as the equivalent of **O_DSYNC**).

Since Linux 2.6.33, proper **O_SYNC** support is provided. However, to ensure backward binary compatibility, **O_DSYNC** was defined with the same value as the historical **O_SYNC**, and **O_SYNC** was defined as a new (two-bit) flag value that includes the **O_DSYNC** flag value. This ensures that applications compiled against new headers get at least **O_DSYNC** semantics before Linux 2.6.33.

C library/kernel differences

Since glibc 2.26, the glibc wrapper function for **open**() employs the **openat**() system call, rather than the kernel's **open**() system call. For certain architectures, this is also true before glibc 2.26.

STANDARDS

open()
creat()
openat()
POSIX.1-2008.

openat2(2) Linux.

The **O_DIRECT**, **O_NOATIME**, **O_PATH**, and **O_TMPFILE** flags are Linux-specific. One must define **_GNU_SOURCE** to obtain their definitions.

The **O_CLOEXEC**, **O_DIRECTORY**, and **O_NOFOLLOW** flags are not specified in POSIX.1-2001, but are specified in POSIX.1-2008. Since glibc 2.12, one can obtain their definitions by defining either **_POSIX_C_SOURCE** with a value greater than or equal to 200809L or **_XOPEN_SOURCE** with a value greater than or equal to 700. In glibc 2.11 and earlier, one obtains the definitions by defining **_GNU_SOURCE**.

HISTORY

open()
creat() SVr4, 4.3BSD, POSIX.1-2001.

openat()
POSIX.1-2008. Linux 2.6.16, glibc 2.4.

NOTES

Under Linux, the **O_NONBLOCK** flag is sometimes used in cases where one wants to open but does not necessarily have the intention to read or write. For example, this may be used to open a device in order to get a file descriptor for use with *ioctl*(2).

Note that **open**() can open device special files, but **creat**() cannot create them; use *mknod*(2) instead.

If the file is newly created, its *st_atime*, *st_ctime*, *st_mtime* fields (respectively, time of last access, time of last status change, and time of last modification; see *stat*(2)) are set to the current time, and so are the *st_ctime* and *st_mtime* fields of the parent directory. Otherwise, if the file is modified because of the **O_TRUNC** flag, its *st_ctime* and *st_mtime* fields are set to the current time.

The files in the */proc/*pid*/fd* directory show the open file descriptors of the process with the PID *pid*. The files in the */proc/*pid*/fdinfo* directory show even more information about these file descriptors. See *proc*(5) for further details of both of these directories.

The Linux header file **<asm/fcntl.h>** doesn't define **O_ASYNC**; the (BSD-derived) **FASYNC** synonym is defined instead.

Open file descriptions

The term open file description is the one used by POSIX to refer to the entries in the system-wide table of open files. In other contexts, this object is variously also called an "open file object", a "file handle", an "open file table entry", or—in kernel-developer parlance—a *struct file*.

When a file descriptor is duplicated (using *dup*(2) or similar), the duplicate refers to the same open file description as the original file descriptor, and the two file descriptors consequently share the file offset and file status flags. Such sharing can also occur between processes: a child process created via *fork*(2) inherits duplicates of its parent's file descriptors, and those duplicates refer to the same open file descriptions.

Each **open**() of a file creates a new open file description; thus, there may be multiple open file descriptions corresponding to a file inode.

On Linux, one can use the *kcmp*(2) **KCMP_FILE** operation to test whether two file descriptors (in the same process or in two different processes) refer to the same open file description.

NFS

There are many infelicities in the protocol underlying NFS, affecting amongst others **O_SYNC** and **O_NDELAY**.

On NFS filesystems with UID mapping enabled, **open**() may return a file descriptor but, for example, *read*(2) requests are denied with **EACCES**. This is because the client performs **open**() by checking the permissions, but UID mapping is performed by the server upon read and write requests.

FIFOs

Opening the read or write end of a FIFO blocks until the other end is also opened (by another process or thread). See *fifo*(7) for further details.

File access mode

Unlike the other values that can be specified in *flags*, the *access mode* values **O_RDONLY**, **O_WRONLY**, and **O_RDWR** do not specify individual bits. Rather, they define the low order two bits of *flags*, and are defined respectively as 0, 1, and 2. In other words, the combination **O_RDONLY | O_WRONLY** is a logical error, and certainly does not have the same meaning as **O_RDWR**.

Linux reserves the special, nonstandard access mode 3 (binary 11) in *flags* to mean: check for read and write permission on the file and return a file descriptor that can't be used for reading or writing. This nonstandard access mode is used by some Linux drivers to return a file descriptor that is to be used only for device-specific *ioctl*(2) operations.

Rationale for openat() and other directory file descriptor APIs

openat() and the other system calls and library functions that take a directory file descriptor argument (i.e., *execveat*(2), *faccessat*(2), *fanotify_mark*(2), *fchmodat*(2), *fchownat*(2), *fspick*(2), *fstatat*(2), *futimesat*(2), *linkat*(2), *mkdirat*(2), *mknodat*(2), *mount_setattr*(2), *move_mount*(2), *name_to_handle_at*(2), *open_tree*(2), *openat2*(2), *readlinkat*(2), *renameat*(2), *renameat2*(2), *statx*(2), *symlinkat*(2), *unlinkat*(2), *utimensat*(2), *mkfifoat*(3), and *scandirat*(3)) address two problems with the older interfaces that preceded them. Here, the explanation is in terms of the **openat**() call, but the rationale is analogous for the other interfaces.

First, **openat**() allows an application to avoid race conditions that could occur when using **open**() to open files in directories other than the current working directory. These race conditions result from the fact that some component of the directory prefix given to **open**() could be changed in parallel with the call to **open**(). Suppose, for example, that we wish to create the file *dir1/dir2/xxx.dep* if the file *dir1/dir2/xxx* exists. The problem is that between the existence check and the file-creation step, *dir1* or *dir2* (which might be symbolic links) could be modified to point to a different location. Such races can be avoided by opening a file descriptor for the target directory, and then specifying that file descriptor as the *dirfd* argument of (say) *fstatat*(2) and **openat**(). The use of the *dirfd* file descriptor also has other benefits:

- the file descriptor is a stable reference to the directory, even if the directory is renamed; and
- the open file descriptor prevents the underlying filesystem from being dismounted, just as when a process has a current working directory on a filesystem.

Second, **openat**() allows the implementation of a per-thread "current working directory", via file descriptor(s) maintained by the application. (This functionality can also be obtained by tricks based on the use of */proc/self/fd/*dirfd, but less efficiently.)

The *dirfd* argument for these APIs can be obtained by using **open**() or **openat**() to open a directory (with either the **O_RDONLY** or the **O_PATH** flag). Alternatively, such a file descriptor can be obtained by applying *dirfd*(3) to a directory stream created using *opendir*(3).

When these APIs are given a *dirfd* argument of **AT_FDCWD** or the specified pathname is absolute, then they handle their pathname argument in the same way as the corresponding conventional APIs. However, in this case, several of the APIs have a *flags* argument that provides access to functionality that is not available with the corresponding conventional APIs.

O_DIRECT

The **O_DIRECT** flag may impose alignment restrictions on the length and address of user-space buffers and the file offset of I/Os. In Linux alignment restrictions vary by filesystem and kernel version and might be absent entirely. The handling of misaligned **O_DIRECT** I/Os also varies; they can either fail with **EINVAL** or fall back to buffered I/O.

Since Linux 6.1, **O_DIRECT** support and alignment restrictions for a file can be queried using *statx*(2), using the **STATX_DIOALIGN** flag. Support for **STATX_DIOALIGN** varies by filesystem; see *statx*(2).

Some filesystems provide their own interfaces for querying **O_DIRECT** alignment restrictions, for example the **XFS_IOC_DIOINFO** operation in *xfsctl*(3)**STATX_DIOALIGN** should be used instead when it is available.

If none of the above is available, then direct I/O support and alignment restrictions can only be assumed from known characteristics of the filesystem, the individual file, the underlying storage device(s), and the kernel version. In Linux 2.4, most filesystems based on block devices require that the file offset and the length and memory address of all I/O segments be multiples of the filesystem block size (typically 4096 bytes). In Linux 2.6.0, this was relaxed to the logical block size of the block device (typically 512 bytes). A block device's logical block size can be determined using the *ioctl*(2) **BLKSSZGET** operation or from the shell using the command:

```
blockdev --getss
```

O_DIRECT I/Os should never be run concurrently with the *fork*(2) system call, if the memory buffer is a private mapping (i.e., any mapping created with the *mmap*(2) **MAP_PRIVATE** flag; this includes memory allocated on the heap and statically allocated buffers). Any such I/Os, whether submitted via an asynchronous I/O interface or from another thread in the process, should be completed before *fork*(2) is called. Failure to do so can result in data corruption and undefined behavior in parent and child processes. This restriction does not apply when the memory buffer for the **O_DIRECT** I/Os was created using *shmat*(2) or *mmap*(2) with the **MAP_SHARED** flag. Nor does this restriction apply when the memory buffer has been advised as **MADV_DONTFORK** with *madvise*(2), ensuring that it will not be available to the child after *fork*(2).

The **O_DIRECT** flag was introduced in SGI IRIX, where it has alignment restrictions similar to those of Linux 2.4. IRIX has also a *fcntl*(2) call to query appropriate alignments, and sizes. FreeBSD 4.x introduced a flag of the same name, but without alignment restrictions.

O_DIRECT support was added in Linux 2.4.10. Older Linux kernels simply ignore this flag. Some filesystems may not implement the flag, in which case **open**() fails with the error **EINVAL** if it is used.

Applications should avoid mixing **O_DIRECT** and normal I/O to the same file, and especially to overlapping byte regions in the same file. Even when the filesystem correctly handles the coherency issues in this situation, overall I/O throughput is likely to be slower than using either mode alone. Likewise, applications should avoid mixing *mmap*(2) of files with direct I/O to the same files.

The behavior of **O_DIRECT** with NFS will differ from local filesystems. Older kernels, or kernels configured in certain ways, may not support this combination. The NFS protocol does not support passing the flag to the server, so **O_DIRECT** I/O will bypass the page cache only on the client; the server may still cache the I/O. The client asks the server to make the I/O synchronous to preserve the synchronous semantics of **O_DIRECT**. Some servers will perform poorly under these circumstances, especially if the I/O size is small. Some servers may also be configured to lie to clients about the I/O having reached stable storage; this will avoid the performance penalty at some risk to data integrity in the event of server power failure. The Linux NFS client places no alignment restrictions on **O_DIRECT** I/O.

In summary, **O_DIRECT** is a potentially powerful tool that should be used with caution. It is recommended that applications treat use of **O_DIRECT** as a performance option which is disabled by default.

BUGS

Currently, it is not possible to enable signal-driven I/O by specifying **O_ASYNC** when calling **open**(); use *fcntl*(2) to enable this flag.

One must check for two different error codes, **EISDIR** and **ENOENT**, when trying to determine whether the kernel supports **O_TMPFILE** functionality.

When both **O_CREAT** and **O_DIRECTORY** are specified in *flags* and the file specified by *pathname* does not exist, **open**() will create a regular file (i.e., **O_DIRECTORY** is ignored).

NAME

name_to_handle_at, open_by_handle_at − obtain handle for a pathname and open file via a handle

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <fcntl.h>

int name_to_handle_at(int dirfd, const char *pathname,
                      struct file_handle *handle,
                      int *mount_id, int flags);
int open_by_handle_at(int mount_fd, struct file_handle *handle,
                      int flags);
```

DESCRIPTION

The **name_to_handle_at**() and **open_by_handle_at**() system calls split the functionality of *openat*(2) into two parts: **name_to_handle_at**() returns an opaque handle that corresponds to a specified file; **open_by_handle_at**() opens the file corresponding to a handle returned by a previous call to **name_to_handle_at**() and returns an open file descriptor.

name_to_handle_at()

The **name_to_handle_at**() system call returns a file handle and a mount ID corresponding to the file specified by the *dirfd* and *pathname* arguments. The file handle is returned via the argument *handle*, which is a pointer to a structure of the following form:

```
struct file_handle {
    unsigned int  handle_bytes;   /* Size of f_handle [in, out] */
    int           handle_type;    /* Handle type [out] */
    unsigned char f_handle[0];    /* File identifier (sized by
                                     caller) [out] */
};
```

It is the caller's responsibility to allocate the structure with a size large enough to hold the handle returned in *f_handle*. Before the call, the *handle_bytes* field should be initialized to contain the allocated size for *f_handle*. (The constant **MAX_HANDLE_SZ**, defined in <*fcntl.h*>, specifies the maximum expected size for a file handle. It is not a guaranteed upper limit as future filesystems may require more space.) Upon successful return, the *handle_bytes* field is updated to contain the number of bytes actually written to *f_handle*.

The caller can discover the required size for the *file_handle* structure by making a call in which *handle−>handle_bytes* is zero; in this case, the call fails with the error **EOVERFLOW** and *handle−>handle_bytes* is set to indicate the required size; the caller can then use this information to allocate a structure of the correct size (see EXAMPLES below). Some care is needed here as **EOVERFLOW** can also indicate that no file handle is available for this particular name in a filesystem which does normally support file-handle lookup. This case can be detected when the **EOVERFLOW** error is returned without *handle_bytes* being increased.

Other than the use of the *handle_bytes* field, the caller should treat the *file_handle* structure as an opaque data type: the *handle_type* and *f_handle* fields can be used in a subsequent call to **open_by_handle_at**(). The caller can also use the opaque *file_handle* to compare the identity of filesystem objects that were queried at different times and possibly at different paths. The *fanotify*(7) subsystem can report events with an information record containing a *file_handle* to identify the filesystem object.

The *flags* argument is a bit mask constructed by ORing together zero or more of **AT_HANDLE_FID**, **AT_EMPTY_PATH**, and **AT_SYMLINK_FOLLOW**, described below.

When *flags* contain the **AT_HANDLE_FID** (since Linux 6.5) flag, the caller indicates that the returned *file_handle* is needed to identify the filesystem object, and not for opening the file later, so it should be expected that a subsequent call to **open_by_handle_at**() with the returned *file_handle* may fail.

Together, the *pathname* and *dirfd* arguments identify the file for which a handle is to be obtained. There are four distinct cases:

- If *pathname* is a nonempty string containing an absolute pathname, then a handle is returned for the file referred to by that pathname. In this case, *dirfd* is ignored.
- If *pathname* is a nonempty string containing a relative pathname and *dirfd* has the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the caller, and a handle is returned for the file to which it refers.
- If *pathname* is a nonempty string containing a relative pathname and *dirfd* is a file descriptor referring to a directory, then *pathname* is interpreted relative to the directory referred to by *dirfd*, and a handle is returned for the file to which it refers. (See *openat*(2) for an explanation of why "directory file descriptors" are useful.)
- If *pathname* is an empty string and *flags* specifies the value **AT_EMPTY_PATH**, then *dirfd* can be an open file descriptor referring to any type of file, or **AT_FDCWD**, meaning the current working directory, and a handle is returned for the file to which it refers.

The *mount_id* argument returns an identifier for the filesystem mount that corresponds to *pathname*. This corresponds to the first field in one of the records in */proc/self/mountinfo*. Opening the pathname in the fifth field of that record yields a file descriptor for the mount point; that file descriptor can be used in a subsequent call to **open_by_handle_at**(). *mount_id* is returned both for a successful call and for a call that results in the error **EOVERFLOW**.

By default, **name_to_handle_at**() does not dereference *pathname* if it is a symbolic link, and thus returns a handle for the link itself. If **AT_SYMLINK_FOLLOW** is specified in *flags*, *pathname* is dereferenced if it is a symbolic link (so that the call returns a handle for the file referred to by the link).

name_to_handle_at() does not trigger a mount when the final component of the pathname is an automount point. When a filesystem supports both file handles and automount points, a **name_to_handle_at**() call on an automount point will return with error **EOVERFLOW** without having increased *handle_bytes*. This can happen since Linux 4.13 with NFS when accessing a directory which is on a separate filesystem on the server. In this case, the automount can be triggered by adding a "/" to the end of the pathname.

open_by_handle_at()

The **open_by_handle_at**() system call opens the file referred to by *handle*, a file handle returned by a previous call to **name_to_handle_at**().

The *mount_fd* argument is a file descriptor for any object (file, directory, etc.) in the mounted filesystem with respect to which *handle* should be interpreted. The special value **AT_FDCWD** can be specified, meaning the current working directory of the caller.

The *flags* argument is as for *open*(2). If *handle* refers to a symbolic link, the caller must specify the **O_PATH** flag, and the symbolic link is not dereferenced; the **O_NOFOLLOW** flag, if specified, is ignored.

The caller must have the **CAP_DAC_READ_SEARCH** capability to invoke **open_by_handle_at**().

RETURN VALUE

On success, **name_to_handle_at**() returns 0, and **open_by_handle_at**() returns a file descriptor (a nonnegative integer).

In the event of an error, both system calls return −1 and set *errno* to indicate the error.

ERRORS

name_to_handle_at() and **open_by_handle_at**() can fail for the same errors as *openat*(2). In addition, they can fail with the errors noted below.

name_to_handle_at() can fail with the following errors:

EFAULT
: *pathname*, *mount_id*, or *handle* points outside your accessible address space.

EINVAL
: *flags* includes an invalid bit value.

EINVAL
: *handle*−>*handle_bytes* is greater than **MAX_HANDLE_SZ**.

ENOENT
pathname is an empty string, but **AT_EMPTY_PATH** was not specified in *flags*.

ENOTDIR
The file descriptor supplied in *dirfd* does not refer to a directory, and it is not the case that both *flags* includes **AT_EMPTY_PATH** and *pathname* is an empty string.

EOPNOTSUPP
The filesystem does not support decoding of a pathname to a file handle.

EOVERFLOW
The *handle->handle_bytes* value passed into the call was too small. When this error occurs, *handle->handle_bytes* is updated to indicate the required size for the handle.

open_by_handle_at() can fail with the following errors:

EBADF
mount_fd is not an open file descriptor.

EBADF
pathname is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT
handle points outside your accessible address space.

EINVAL
handle->handle_bytes is greater than **MAX_HANDLE_SZ** or is equal to zero.

ELOOP
handle refers to a symbolic link, but **O_PATH** was not specified in *flags*.

EPERM
The caller does not have the **CAP_DAC_READ_SEARCH** capability.

ESTALE
The specified *handle* is not valid for opening a file. This error will occur if, for example, the file has been deleted. This error can also occur if the *handle* was acquired using the **AT_HANDLE_FID** flag and the filesystem does not support **open_by_handle_at**().

VERSIONS
FreeBSD has a broadly similar pair of system calls in the form of **getfh**() and **openfh**().

STANDARDS
Linux.

HISTORY
Linux 2.6.39, glibc 2.14.

NOTES
A file handle can be generated in one process using **name_to_handle_at**() and later used in a different process that calls **open_by_handle_at**().

Some filesystem don't support the translation of pathnames to file handles, for example, */proc*, */sys*, and various network filesystems. Some filesystems support the translation of pathnames to file handles, but do not support using those file handles in **open_by_handle_at**().

A file handle may become invalid ("stale") if a file is deleted, or for other filesystem-specific reasons. Invalid handles are notified by an **ESTALE** error from **open_by_handle_at**().

These system calls are designed for use by user-space file servers. For example, a user-space NFS server might generate a file handle and pass it to an NFS client. Later, when the client wants to open the file, it could pass the handle back to the server. This sort of functionality allows a user-space file server to operate in a stateless fashion with respect to the files it serves.

If *pathname* refers to a symbolic link and *flags* does not specify **AT_SYMLINK_FOLLOW**, then **name_to_handle_at**() returns a handle for the link (rather than the file to which it refers). The process receiving the handle can later perform operations on the symbolic link by converting the handle to a file descriptor using **open_by_handle_at**() with the **O_PATH** flag, and then passing the file descriptor as the *dirfd* argument in system calls such as *readlinkat*(2) and *fchownat*(2).

Obtaining a persistent filesystem ID

The mount IDs in */proc/self/mountinfo* can be reused as filesystems are unmounted and mounted. Therefore, the mount ID returned by **name_to_handle_at**() (in **mount_id*) should not be treated as a persistent identifier for the corresponding mounted filesystem. However, an application can use the information in the *mountinfo* record that corresponds to the mount ID to derive a persistent identifier.

For example, one can use the device name in the fifth field of the *mountinfo* record to search for the corresponding device UUID via the symbolic links in */dev/disks/by−uuid*. (A more comfortable way of obtaining the UUID is to use the *libblkid*(3) library.) That process can then be reversed, using the UUID to look up the device name, and then obtaining the corresponding mount point, in order to produce the *mount_fd* argument used by **open_by_handle_at**().

EXAMPLES

The two programs below demonstrate the use of **name_to_handle_at**() and **open_by_handle_at**(). The first program (*t_name_to_handle_at.c*) uses **name_to_handle_at**() to obtain the file handle and mount ID for the file specified in its command-line argument; the handle and mount ID are written to standard output.

The second program (*t_open_by_handle_at.c*) reads a mount ID and file handle from standard input. The program then employs **open_by_handle_at**() to open the file using that handle. If an optional command-line argument is supplied, then the *mount_fd* argument for **open_by_handle_at**() is obtained by opening the directory named in that argument. Otherwise, *mount_fd* is obtained by scanning */proc/self/mountinfo* to find a record whose mount ID matches the mount ID read from standard input, and the mount directory specified in that record is opened. (These programs do not deal with the fact that mount IDs are not persistent.)

The following shell session demonstrates the use of these two programs:

```
$ echo 'Can you please think about it?' > cecilia.txt
$ ./t_name_to_handle_at cecilia.txt > fh
$ ./t_open_by_handle_at < fh
open_by_handle_at: Operation not permitted
$ sudo ./t_open_by_handle_at < fh      # Need CAP_SYS_ADMIN
Read 31 bytes
$ rm cecilia.txt
```

Now we delete and (quickly) re-create the file so that it has the same content and (by chance) the same inode. Nevertheless, **open_by_handle_at**() recognizes that the original file referred to by the file handle no longer exists.

```
$ stat --printf="%i\n" cecilia.txt     # Display inode number
4072121
$ rm cecilia.txt
$ echo 'Can you please think about it?' > cecilia.txt
$ stat --printf="%i\n" cecilia.txt     # Check inode number
4072121
$ sudo ./t_open_by_handle_at < fh
open_by_handle_at: Stale NFS file handle
```

NAME

openat2 − open and possibly create a file (extended)

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <fcntl.h>          /* Definition of O_* and S_* constants */
#include <linux/openat2.h>  /* Definition of RESOLVE_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

long syscall(SYS_openat2, int dirfd, const char *pathname,
             struct open_how *how, size_t size);
```

Note: glibc provides no wrapper for **openat2**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **openat2**() system call is an extension of *openat*(2) and provides a superset of its functionality.

The **openat2**() system call opens the file specified by *pathname*. If the specified file does not exist, it may optionally (if **O_CREAT** is specified in *how.flags*) be created.

As with *openat*(2), if *pathname* is a relative pathname, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (or the current working directory of the calling process, if *dirfd* is the special value **AT_FDCWD**). If *pathname* is an absolute pathname, then *dirfd* is ignored (unless *how.resolve* contains **RESOLVE_IN_ROOT**, in which case *pathname* is resolved relative to *dirfd*).

Rather than taking a single *flags* argument, an extensible structure (*how*) is passed to allow for future extensions. The *size* argument must be specified as *sizeof(struct open_how)*.

The open_how structure

The *how* argument specifies how *pathname* should be opened, and acts as a superset of the *flags* and *mode* arguments to *openat*(2). This argument is a pointer to an *open_how* structure, described in *open_how*(2type).

Any future extensions to **openat2**() will be implemented as new fields appended to the *open_how* structure, with a zero value in a new field resulting in the kernel behaving as though that extension field was not present. Therefore, the caller *must* zero-fill this structure on initialization. (See the "Extensibility" section of the **NOTES** for more detail on why this is necessary.)

The fields of the *open_how* structure are as follows:

flags This field specifies the file creation and file status flags to use when opening the file. All of the **O_*** flags defined for *openat*(2) are valid **openat2**() flag values.

Whereas *openat*(2) ignores unknown bits in its *flags* argument, **openat2**() returns an error if unknown or conflicting flags are specified in *how.flags*.

mode This field specifies the mode for the new file, with identical semantics to the *mode* argument of *openat*(2).

Whereas *openat*(2) ignores bits other than those in the range *07777* in its *mode* argument, **openat2**() returns an error if *how.mode* contains bits other than *07777*. Similarly, an error is returned if **openat2**() is called with a nonzero *how.mode* and *how.flags* does not contain **O_CREAT** or **O_TMPFILE**.

resolve This is a bit-mask of flags that modify the way in which **all** components of *pathname* will be resolved. (See *path_resolution*(7) for background information.)

The primary use case for these flags is to allow trusted programs to restrict how untrusted paths (or paths inside untrusted directories) are resolved. The full list of *resolve* flags is as follows:

RESOLVE_BENEATH

Do not permit the path resolution to succeed if any component of the resolution is not a descendant of the directory indicated by *dirfd*. This causes absolute symbolic links (and absolute values of *pathname*) to be rejected.

Currently, this flag also disables magic-link resolution (see below). However, this may change in the future. Therefore, to ensure that magic links are not resolved, the caller should explicitly specify **RESOLVE_NO_MAGICLINKS**.

RESOLVE_IN_ROOT
Treat the directory referred to by *dirfd* as the root directory while resolving *pathname*. Absolute symbolic links are interpreted relative to *dirfd*. If a prefix component of *pathname* equates to *dirfd*, then an immediately following .. component likewise equates to *dirfd* (just as */..* is traditionally equivalent to */*). If *pathname* is an absolute path, it is also interpreted relative to *dirfd*.

The effect of this flag is as though the calling process had used *chroot*(2) to (temporarily) modify its root directory (to the directory referred to by *dirfd*). However, unlike *chroot*(2) (which changes the filesystem root permanently for a process), **RESOLVE_IN_ROOT** allows a program to efficiently restrict path resolution on a per-open basis.

Currently, this flag also disables magic-link resolution. However, this may change in the future. Therefore, to ensure that magic links are not resolved, the caller should explicitly specify **RESOLVE_NO_MAGICLINKS**.

RESOLVE_NO_MAGICLINKS
Disallow all magic-link resolution during path resolution.

Magic links are symbolic link-like objects that are most notably found in *proc*(5); examples include */proc/*pid*/exe* and */proc/*pid*/fd/**. (See *symlink*(7) for more details.)

Unknowingly opening magic links can be risky for some applications. Examples of such risks include the following:

- If the process opening a pathname is a controlling process that currently has no controlling terminal (see *credentials*(7)), then opening a magic link inside */proc/*pid*/fd* that happens to refer to a terminal would cause the process to acquire a controlling terminal.
- In a containerized environment, a magic link inside */proc* may refer to an object outside the container, and thus may provide a means to escape from the container.

Because of such risks, an application may prefer to disable magic link resolution using the **RESOLVE_NO_MAGICLINKS** flag.

If the trailing component (i.e., basename) of *pathname* is a magic link, *how.resolve* contains **RESOLVE_NO_MAGICLINKS**, and *how.flags* contains both **O_PATH** and **O_NOFOLLOW**, then an **O_PATH** file descriptor referencing the magic link will be returned.

RESOLVE_NO_SYMLINKS
Disallow resolution of symbolic links during path resolution. This option implies **RESOLVE_NO_MAGICLINKS**.

If the trailing component (i.e., basename) of *pathname* is a symbolic link, *how.resolve* contains **RESOLVE_NO_SYMLINKS**, and *how.flags* contains both **O_PATH** and **O_NOFOLLOW**, then an **O_PATH** file descriptor referencing the symbolic link will be returned.

Note that the effect of the **RESOLVE_NO_SYMLINKS** flag, which affects the treatment of symbolic links in all of the components of *pathname*, differs from the effect of the **O_NOFOLLOW** file creation flag (in *how.flags*), which affects the handling of symbolic links only in the final component of *pathname*.

Applications that employ the **RESOLVE_NO_SYMLINKS** flag are encouraged to make its use configurable (unless it is used for a specific security purpose), as symbolic links are very widely used by end-users. Setting this flag indiscriminately—i.e., for purposes not specifically related to security—for all uses of **openat2**() may result in spurious errors on previously functional systems. This may occur if, for example, a system pathname that is used by an application is modified (e.g., in a new distribution release) so that a pathname component (now) contains a symbolic link.

RESOLVE_NO_XDEV
Disallow traversal of mount points during path resolution (including all bind mounts). Consequently, *pathname* must either be on the same mount as the directory referred to by *dirfd*, or on the same mount as the current working directory if *dirfd* is specified as **AT_FDCWD**.

Applications that employ the **RESOLVE_NO_XDEV** flag are encouraged to make its use configurable (unless it is used for a specific security purpose), as bind mounts are widely used by end-users. Setting this flag indiscriminately—i.e., for purposes not specifically related to security—for all uses of **openat2**() may result in spurious errors on previously functional systems. This may occur if, for example, a system pathname that is used by an application is modified (e.g., in a new distribution release) so that a pathname component (now) contains a bind mount.

RESOLVE_CACHED
Make the open operation fail unless all path components are already present in the kernel's lookup cache. If any kind of revalidation or I/O is needed to satisfy the lookup, **openat2**() fails with the error **EAGAIN**. This is useful in providing a fast-path open that can be performed without resorting to thread offload, or other mechanisms that an application might use to offload slower operations.

If any bits other than those listed above are set in *how.resolve*, an error is returned.

RETURN VALUE

On success, a new file descriptor is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

The set of errors returned by **openat2**() includes all of the errors returned by *openat*(2), as well as the following additional errors:

E2BIG An extension that this kernel does not support was specified in *how*. (See the "Extensibility" section of **NOTES** for more detail on how extensions are handled.)

EAGAIN
how.resolve contains either **RESOLVE_IN_ROOT** or **RESOLVE_BENEATH**, and the kernel could not ensure that a ".." component didn't escape (due to a race condition or potential attack). The caller may choose to retry the **openat2**() call.

EAGAIN
RESOLVE_CACHED was set, and the open operation cannot be performed using only cached information. The caller should retry without **RESOLVE_CACHED** set in *how.resolve*.

EINVAL
An unknown flag or invalid value was specified in *how*.

EINVAL
mode is nonzero, but *how.flags* does not contain **O_CREAT** or **O_TMPFILE**.

EINVAL
size was smaller than any known version of *struct open_how*.

ELOOP
how.resolve contains **RESOLVE_NO_SYMLINKS**, and one of the path components was a symbolic link (or magic link).

ELOOP
how.resolve contains **RESOLVE_NO_MAGICLINKS**, and one of the path components was a magic link.

EXDEV
how.resolve contains either **RESOLVE_IN_ROOT** or **RESOLVE_BENEATH**, and an escape from the root during path resolution was detected.

EXDEV
how.resolve contains **RESOLVE_NO_XDEV**, and a path component crosses a mount point.

STANDARDS

Linux.

HISTORY

Linux 5.6.

The semantics of **RESOLVE_BENEATH** were modeled after FreeBSD's **O_BENEATH**.

NOTES

Extensibility

In order to allow for future extensibility, **openat2**() requires the user-space application to specify the size of the *open_how* structure that it is passing. By providing this information, it is possible for **openat2**() to provide both forwards- and backwards-compatibility, with *size* acting as an implicit version number. (Because new extension fields will always be appended, the structure size will always increase.) This extensibility design is very similar to other system calls such as *sched_setattr*(2), *perf_event_open*(2), and *clone3*(2).

If we let *usize* be the size of the structure as specified by the user-space application, and *ksize* be the size of the structure which the kernel supports, then there are three cases to consider:

- If *ksize* equals *usize*, then there is no version mismatch and *how* can be used verbatim.
- If *ksize* is larger than *usize*, then there are some extension fields that the kernel supports which the user-space application is unaware of. Because a zero value in any added extension field signifies a no-op, the kernel treats all of the extension fields not provided by the user-space application as having zero values. This provides backwards-compatibility.
- If *ksize* is smaller than *usize*, then there are some extension fields which the user-space application is aware of but which the kernel does not support. Because any extension field must have its zero values signify a no-op, the kernel can safely ignore the unsupported extension fields if they are all-zero. If any unsupported extension fields are nonzero, then −1 is returned and *errno* is set to **E2BIG**. This provides forwards-compatibility.

Because the definition of *struct open_how* may change in the future (with new fields being added when system headers are updated), user-space applications should zero-fill *struct open_how* to ensure that recompiling the program with new headers will not result in spurious errors at run time. The simplest way is to use a designated initializer:

```
struct open_how how = { .flags = O_RDWR,
                        .resolve = RESOLVE_IN_ROOT };
```

or explicitly using *memset*(3) or similar:

```
struct open_how how;
memset(&how, 0, sizeof(how));
how.flags = O_RDWR;
how.resolve = RESOLVE_IN_ROOT;
```

A user-space application that wishes to determine which extensions the running kernel supports can do so by conducting a binary search on *size* with a structure which has every byte nonzero (to find the largest value which doesn't produce an error of **E2BIG**).

        unsigned long count);
void outsl(unsigned short port, const void addr[.count],
        unsigned long count);
```

DESCRIPTION

This family of functions is used to do low-level port input and output. The out* functions do port output, the in* functions do port input; the b-suffix functions are byte-width and the w-suffix functions word-width; the _p-suffix functions pause until the I/O completes.

They are primarily designed for internal kernel use, but can be used from user space.

You must compile with **−O** or **−O2** or similar. The functions are defined as inline macros, and will not be substituted in without optimization enabled, causing unresolved references at link time.

You use *ioperm*(2) or alternatively *iopl*(2) to tell the kernel to allow the user space application to access the I/O ports in question. Failure to do this will cause the application to receive a segmentation fault.

VERSIONS

outb() and friends are hardware-specific. The *value* argument is passed first and the *port* argument is passed second, which is the opposite order from most DOS implementations.

STANDARDS

None.

NAME

pause − wait for signal

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int pause(void);
```

DESCRIPTION

pause() causes the calling process (or thread) to sleep until a signal is delivered that either terminates the process or causes the invocation of a signal-catching function.

RETURN VALUE

pause() returns only when a signal was caught and the signal-catching function returned. In this case, **pause**() returns −1, and *errno* is set to **EINTR**.

ERRORS

EINTR
: a signal was caught and the signal-catching function returned.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

SEE ALSO

kill(2), *select*(2), *signal*(2), *sigsuspend*(2)

NAME

pciconfig_read, pciconfig_write, pciconfig_iobase − pci device information handling

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <pci.h>

int pciconfig_read(unsigned long bus, unsigned long dfn,
                   unsigned long off, unsigned long len,
                   unsigned char *buf);
int pciconfig_write(unsigned long bus, unsigned long dfn,
                   unsigned long off, unsigned long len,
                   unsigned char *buf);
int pciconfig_iobase(int which, unsigned long bus,
                   unsigned long devfn);
```

DESCRIPTION

Most of the interaction with PCI devices is already handled by the kernel PCI layer, and thus these calls should not normally need to be accessed from user space.

pciconfig_read()
: Reads to *buf* from device *dev* at offset *off* value.

pciconfig_write()
: Writes from *buf* to device *dev* at offset *off* value.

pciconfig_iobase()
: You pass it a bus/devfn pair and get a physical address for either the memory offset (for things like prep, this is 0xc0000000), the IO base for PIO cycles, or the ISA holes if any.

RETURN VALUE

pciconfig_read()
: On success, zero is returned. On error, −1 is returned and *errno* is set to indicate the error.

pciconfig_write()
: On success, zero is returned. On error, −1 is returned and *errno* is set to indicate the error.

pciconfig_iobase()
: Returns information on locations of various I/O regions in physical memory according to the *which* value. Values for *which* are: **IOBASE_BRIDGE_NUMBER**, **IOBASE_MEMORY**, **IOBASE_IO**, **IOBASE_ISA_IO**, **IOBASE_ISA_MEM**.

ERRORS

EINVAL
: *len* value is invalid. This does not apply to **pciconfig_iobase**().

EIO I/O error.

ENODEV
: For **pciconfig_iobase**(), "hose" value is NULL. For the other calls, could not find a slot.

ENOSYS
: The system has not implemented these calls (**CONFIG_PCI** not defined).

EOPNOTSUPP
: This return value is valid only for **pciconfig_iobase**(). It is returned if the value for *which* is invalid.

EPERM
: User does not have the **CAP_SYS_ADMIN** capability. This does not apply to **pciconfig_iobase**().

STANDARDS

Linux.

NAME

perf_event_open − set up performance monitoring

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/perf_event.h>    /* Definition of PERF_* constants */
#include <linux/hw_breakpoint.h> /* Definition of HW_* constants */
#include <sys/syscall.h>         /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_perf_event_open, struct perf_event_attr *attr,
            pid_t pid, int cpu, int group_fd, unsigned long flags);
```

Note: glibc provides no wrapper for **perf_event_open**(), necessitating the use of *syscall*(2).

DESCRIPTION

Given a list of parameters, **perf_event_open**() returns a file descriptor, for use in subsequent system calls (*read*(2), *mmap*(2), *prctl*(2), *fcntl*(2), etc.).

A call to **perf_event_open**() creates a file descriptor that allows measuring performance information. Each file descriptor corresponds to one event that is measured; these can be grouped together to measure multiple events simultaneously.

Events can be enabled and disabled in two ways: via *ioctl*(2) and via *prctl*(2). When an event is disabled it does not count or generate overflows but does continue to exist and maintain its count value.

Events come in two flavors: counting and sampled. A *counting* event is one that is used for counting the aggregate number of events that occur. In general, counting event results are gathered with a *read*(2) call. A *sampling* event periodically writes measurements to a buffer that can then be accessed via *mmap*(2).

Arguments

The *pid* and *cpu* arguments allow specifying which process and CPU to monitor:

pid == 0 and **cpu == -1**
: This measures the calling process/thread on any CPU.

pid == 0 and **cpu >= 0**
: This measures the calling process/thread only when running on the specified CPU.

pid > 0 and **cpu == -1**
: This measures the specified process/thread on any CPU.

pid > 0 and **cpu >= 0**
: This measures the specified process/thread only when running on the specified CPU.

pid == -1 and **cpu >= 0**
: This measures all processes/threads on the specified CPU. This requires **CAP_PERFMON** (since Linux 5.8) or **CAP_SYS_ADMIN** capability or a */proc/sys/kernel/perf_event_paranoid* value of less than 1.

pid == -1 and **cpu == -1**
: This setting is invalid and will return an error.

When *pid* is greater than zero, permission to perform this system call is governed by **CAP_PERFMON** (since Linux 5.9) and a ptrace access mode **PTRACE_MODE_READ_REALCREDS** check on older Linux versions; see *ptrace*(2).

The *group_fd* argument allows event groups to be created. An event group has one event which is the group leader. The leader is created first, with *group_fd* = −1. The rest of the group members are created with subsequent **perf_event_open**() calls with *group_fd* being set to the file descriptor of the group leader. (A single event on its own is created with *group_fd* = −1 and is considered to be a group with only 1 member.) An event group is scheduled onto the CPU as a unit: it will be put onto the CPU only if all of the events in the group can be put onto the CPU. This means that the values of the member events can be meaningfully compared —added, divided (to get ratios), and so on— with each other, since they have counted events for the same set of executed instructions.

The *flags* argument is formed by ORing together zero or more of the following values:

PERF_FLAG_FD_CLOEXEC (since Linux 3.14)
This flag enables the close-on-exec flag for the created event file descriptor, so that the file descriptor is automatically closed on *execve*(2). Setting the close-on-exec flags at creation time, rather than later with *fcntl*(2), avoids potential race conditions where the calling thread invokes **perf_event_open**() and *fcntl*(2) at the same time as another thread calls *fork*(2) then *execve*(2).

PERF_FLAG_FD_NO_GROUP
This flag tells the event to ignore the *group_fd* parameter except for the purpose of setting up output redirection using the **PERF_FLAG_FD_OUTPUT** flag.

PERF_FLAG_FD_OUTPUT (broken since Linux 2.6.35)
This flag re-routes the event's sampled output to instead be included in the mmap buffer of the event specified by *group_fd*.

PERF_FLAG_PID_CGROUP (since Linux 2.6.39)
This flag activates per-container system-wide monitoring. A container is an abstraction that isolates a set of resources for finer-grained control (CPUs, memory, etc.). In this mode, the event is measured only if the thread running on the monitored CPU belongs to the designated container (cgroup). The cgroup is identified by passing a file descriptor opened on its directory in the cgroupfs filesystem. For instance, if the cgroup to monitor is called *test*, then a file descriptor opened on */dev/cgroup/test* (assuming cgroupfs is mounted on */dev/cgroup*) must be passed as the *pid* parameter. cgroup monitoring is available only for system-wide events and may therefore require extra permissions.

The *perf_event_attr* structure provides detailed configuration information for the event being created.

```
struct perf_event_attr {
    __u32 type;                 /* Type of event */
    __u32 size;                 /* Size of attribute structure */
    __u64 config;               /* Type-specific configuration */

    union {
        __u64 sample_period;    /* Period of sampling */
        __u64 sample_freq;      /* Frequency of sampling */
    };

    __u64 sample_type;  /* Specifies values included in sample */
    __u64 read_format;  /* Specifies values returned in read */

    __u64 disabled       : 1,   /* off by default */
          inherit        : 1,   /* children inherit it */
          pinned         : 1,   /* must always be on PMU */
          exclusive      : 1,   /* only group on PMU */
          exclude_user   : 1,   /* don't count user */
          exclude_kernel : 1,   /* don't count kernel */
          exclude_hv     : 1,   /* don't count hypervisor */
          exclude_idle   : 1,   /* don't count when idle */
          mmap           : 1,   /* include mmap data */
          comm           : 1,   /* include comm data */
          freq           : 1,   /* use freq, not period */
          inherit_stat   : 1,   /* per task counts */
          enable_on_exec : 1,   /* next exec enables */
          task           : 1,   /* trace fork/exit */
          watermark      : 1,   /* wakeup_watermark */
          precise_ip     : 2,   /* skid constraint */
          mmap_data      : 1,   /* non-exec mmap data */
          sample_id_all  : 1,   /* sample_type all events */
          exclude_host   : 1,   /* don't count in host */
          exclude_guest  : 1,   /* don't count in guest */
          exclude_callchain_kernel : 1,
```

```
                            /* exclude kernel callchains */
        exclude_callchain_user   : 1,
                            /* exclude user callchains */
        mmap2          :  1,  /* include mmap with inode data */
        comm_exec      :  1,  /* flag comm events that are
                                 due to exec */
        use_clockid    :  1,  /* use clockid for time fields */
        context_switch :  1,  /* context switch data */
        write_backward :  1,  /* Write ring buffer from end
                                 to beginning */
        namespaces     :  1,  /* include namespaces data */
        ksymbol        :  1,  /* include ksymbol events */
        bpf_event      :  1,  /* include bpf events */
        aux_output     :  1,  /* generate AUX records
                                 instead of events */
        cgroup         :  1,  /* include cgroup events */
        text_poke      :  1,  /* include text poke events */
        build_id       :  1,  /* use build id in mmap2 events */
        inherit_thread :  1,  /* children only inherit */
                            /* if cloned with CLONE_THREAD */
        remove_on_exec :  1,  /* event is removed from task
                                 on exec */
        sigtrap        :  1,  /* send synchronous SIGTRAP
                                 on event */

        __reserved_1   : 26;

    union {
        __u32 wakeup_events;    /* wakeup every n events */
        __u32 wakeup_watermark; /* bytes before wakeup */
    };

    __u32     bp_type;          /* breakpoint type */

    union {
        __u64 bp_addr;          /* breakpoint address */
        __u64 kprobe_func;      /* for perf_kprobe */
        __u64 uprobe_path;      /* for perf_uprobe */
        __u64 config1;          /* extension of config */
    };

    union {
        __u64 bp_len;           /* breakpoint length */
        __u64 kprobe_addr;      /* with kprobe_func == NULL */
        __u64 probe_offset;     /* for perf_[k,u]probe */
        __u64 config2;          /* extension of config1 */
    };
    __u64 branch_sample_type;   /* enum perf_branch_sample_type */
    __u64 sample_regs_user;     /* user regs to dump on samples */
    __u32 sample_stack_user;    /* size of stack to dump on
                                   samples */
    __s32 clockid;              /* clock to use for time fields */
    __u64 sample_regs_intr;     /* regs to dump on samples */
    __u32 aux_watermark;        /* aux bytes before wakeup */
    __u16 sample_max_stack;     /* max frames in callchain */
    __u16 __reserved_2;         /* align to u64 */
    __u32 aux_sample_size;      /* max aux sample size */
    __u32 __reserved_3;         /* align to u64 */
    __u64 sig_data;             /* user data for sigtrap */
```

```
};
```

The fields of the *perf_event_attr* structure are described in more detail below:

type This field specifies the overall event type. It has one of the following values:

PERF_TYPE_HARDWARE
This indicates one of the "generalized" hardware events provided by the kernel. See the *config* field definition for more details.

PERF_TYPE_SOFTWARE
This indicates one of the software-defined events provided by the kernel (even if no hardware support is available).

PERF_TYPE_TRACEPOINT
This indicates a tracepoint provided by the kernel tracepoint infrastructure.

PERF_TYPE_HW_CACHE
This indicates a hardware cache event. This has a special encoding, described in the *config* field definition.

PERF_TYPE_RAW
This indicates a "raw" implementation-specific event in the *config* field.

PERF_TYPE_BREAKPOINT (since Linux 2.6.33)
This indicates a hardware breakpoint as provided by the CPU. Breakpoints can be read/write accesses to an address as well as execution of an instruction address.

dynamic PMU
Since Linux 2.6.38, **perf_event_open**() can support multiple PMUs. To enable this, a value exported by the kernel can be used in the *type* field to indicate which PMU to use. The value to use can be found in the sysfs filesystem: there is a subdirectory per PMU instance under */sys/bus/event_source/devices*. In each subdirectory there is a *type* file whose content is an integer that can be used in the *type* field. For instance, */sys/bus/event_source/devices/cpu/type* contains the value for the core CPU PMU, which is usually 4.

kprobe and **uprobe** (since Linux 4.17)
These two dynamic PMUs create a kprobe/uprobe and attach it to the file descriptor generated by perf_event_open. The kprobe/uprobe will be destroyed on the destruction of the file descriptor. See fields *kprobe_func*, *uprobe_path*, *kprobe_addr*, and *probe_offset* for more details.

size The size of the *perf_event_attr* structure for forward/backward compatibility. Set this using *sizeof(struct perf_event_attr)* to allow the kernel to see the struct size at the time of compilation.

The related define **PERF_ATTR_SIZE_VER0** is set to 64; this was the size of the first published struct. **PERF_ATTR_SIZE_VER1** is 72, corresponding to the addition of breakpoints in Linux 2.6.33. **PERF_ATTR_SIZE_VER2** is 80 corresponding to the addition of branch sampling in Linux 3.4. **PERF_ATTR_SIZE_VER3** is 96 corresponding to the addition of *sample_regs_user* and *sample_stack_user* in Linux 3.7. **PERF_ATTR_SIZE_VER4** is 104 corresponding to the addition of *sample_regs_intr* in Linux 3.19. **PERF_ATTR_SIZE_VER5** is 112 corresponding to the addition of *aux_watermark* in Linux 4.1.

config This specifies which event you want, in conjunction with the *type* field. The *config1* and *config2* fields are also taken into account in cases where 64 bits is not enough to fully specify the event. The encoding of these fields are event dependent.

There are various ways to set the *config* field that are dependent on the value of the previously described *type* field. What follows are various possible settings for *config* separated out by *type*.

If *type* is **PERF_TYPE_HARDWARE**, we are measuring one of the generalized hardware CPU events. Not all of these are available on all platforms. Set *config* to one of the following:

PERF_COUNT_HW_CPU_CYCLES
Total cycles. Be wary of what happens during CPU frequency scaling.

PERF_COUNT_HW_INSTRUCTIONS
Retired instructions. Be careful, these can be affected by various issues, most notably hardware interrupt counts.

PERF_COUNT_HW_CACHE_REFERENCES
Cache accesses. Usually this indicates Last Level Cache accesses but this may vary depending on your CPU. This may include prefetches and coherency messages; again this depends on the design of your CPU.

PERF_COUNT_HW_CACHE_MISSES
Cache misses. Usually this indicates Last Level Cache misses; this is intended to be used in conjunction with the **PERF_COUNT_HW_CACHE_REFERENCES** event to calculate cache miss rates.

PERF_COUNT_HW_BRANCH_INSTRUCTIONS
Retired branch instructions. Prior to Linux 2.6.35, this used the wrong event on AMD processors.

PERF_COUNT_HW_BRANCH_MISSES
Mispredicted branch instructions.

PERF_COUNT_HW_BUS_CYCLES
Bus cycles, which can be different from total cycles.

PERF_COUNT_HW_STALLED_CYCLES_FRONTEND (since Linux 3.0)
Stalled cycles during issue.

PERF_COUNT_HW_STALLED_CYCLES_BACKEND (since Linux 3.0)
Stalled cycles during retirement.

PERF_COUNT_HW_REF_CPU_CYCLES (since Linux 3.3)
Total cycles; not affected by CPU frequency scaling.

If *type* is **PERF_TYPE_SOFTWARE**, we are measuring software events provided by the kernel. Set *config* to one of the following:

PERF_COUNT_SW_CPU_CLOCK
This reports the CPU clock, a high-resolution per-CPU timer.

PERF_COUNT_SW_TASK_CLOCK
This reports a clock count specific to the task that is running.

PERF_COUNT_SW_PAGE_FAULTS
This reports the number of page faults.

PERF_COUNT_SW_CONTEXT_SWITCHES
This counts context switches. Until Linux 2.6.34, these were all reported as user-space events, after that they are reported as happening in the kernel.

PERF_COUNT_SW_CPU_MIGRATIONS
This reports the number of times the process has migrated to a new CPU.

PERF_COUNT_SW_PAGE_FAULTS_MIN
This counts the number of minor page faults. These did not require disk I/O to handle.

PERF_COUNT_SW_PAGE_FAULTS_MAJ
This counts the number of major page faults. These required disk I/O to handle.

PERF_COUNT_SW_ALIGNMENT_FAULTS (since Linux 2.6.33)
This counts the number of alignment faults. These happen when unaligned memory accesses happen; the kernel can handle these but it reduces performance. This happens only on some architectures (never on x86).

PERF_COUNT_SW_EMULATION_FAULTS (since Linux 2.6.33)
This counts the number of emulation faults. The kernel sometimes traps on unimplemented instructions and emulates them for user space. This can negatively impact performance.

PERF_COUNT_SW_DUMMY (since Linux 3.12)
This is a placeholder event that counts nothing. Informational sample record types such as mmap or comm must be associated with an active event. This dummy event allows gathering such records without requiring a counting event.

PERF_COUNT_SW_BPF_OUTPUT (since Linux 4.4)
This is used to generate raw sample data from BPF. BPF programs can write to this event using **bpf_perf_event_output** helper.

PERF_COUNT_SW_CGROUP_SWITCHES (since Linux 5.13)
This counts context switches to a task in a different cgroup. In other words, if the next task is in the same cgroup, it won't count the switch.

If *type* is **PERF_TYPE_TRACEPOINT**, then we are measuring kernel tracepoints. The value to use in *config* can be obtained from under debugfs *tracing/events/*/*/id* if ftrace is enabled in the kernel.

If *type* is **PERF_TYPE_HW_CACHE**, then we are measuring a hardware CPU cache event. To calculate the appropriate *config* value, use the following equation:

```
config = (perf_hw_cache_id) |
         (perf_hw_cache_op_id << 8) |
         (perf_hw_cache_op_result_id << 16);
```

where *perf_hw_cache_id* is one of:

PERF_COUNT_HW_CACHE_L1D
for measuring Level 1 Data Cache

PERF_COUNT_HW_CACHE_L1I
for measuring Level 1 Instruction Cache

PERF_COUNT_HW_CACHE_LL
for measuring Last-Level Cache

PERF_COUNT_HW_CACHE_DTLB
for measuring the Data TLB

PERF_COUNT_HW_CACHE_ITLB
for measuring the Instruction TLB

PERF_COUNT_HW_CACHE_BPU
for measuring the branch prediction unit

PERF_COUNT_HW_CACHE_NODE (since Linux 3.1)
for measuring local memory accesses

and *perf_hw_cache_op_id* is one of:

PERF_COUNT_HW_CACHE_OP_READ
for read accesses

PERF_COUNT_HW_CACHE_OP_WRITE
for write accesses

PERF_COUNT_HW_CACHE_OP_PREFETCH
for prefetch accesses

and *perf_hw_cache_op_result_id* is one of:

PERF_COUNT_HW_CACHE_RESULT_ACCESS
to measure accesses

PERF_COUNT_HW_CACHE_RESULT_MISS
to measure misses

If *type* is **PERF_TYPE_RAW**, then a custom "raw" *config* value is needed. Most CPUs

support events that are not covered by the "generalized" events. These are implementation defined; see your CPU manual (for example the Intel Volume 3B documentation or the AMD BIOS and Kernel Developer Guide). The libpfm4 library can be used to translate from the name in the architectural manuals to the raw hex value **perf_event_open**() expects in this field.

If *type* is **PERF_TYPE_BREAKPOINT**, then leave *config* set to zero. Its parameters are set in other places.

If *type* is **kprobe** or **uprobe**, set *retprobe* (bit 0 of *config*, see */sys/bus/event_source/devices/[k,u]probe/format/retprobe*) for kretprobe/uretprobe. See fields *kprobe_func*, *uprobe_path*, *kprobe_addr*, and *probe_offset* for more details.

kprobe_func
uprobe_path
kprobe_addr
probe_offset
: These fields describe the kprobe/uprobe for dynamic PMUs **kprobe** and **uprobe**. For **kprobe**: use *kprobe_func* and *probe_offset*, or use *kprobe_addr* and leave *kprobe_func* as NULL. For **uprobe**: use *uprobe_path* and *probe_offset*.

sample_period
sample_freq
: A "sampling" event is one that generates an overflow notification every N events, where N is given by *sample_period*. A sampling event has *sample_period* > 0. When an overflow occurs, requested data is recorded in the mmap buffer. The *sample_type* field controls what data is recorded on each overflow.

sample_freq can be used if you wish to use frequency rather than period. In this case, you set the *freq* flag. The kernel will adjust the sampling period to try and achieve the desired rate. The rate of adjustment is a timer tick.

sample_type
: The various bits in this field specify which values to include in the sample. They will be recorded in a ring-buffer, which is available to user space using *mmap*(2). The order in which the values are saved in the sample are documented in the MMAP Layout subsection below; it is not the *enum perf_event_sample_format* order.

PERF_SAMPLE_IP
: Records instruction pointer.

PERF_SAMPLE_TID
: Records the process and thread IDs.

PERF_SAMPLE_TIME
: Records a timestamp.

PERF_SAMPLE_ADDR
: Records an address, if applicable.

PERF_SAMPLE_READ
: Record counter values for all events in a group, not just the group leader.

PERF_SAMPLE_CALLCHAIN
: Records the callchain (stack backtrace).

PERF_SAMPLE_ID
: Records a unique ID for the opened event's group leader.

PERF_SAMPLE_CPU
: Records CPU number.

PERF_SAMPLE_PERIOD
: Records the current sampling period.

PERF_SAMPLE_STREAM_ID
: Records a unique ID for the opened event. Unlike **PERF_SAMPLE_ID** the actual ID is returned, not the group leader. This ID is the same as the one returned by

PERF_FORMAT_ID.

PERF_SAMPLE_RAW
Records additional data, if applicable. Usually returned by tracepoint events.

PERF_SAMPLE_BRANCH_STACK (since Linux 3.4)
This provides a record of recent branches, as provided by CPU branch sampling hardware (such as Intel Last Branch Record). Not all hardware supports this feature.

See the *branch_sample_type* field for how to filter which branches are reported.

PERF_SAMPLE_REGS_USER (since Linux 3.7)
Records the current user-level CPU register state (the values in the process before the kernel was called).

PERF_SAMPLE_STACK_USER (since Linux 3.7)
Records the user level stack, allowing stack unwinding.

PERF_SAMPLE_WEIGHT (since Linux 3.10)
Records a hardware provided weight value that expresses how costly the sampled event was. This allows the hardware to highlight expensive events in a profile.

PERF_SAMPLE_DATA_SRC (since Linux 3.10)
Records the data source: where in the memory hierarchy the data associated with the sampled instruction came from. This is available only if the underlying hardware supports this feature.

PERF_SAMPLE_IDENTIFIER (since Linux 3.12)
Places the **SAMPLE_ID** value in a fixed position in the record, either at the beginning (for sample events) or at the end (if a non-sample event).

This was necessary because a sample stream may have records from various different event sources with different *sample_type* settings. Parsing the event stream properly was not possible because the format of the record was needed to find **SAMPLE_ID**, but the format could not be found without knowing what event the sample belonged to (causing a circular dependency).

The **PERF_SAMPLE_IDENTIFIER** setting makes the event stream always parsable by putting **SAMPLE_ID** in a fixed location, even though it means having duplicate **SAMPLE_ID** values in records.

PERF_SAMPLE_TRANSACTION (since Linux 3.13)
Records reasons for transactional memory abort events (for example, from Intel TSX transactional memory support).

The *precise_ip* setting must be greater than 0 and a transactional memory abort event must be measured or no values will be recorded. Also note that some perf_event measurements, such as sampled cycle counting, may cause extraneous aborts (by causing an interrupt during a transaction).

PERF_SAMPLE_REGS_INTR (since Linux 3.19)
Records a subset of the current CPU register state as specified by *sample_regs_intr*. Unlike **PERF_SAMPLE_REGS_USER** the register values will return kernel register state if the overflow happened while kernel code is running. If the CPU supports hardware sampling of register state (i.e., PEBS on Intel x86) and *precise_ip* is set higher than zero then the register values returned are those captured by hardware at the time of the sampled instruction's retirement.

PERF_SAMPLE_PHYS_ADDR (since Linux 4.13)
Records physical address of data like in **PERF_SAMPLE_ADDR**.

PERF_SAMPLE_CGROUP (since Linux 5.7)
Records (perf_event) cgroup ID of the process. This corresponds to the *id* field in the **PERF_RECORD_CGROUP** event.

PERF_SAMPLE_DATA_PAGE_SIZE (since Linux 5.11)
Records page size of data like in **PERF_SAMPLE_ADDR**.

PERF_SAMPLE_CODE_PAGE_SIZE (since Linux 5.11)
Records page size of ip like in **PERF_SAMPLE_IP**.

PERF_SAMPLE_WEIGHT_STRUCT (since Linux 5.12)
Records hardware provided weight values like in **PERF_SAMPLE_WEIGHT**, but it can represent multiple values in a struct. This shares the same space as **PERF_SAMPLE_WEIGHT**, so users can apply either of those, not both. It has the following format and the meaning of each field is dependent on the hardware implementation.

```
union perf_sample_weight {
    u64  full;           /* PERF_SAMPLE_WEIGHT */
    struct {             /* PERF_SAMPLE_WEIGHT_STRUCT */
        u32  var1_dw;
        u16  var2_w;
        u16  var3_w;
    };
};
```

read_format
This field specifies the format of the data returned by *read*(2) on a **perf_event_open**() file descriptor.

PERF_FORMAT_TOTAL_TIME_ENABLED
Adds the 64-bit *time_enabled* field. This can be used to calculate estimated totals if the PMU is overcommitted and multiplexing is happening.

PERF_FORMAT_TOTAL_TIME_RUNNING
Adds the 64-bit *time_running* field. This can be used to calculate estimated totals if the PMU is overcommitted and multiplexing is happening.

PERF_FORMAT_ID
Adds a 64-bit unique value that corresponds to the event group.

PERF_FORMAT_GROUP
Allows all counter values in an event group to be read with one read.

PERF_FORMAT_LOST (since Linux 6.0)
Adds a 64-bit value that is the number of lost samples for this event. This would be only meaningful when *sample_period* or *sample_freq* is set.

disabled
The *disabled* bit specifies whether the counter starts out disabled or enabled. If disabled, the event can later be enabled by *ioctl*(2), *prctl*(2), or *enable_on_exec*.

When creating an event group, typically the group leader is initialized with *disabled* set to 1 and any child events are initialized with *disabled* set to 0. Despite *disabled* being 0, the child events will not start until the group leader is enabled.

inherit The *inherit* bit specifies that this counter should count events of child tasks as well as the task specified. This applies only to new children, not to any existing children at the time the counter is created (nor to any new children of existing children).

Inherit does not work for some combinations of *read_format* values, such as **PERF_FORMAT_GROUP**.

pinned The *pinned* bit specifies that the counter should always be on the CPU if at all possible. It applies only to hardware counters and only to group leaders. If a pinned counter cannot be put onto the CPU (e.g., because there are not enough hardware counters or because of a conflict with some other event), then the counter goes into an 'error' state, where reads return end-of-file (i.e., *read*(2) returns 0) until the counter is subsequently enabled or disabled.

exclusive
The *exclusive* bit specifies that when this counter's group is on the CPU, it should be the only group using the CPU's counters. In the future this may allow monitoring programs to support PMU features that need to run alone so that they do not disrupt other hardware counters.

Note that many unexpected situations may prevent events with the *exclusive* bit set from ever running. This includes any users running a system-wide measurement as well as any kernel use of the performance counters (including the commonly enabled NMI Watchdog Timer interface).

exclude_user
If this bit is set, the count excludes events that happen in user space.

exclude_kernel
If this bit is set, the count excludes events that happen in kernel space.

exclude_hv
If this bit is set, the count excludes events that happen in the hypervisor. This is mainly for PMUs that have built-in support for handling this (such as POWER). Extra support is needed for handling hypervisor measurements on most machines.

exclude_idle
If set, don't count when the CPU is running the idle task. While you can currently enable this for any event type, it is ignored for all but software events.

mmap The *mmap* bit enables generation of **PERF_RECORD_MMAP** samples for every *mmap*(2) call that has **PROT_EXEC** set. This allows tools to notice new executable code being mapped into a program (dynamic shared libraries for example) so that addresses can be mapped back to the original code.

comm The *comm* bit enables tracking of process command name as modified by the *execve*(2) and *prctl*(PR_SET_NAME) system calls as well as writing to */proc/self/comm*. If the *comm_exec* flag is also successfully set (possible since Linux 3.16), then the misc flag **PERF_RECORD_MISC_COMM_EXEC** can be used to differentiate the *execve*(2) case from the others.

freq If this bit is set, then *sample_frequency* not *sample_period* is used when setting up the sampling interval.

inherit_stat
This bit enables saving of event counts on context switch for inherited tasks. This is meaningful only if the *inherit* field is set.

enable_on_exec
If this bit is set, a counter is automatically enabled after a call to *execve*(2).

task If this bit is set, then fork/exit notifications are included in the ring buffer.

watermark
If set, have an overflow notification happen when we cross the *wakeup_watermark* boundary. Otherwise, overflow notifications happen after *wakeup_events* samples.

precise_ip (since Linux 2.6.35)
This controls the amount of skid. Skid is how many instructions execute between an event of interest happening and the kernel being able to stop and record the event. Smaller skid is better and allows more accurate reporting of which events correspond to which instructions, but hardware is often limited with how small this can be.

The possible values of this field are the following:

0 **SAMPLE_IP** can have arbitrary skid.

1 **SAMPLE_IP** must have constant skid.

2 **SAMPLE_IP** requested to have 0 skid.

3 **SAMPLE_IP** must have 0 skid. See also the description of **PERF_RECORD_MISC_EXACT_IP**.

mmap_data (since Linux 2.6.36)
This is the counterpart of the *mmap* field. This enables generation of **PERF_RECORD_MMAP** samples for *mmap*(2) calls that do not have **PROT_EXEC** set (for example data and SysV shared memory).

sample_id_all (since Linux 2.6.38)
: If set, then TID, TIME, ID, STREAM_ID, and CPU can additionally be included in non-**PERF_RECORD_SAMPLE**s if the corresponding *sample_type* is selected.

  If **PERF_SAMPLE_IDENTIFIER** is specified, then an additional ID value is included as the last value to ease parsing the record stream. This may lead to the *id* value appearing twice.

  The layout is described by this pseudo-structure:

```
struct sample_id {
    { u32 pid, tid; }   /* if PERF_SAMPLE_TID set */
    { u64 time;     }   /* if PERF_SAMPLE_TIME set */
    { u64 id;       }   /* if PERF_SAMPLE_ID set */
    { u64 stream_id;}   /* if PERF_SAMPLE_STREAM_ID set  */
    { u32 cpu, res; }   /* if PERF_SAMPLE_CPU set */
    { u64 id;       }   /* if PERF_SAMPLE_IDENTIFIER set */
};
```

exclude_host (since Linux 3.2)
: When conducting measurements that include processes running VM instances (i.e., have executed a **KVM_RUN** *ioctl*(2)), only measure events happening inside a guest instance. This is only meaningful outside the guests; this setting does not change counts gathered inside of a guest. Currently, this functionality is x86 only.

exclude_guest (since Linux 3.2)
: When conducting measurements that include processes running VM instances (i.e., have executed a **KVM_RUN** *ioctl*(2)), do not measure events happening inside guest instances. This is only meaningful outside the guests; this setting does not change counts gathered inside of a guest. Currently, this functionality is x86 only.

exclude_callchain_kernel (since Linux 3.7)
: Do not include kernel callchains.

exclude_callchain_user (since Linux 3.7)
: Do not include user callchains.

mmap2 (since Linux 3.16)
: Generate an extended executable mmap record that contains enough additional information to uniquely identify shared mappings. The *mmap* flag must also be set for this to work.

comm_exec (since Linux 3.16)
: This is purely a feature-detection flag, it does not change kernel behavior. If this flag can successfully be set, then, when *comm* is enabled, the **PERF_RECORD_MISC_COMM_EXEC** flag will be set in the *misc* field of a comm record header if the rename event being reported was caused by a call to *execve*(2). This allows tools to distinguish between the various types of process renaming.

use_clockid (since Linux 4.1)
: This allows selecting which internal Linux clock to use when generating timestamps via the *clockid* field. This can make it easier to correlate perf sample times with timestamps generated by other tools.

context_switch (since Linux 4.3)
: This enables the generation of **PERF_RECORD_SWITCH** records when a context switch occurs. It also enables the generation of **PERF_RECORD_SWITCH_CPU_WIDE** records when sampling in CPU-wide mode. This functionality is in addition to existing tracepoint and software events for measuring context switches. The advantage of this method is that it will give full information even with strict *perf_event_paranoid* settings.

write_backward (since Linux 4.6)
: This causes the ring buffer to be written from the end to the beginning. This is to support reading from overwritable ring buffer.

namespaces (since Linux 4.11)
: This enables the generation of **PERF_RECORD_NAMESPACES** records when a task enters a new namespace. Each namespace has a combination of device and inode numbers.

ksymbol (since Linux 5.0)
This enables the generation of **PERF_RECORD_KSYMBOL** records when new kernel symbols are registered or unregistered. This is analyzing dynamic kernel functions like eBPF.

bpf_event (since Linux 5.0)
This enables the generation of **PERF_RECORD_BPF_EVENT** records when an eBPF program is loaded or unloaded.

aux_output (since Linux 5.4)
This allows normal (non-AUX) events to generate data for AUX events if the hardware supports it.

cgroup (since Linux 5.7)
This enables the generation of **PERF_RECORD_CGROUP** records when a new cgroup is created (and activated).

text_poke (since Linux 5.8)
This enables the generation of **PERF_RECORD_TEXT_POKE** records when there's a change to the kernel text (i.e., self-modifying code).

build_id (since Linux 5.12)
This changes the contents in the **PERF_RECORD_MMAP2** to have a build-id instead of device and inode numbers.

inherit_thread (since Linux 5.13)
This disables the inheritance of the event to a child process. Only new threads in the same process (which is cloned with **CLONE_THREAD**) will inherit the event.

remove_on_exec (since Linux 5.13)
This closes the event when it starts a new process image by *execve*(2).

sigtrap (since Linux 5.13)
This enables synchronous signal delivery of **SIGTRAP** on event overflow.

wakeup_events
wakeup_watermark
This union sets how many samples (*wakeup_events*) or bytes (*wakeup_watermark*) happen before an overflow notification happens. Which one is used is selected by the *watermark* bit flag.

wakeup_events counts only **PERF_RECORD_SAMPLE** record types. To receive overflow notification for all **PERF_RECORD** types choose watermark and set *wakeup_watermark* to 1.

Prior to Linux 3.0, setting *wakeup_events* to 0 resulted in no overflow notifications; more recent kernels treat 0 the same as 1.

bp_type (since Linux 2.6.33)
This chooses the breakpoint type. It is one of:

HW_BREAKPOINT_EMPTY
No breakpoint.

HW_BREAKPOINT_R
Count when we read the memory location.

HW_BREAKPOINT_W
Count when we write the memory location.

HW_BREAKPOINT_RW
Count when we read or write the memory location.

HW_BREAKPOINT_X
Count when we execute code at the memory location.

The values can be combined via a bitwise or, but the combination of **HW_BREAKPOINT_R** or **HW_BREAKPOINT_W** with **HW_BREAKPOINT_X** is not allowed.

bp_addr (since Linux 2.6.33)
This is the address of the breakpoint. For execution breakpoints, this is the memory address of the instruction of interest; for read and write breakpoints, it is the memory address of the memory location of interest.

config1 (since Linux 2.6.39)
config1 is used for setting events that need an extra register or otherwise do not fit in the regular config field. Raw OFFCORE_EVENTS on Nehalem/Westmere/SandyBridge use this field on Linux 3.3 and later kernels.

bp_len (since Linux 2.6.33)
bp_len is the length of the breakpoint being measured if *type* is **PERF_TYPE_BREAKPOINT**. Options are **HW_BREAKPOINT_LEN_1**, **HW_BREAKPOINT_LEN_2**, **HW_BREAKPOINT_LEN_4**, and **HW_BREAKPOINT_LEN_8**. For an execution breakpoint, set this to *sizeof(long)*.

config2 (since Linux 2.6.39)
config2 is a further extension of the *config1* field.

branch_sample_type (since Linux 3.4)
If **PERF_SAMPLE_BRANCH_STACK** is enabled, then this specifies what branches to include in the branch record.

The first part of the value is the privilege level, which is a combination of one of the values listed below. If the user does not set privilege level explicitly, the kernel will use the event's privilege level. Event and branch privilege levels do not have to match.

PERF_SAMPLE_BRANCH_USER
Branch target is in user space.

PERF_SAMPLE_BRANCH_KERNEL
Branch target is in kernel space.

PERF_SAMPLE_BRANCH_HV
Branch target is in hypervisor.

PERF_SAMPLE_BRANCH_PLM_ALL
A convenience value that is the three preceding values ORed together.

In addition to the privilege value, at least one or more of the following bits must be set.

PERF_SAMPLE_BRANCH_ANY
Any branch type.

PERF_SAMPLE_BRANCH_ANY_CALL
Any call branch (includes direct calls, indirect calls, and far jumps).

PERF_SAMPLE_BRANCH_IND_CALL
Indirect calls.

PERF_SAMPLE_BRANCH_CALL (since Linux 4.4)
Direct calls.

PERF_SAMPLE_BRANCH_ANY_RETURN
Any return branch.

PERF_SAMPLE_BRANCH_IND_JUMP (since Linux 4.2)
Indirect jumps.

PERF_SAMPLE_BRANCH_COND (since Linux 3.16)
Conditional branches.

PERF_SAMPLE_BRANCH_ABORT_TX (since Linux 3.11)
Transactional memory aborts.

PERF_SAMPLE_BRANCH_IN_TX (since Linux 3.11)
Branch in transactional memory transaction.

PERF_SAMPLE_BRANCH_NO_TX (since Linux 3.11)
Branch not in transactional memory transaction. **PERF_SAMPLE_BRANCH_CALL_STACK** (since Linux 4.1) Branch is part of a hardware-

generated call stack. This requires hardware support, currently only found on Intel x86 Haswell or newer.

sample_regs_user (since Linux 3.7)
This bit mask defines the set of user CPU registers to dump on samples. The layout of the register mask is architecture-specific and is described in the kernel header file *arch/ARCH/include/uapi/asm/perf_regs.h*.

sample_stack_user (since Linux 3.7)
This defines the size of the user stack to dump if **PERF_SAMPLE_STACK_USER** is specified.

clockid (since Linux 4.1)
If *use_clockid* is set, then this field selects which internal Linux timer to use for timestamps. The available timers are defined in *linux/time.h*, with **CLOCK_MONOTONIC**, **CLOCK_MONOTONIC_RAW**, **CLOCK_REALTIME**, **CLOCK_BOOTTIME**, and **CLOCK_TAI** currently supported.

aux_watermark (since Linux 4.1)
This specifies how much data is required to trigger a **PERF_RECORD_AUX** sample.

sample_max_stack (since Linux 4.8)
When *sample_type* includes **PERF_SAMPLE_CALLCHAIN**, this field specifies how many stack frames to report when generating the callchain.

aux_sample_size (since Linux 5.5)
When **PERF_SAMPLE_AUX** flag is set, specify the desired size of AUX data. Note that it can get smaller data than the specified size.

sig_data (since Linux 5.13)
This data will be copied to user's signal handler (through *si_perf* in the *siginfo_t*) to disambiguate which event triggered the signal.

Reading results

Once a **perf_event_open**() file descriptor has been opened, the values of the events can be read from the file descriptor. The values that are there are specified by the *read_format* field in the *attr* structure at open time.

If you attempt to read into a buffer that is not big enough to hold the data, the error **ENOSPC** results.

Here is the layout of the data returned by a read:

- If **PERF_FORMAT_GROUP** was specified to allow reading all events in a group at once:

```
struct read_format {
    u64 nr;            /* The number of events */
    u64 time_enabled;  /* if PERF_FORMAT_TOTAL_TIME_ENABLED */
    u64 time_running;  /* if PERF_FORMAT_TOTAL_TIME_RUNNING */
    struct {
        u64 value;     /* The value of the event */
        u64 id;        /* if PERF_FORMAT_ID */
        u64 lost;      /* if PERF_FORMAT_LOST */
    } values[nr];
};
```

- If **PERF_FORMAT_GROUP** was *not* specified:

```
struct read_format {
    u64 value;         /* The value of the event */
    u64 time_enabled;  /* if PERF_FORMAT_TOTAL_TIME_ENABLED */
    u64 time_running;  /* if PERF_FORMAT_TOTAL_TIME_RUNNING */
    u64 id;            /* if PERF_FORMAT_ID */
    u64 lost;          /* if PERF_FORMAT_LOST */
};
```

The values read are as follows:

nr The number of events in this file descriptor. Available only if **PERF_FORMAT_GROUP** was specified.

time_enabled
time_running
Total time the event was enabled and running. Normally these values are the same. Multiplexing happens if the number of events is more than the number of available PMU counter slots. In that case the events run only part of the time and the *time_enabled* and *time running* values can be used to scale an estimated value for the count.

value An unsigned 64-bit value containing the counter result.

id A globally unique value for this particular event; only present if **PERF_FORMAT_ID** was specified in *read_format*.

lost The number of lost samples of this event; only present if **PERF_FORMAT_LOST** was specified in *read_format*.

MMAP layout

When using **perf_event_open**() in sampled mode, asynchronous events (like counter overflow or **PROT_EXEC** mmap tracking) are logged into a ring-buffer. This ring-buffer is created and accessed through *mmap*(2).

The mmap size should be 1+2^n pages, where the first page is a metadata page (*struct perf_event_mmap_page*) that contains various bits of information such as where the ring-buffer head is.

Before Linux 2.6.39, there is a bug that means you must allocate an mmap ring buffer when sampling even if you do not plan to access it.

The structure of the first metadata mmap page is as follows:

```
struct perf_event_mmap_page {
    __u32 version;        /* version number of this structure */
    __u32 compat_version; /* lowest version this is compat with */
    __u32 lock;           /* seqlock for synchronization */
    __u32 index;          /* hardware counter identifier */
    __s64 offset;         /* add to hardware counter value */
    __u64 time_enabled;   /* time event active */
    __u64 time_running;   /* time event on CPU */
    union {
        __u64   capabilities;
        struct {
            __u64 cap_usr_time / cap_usr_rdpmc / cap_bit0 : 1,
                  cap_bit0_is_deprecated : 1,
                  cap_user_rdpmc         : 1,
                  cap_user_time          : 1,
                  cap_user_time_zero     : 1,
        };
    };
    __u16 pmc_width;
    __u16 time_shift;
    __u32 time_mult;
    __u64 time_offset;
    __u64 __reserved[120];   /* Pad to 1 k */
    __u64 data_head;         /* head in the data section */
    __u64 data_tail;         /* user-space written tail */
    __u64 data_offset;       /* where the buffer starts */
    __u64 data_size;         /* data buffer size */
    __u64 aux_head;
    __u64 aux_tail;
    __u64 aux_offset;
    __u64 aux_size;

}
```

The following list describes the fields in the *perf_event_mmap_page* structure in more detail:

version Version number of this structure.

compat_version
The lowest version this is compatible with.

lock A seqlock for synchronization.

index A unique hardware counter identifier.

offset When using rdpmc for reads this offset value must be added to the one returned by rdpmc to get the current total event count.

time_enabled
Time the event was active.

time_running
Time the event was running.

cap_usr_time / *cap_usr_rdpmc* / *cap_bit0* (since Linux 3.4)
There was a bug in the definition of *cap_usr_time* and *cap_usr_rdpmc* from Linux 3.4 until Linux 3.11. Both bits were defined to point to the same location, so it was impossible to know if *cap_usr_time* or *cap_usr_rdpmc* were actually set.

Starting with Linux 3.12, these are renamed to *cap_bit0* and you should use the *cap_user_time* and *cap_user_rdpmc* fields instead.

cap_bit0_is_deprecated (since Linux 3.12)
If set, this bit indicates that the kernel supports the properly separated *cap_user_time* and *cap_user_rdpmc* bits.

If not-set, it indicates an older kernel where *cap_usr_time* and *cap_usr_rdpmc* map to the same bit and thus both features should be used with caution.

cap_user_rdpmc (since Linux 3.12)
If the hardware supports user-space read of performance counters without syscall (this is the "rdpmc" instruction on x86), then the following code can be used to do a read:

```
u32 seq, time_mult, time_shift, idx, width;
u64 count, enabled, running;
u64 cyc, time_offset;

do {
    seq = pc->lock;
    barrier();
    enabled = pc->time_enabled;
    running = pc->time_running;

    if (pc->cap_usr_time && enabled != running) {
        cyc = rdtsc();
        time_offset = pc->time_offset;
        time_mult   = pc->time_mult;
        time_shift  = pc->time_shift;
    }

    idx = pc->index;
    count = pc->offset;

    if (pc->cap_usr_rdpmc && idx) {
        width = pc->pmc_width;
        count += rdpmc(idx - 1);
    }

    barrier();
} while (pc->lock != seq);
```

cap_user_time (since Linux 3.12)
This bit indicates the hardware has a constant, nonstop timestamp counter (TSC on x86).

cap_user_time_zero (since Linux 3.12)
Indicates the presence of *time_zero* which allows mapping timestamp values to the hardware clock.

pmc_width
If *cap_usr_rdpmc*, this field provides the bit-width of the value read using the rdpmc or equivalent instruction. This can be used to sign extend the result like:

```
pmc <<= 64 - pmc_width;
pmc >>= 64 - pmc_width; // signed shift right
count += pmc;
```

time_shift
time_mult
time_offset

If *cap_usr_time*, these fields can be used to compute the time delta since *time_enabled* (in nanoseconds) using rdtsc or similar.

```
u64 quot, rem;
u64 delta;

quot  = cyc >> time_shift;
rem   = cyc & (((u64)1 << time_shift) - 1);
delta = time_offset + quot * time_mult +
        ((rem * time_mult) >> time_shift);
```

Where *time_offset*, *time_mult*, *time_shift*, and *cyc* are read in the seqcount loop described above. This delta can then be added to enabled and possible running (if idx), improving the scaling:

```
enabled += delta;
if (idx)
    running += delta;
quot  = count / running;
rem   = count % running;
count = quot * enabled + (rem * enabled) / running;
```

time_zero (since Linux 3.12)

If *cap_usr_time_zero* is set, then the hardware clock (the TSC timestamp counter on x86) can be calculated from the *time_zero*, *time_mult*, and *time_shift* values:

```
time = timestamp - time_zero;
quot = time / time_mult;
rem  = time % time_mult;
cyc  = (quot << time_shift) + (rem << time_shift) / time_mult;
```

And vice versa:

```
quot = cyc >> time_shift;
rem  = cyc & (((u64)1 << time_shift) - 1);
timestamp = time_zero + quot * time_mult +
            ((rem * time_mult) >> time_shift);
```

data_head
This points to the head of the data section. The value continuously increases, it does not wrap. The value needs to be manually wrapped by the size of the mmap buffer before accessing the samples.

On SMP-capable platforms, after reading the *data_head* value, user space should issue an rmb().

data_tail
: When the mapping is **PROT_WRITE**, the *data_tail* value should be written by user space to reflect the last read data. In this case, the kernel will not overwrite unread data.

data_offset (since Linux 4.1)
: Contains the offset of the location in the mmap buffer where perf sample data begins.

data_size (since Linux 4.1)
: Contains the size of the perf sample region within the mmap buffer.

aux_head
aux_tail
aux_offset
aux_size (since Linux 4.1)
: The AUX region allows *mmap*(2)-ing a separate sample buffer for high-bandwidth data streams (separate from the main perf sample buffer). An example of a high-bandwidth stream is instruction tracing support, as is found in newer Intel processors.

  To set up an AUX area, first *aux_offset* needs to be set with an offset greater than *data_offset+data_size* and *aux_size* needs to be set to the desired buffer size. The desired offset and size must be page aligned, and the size must be a power of two. These values are then passed to mmap in order to map the AUX buffer. Pages in the AUX buffer are included as part of the **RLIMIT_MEMLOCK** resource limit (see *setrlimit*(2)), and also as part of the *perf_event_mlock_kb* allowance.

  By default, the AUX buffer will be truncated if it will not fit in the available space in the ring buffer. If the AUX buffer is mapped as a read only buffer, then it will operate in ring buffer mode where old data will be overwritten by new. In overwrite mode, it might not be possible to infer where the new data began, and it is the consumer's job to disable measurement while reading to avoid possible data races.

  The *aux_head* and *aux_tail* ring buffer pointers have the same behavior and ordering rules as the previous described *data_head* and *data_tail*.

The following 2^n ring-buffer pages have the layout described below.

If *perf_event_attr.sample_id_all* is set, then all event types will have the sample_type selected fields related to where/when (identity) an event took place (TID, TIME, ID, CPU, STREAM_ID) described in **PERF_RECORD_SAMPLE** below, it will be stashed just after the *perf_event_header* and the fields already present for the existing fields, that is, at the end of the payload. This allows a newer perf.data file to be supported by older perf tools, with the new optional fields being ignored.

The mmap values start with a header:

```
struct perf_event_header {
    __u32   type;
    __u16   misc;
    __u16   size;
};
```

Below, we describe the *perf_event_header* fields in more detail. For ease of reading, the fields with shorter descriptions are presented first.

size This indicates the size of the record.

misc The *misc* field contains additional information about the sample.

The CPU mode can be determined from this value by masking with **PERF_RECORD_MISC_CPUMODE_MASK** and looking for one of the following (note these are not bit masks, only one can be set at a time):

PERF_RECORD_MISC_CPUMODE_UNKNOWN
: Unknown CPU mode.

PERF_RECORD_MISC_KERNEL
: Sample happened in the kernel.

PERF_RECORD_MISC_USER
Sample happened in user code.

PERF_RECORD_MISC_HYPERVISOR
Sample happened in the hypervisor.

PERF_RECORD_MISC_GUEST_KERNEL (since Linux 2.6.35)
Sample happened in the guest kernel.

PERF_RECORD_MISC_GUEST_USER (since Linux 2.6.35)
Sample happened in guest user code.

Since the following three statuses are generated by different record types, they alias to the same bit:

PERF_RECORD_MISC_MMAP_DATA (since Linux 3.10)
This is set when the mapping is not executable; otherwise the mapping is executable.

PERF_RECORD_MISC_COMM_EXEC (since Linux 3.16)
This is set for a **PERF_RECORD_COMM** record on kernels more recent than Linux 3.16 if a process name change was caused by an *execve*(2) system call.

PERF_RECORD_MISC_SWITCH_OUT (since Linux 4.3)
When a **PERF_RECORD_SWITCH** or **PERF_RECORD_SWITCH_CPU_WIDE** record is generated, this bit indicates that the context switch is away from the current process (instead of into the current process).

In addition, the following bits can be set:

PERF_RECORD_MISC_EXACT_IP
This indicates that the content of **PERF_SAMPLE_IP** points to the actual instruction that triggered the event. See also *perf_event_attr.precise_ip*.

PERF_RECORD_MISC_SWITCH_OUT_PREEMPT (since Linux 4.17)
When a **PERF_RECORD_SWITCH** or **PERF_RECORD_SWITCH_CPU_WIDE** record is generated, this indicates the context switch was a preemption.

PERF_RECORD_MISC_MMAP_BUILD_ID (since Linux 5.12)
This indicates that the content of **PERF_SAMPLE_MMAP2** contains build-ID data instead of device major and minor numbers as well as the inode number.

PERF_RECORD_MISC_EXT_RESERVED (since Linux 2.6.35)
This indicates there is extended data available (currently not used).

PERF_RECORD_MISC_PROC_MAP_PARSE_TIMEOUT
This bit is not set by the kernel. It is reserved for the user-space perf utility to indicate that */proc/*pid*/maps* parsing was taking too long and was stopped, and thus the mmap records may be truncated.

type The *type* value is one of the below. The values in the corresponding record (that follows the header) depend on the *type* selected as shown.

PERF_RECORD_MMAP
The MMAP events record the **PROT_EXEC** mappings so that we can correlate user-space IPs to code. They have the following structure:

```
struct {
    struct perf_event_header header;
    u32    pid, tid;
    u64    addr;
    u64    len;
    u64    pgoff;
    char   filename[];
};
```

pid is the process ID.

tid is the thread ID.

addr is the address of the allocated memory. *len* is the length of the allocated memory. *pgoff* is the page offset of the allocated memory. *filename* is a string describing the backing of the allocated memory.

PERF_RECORD_LOST

This record indicates when events are lost.

```
struct {
    struct perf_event_header header;
    u64    id;
    u64    lost;
    struct sample_id sample_id;
};
```

id is the unique event ID for the samples that were lost.

lost is the number of events that were lost.

PERF_RECORD_COMM

This record indicates a change in the process name.

```
struct {
    struct perf_event_header header;
    u32    pid;
    u32    tid;
    char   comm[];
    struct sample_id sample_id;
};
```

pid is the process ID.

tid is the thread ID.

comm is a string containing the new name of the process.

PERF_RECORD_EXIT

This record indicates a process exit event.

```
struct {
    struct perf_event_header header;
    u32    pid, ppid;
    u32    tid, ptid;
    u64    time;
    struct sample_id sample_id;
};
```

PERF_RECORD_THROTTLE
PERF_RECORD_UNTHROTTLE

This record indicates a throttle/unthrottle event.

```
struct {
    struct perf_event_header header;
    u64    time;
    u64    id;
    u64    stream_id;
    struct sample_id sample_id;
};
```

PERF_RECORD_FORK

This record indicates a fork event.

```
struct {
    struct perf_event_header header;
    u32    pid, ppid;
    u32    tid, ptid;
```

```
        u64    time;
        struct sample_id sample_id;
    };
```

PERF_RECORD_READ
This record indicates a read event.

```
    struct {
        struct perf_event_header header;
        u32    pid, tid;
        struct read_format values;
        struct sample_id sample_id;
    };
```

PERF_RECORD_SAMPLE
This record indicates a sample.

```
    struct {
        struct perf_event_header header;
        u64    sample_id;   /* if PERF_SAMPLE_IDENTIFIER */
        u64    ip;          /* if PERF_SAMPLE_IP */
        u32    pid, tid;    /* if PERF_SAMPLE_TID */
        u64    time;        /* if PERF_SAMPLE_TIME */
        u64    addr;        /* if PERF_SAMPLE_ADDR */
        u64    id;          /* if PERF_SAMPLE_ID */
        u64    stream_id;   /* if PERF_SAMPLE_STREAM_ID */
        u32    cpu, res;    /* if PERF_SAMPLE_CPU */
        u64    period;      /* if PERF_SAMPLE_PERIOD */
        struct read_format v;
                            /* if PERF_SAMPLE_READ */
        u64    nr;          /* if PERF_SAMPLE_CALLCHAIN */
        u64    ips[nr];     /* if PERF_SAMPLE_CALLCHAIN */
        u32    size;        /* if PERF_SAMPLE_RAW */
        char   data[size];  /* if PERF_SAMPLE_RAW */
        u64    bnr;         /* if PERF_SAMPLE_BRANCH_STACK */
        struct perf_branch_entry lbr[bnr];
                            /* if PERF_SAMPLE_BRANCH_STACK */
        u64    abi;         /* if PERF_SAMPLE_REGS_USER */
        u64    regs[weight(mask)];
                            /* if PERF_SAMPLE_REGS_USER */
        u64    size;        /* if PERF_SAMPLE_STACK_USER */
        char   data[size];  /* if PERF_SAMPLE_STACK_USER */
        u64    dyn_size;    /* if PERF_SAMPLE_STACK_USER &&
                               size != 0 */
        union perf_sample_weight weight;
                            /* if PERF_SAMPLE_WEIGHT */
                            /* || PERF_SAMPLE_WEIGHT_STRUCT */
        u64    data_src;    /* if PERF_SAMPLE_DATA_SRC */
        u64    transaction; /* if PERF_SAMPLE_TRANSACTION */
        u64    abi;         /* if PERF_SAMPLE_REGS_INTR */
        u64    regs[weight(mask)];
                            /* if PERF_SAMPLE_REGS_INTR */
        u64    phys_addr;   /* if PERF_SAMPLE_PHYS_ADDR */
        u64    cgroup;      /* if PERF_SAMPLE_CGROUP */
        u64    data_page_size;
                           /* if PERF_SAMPLE_DATA_PAGE_SIZE */
        u64    code_page_size;
                          /* if PERF_SAMPLE_CODE_PAGE_SIZE */
        u64    size;        /* if PERF_SAMPLE_AUX */
        char   data[size];  /* if PERF_SAMPLE_AUX */
    };
```

sample_id
: If **PERF_SAMPLE_IDENTIFIER** is enabled, a 64-bit unique ID is included. This is a duplication of the **PERF_SAMPLE_ID** *id* value, but included at the beginning of the sample so parsers can easily obtain the value.

ip
: If **PERF_SAMPLE_IP** is enabled, then a 64-bit instruction pointer value is included.

pid
tid
: If **PERF_SAMPLE_TID** is enabled, then a 32-bit process ID and 32-bit thread ID are included.

time
: If **PERF_SAMPLE_TIME** is enabled, then a 64-bit timestamp is included. This is obtained via local_clock() which is a hardware timestamp if available and the jiffies value if not.

addr
: If **PERF_SAMPLE_ADDR** is enabled, then a 64-bit address is included. This is usually the address of a tracepoint, breakpoint, or software event; otherwise the value is 0.

id
: If **PERF_SAMPLE_ID** is enabled, a 64-bit unique ID is included. If the event is a member of an event group, the group leader ID is returned. This ID is the same as the one returned by **PERF_FORMAT_ID**.

stream_id
: If **PERF_SAMPLE_STREAM_ID** is enabled, a 64-bit unique ID is included. Unlike **PERF_SAMPLE_ID** the actual ID is returned, not the group leader. This ID is the same as the one returned by **PERF_FORMAT_ID**.

cpu
res
: If **PERF_SAMPLE_CPU** is enabled, this is a 32-bit value indicating which CPU was being used, in addition to a reserved (unused) 32-bit value.

period
: If **PERF_SAMPLE_PERIOD** is enabled, a 64-bit value indicating the current sampling period is written.

v
: If **PERF_SAMPLE_READ** is enabled, a structure of type read_format is included which has values for all events in the event group. The values included depend on the *read_format* value used at **perf_event_open**() time.

nr
ips[nr]
: If **PERF_SAMPLE_CALLCHAIN** is enabled, then a 64-bit number is included which indicates how many following 64-bit instruction pointers will follow. This is the current callchain.

size
data[size]
: If **PERF_SAMPLE_RAW** is enabled, then a 32-bit value indicating size is included followed by an array of 8-bit values of length size. The values are padded with 0 to have 64-bit alignment.

  This RAW record data is opaque with respect to the ABI. The ABI doesn't make any promises with respect to the stability of its content, it may vary depending on event, hardware, and kernel version.

bnr
lbr[bnr]
: If **PERF_SAMPLE_BRANCH_STACK** is enabled, then a 64-bit value indicating the number of records is included, followed by *bnr* *perf_branch_entry* structures which each include the fields:

from This indicates the source instruction (may not be a branch).

to The branch target.

mispred
The branch target was mispredicted.

predicted
The branch target was predicted.

in_tx (since Linux 3.11)
The branch was in a transactional memory transaction.

abort (since Linux 3.11)
The branch was in an aborted transactional memory transaction.

cycles (since Linux 4.3)
This reports the number of cycles elapsed since the previous branch stack update.

The entries are from most to least recent, so the first entry has the most recent branch.

Support for *mispred*, *predicted*, and *cycles* is optional; if not supported, those values will be 0.

The type of branches recorded is specified by the *branch_sample_type* field.

abi
regs[weight(mask)]
If **PERF_SAMPLE_REGS_USER** is enabled, then the user CPU registers are recorded.

The *abi* field is one of **PERF_SAMPLE_REGS_ABI_NONE**, **PERF_SAMPLE_REGS_ABI_32**, or **PERF_SAMPLE_REGS_ABI_64**.

The *regs* field is an array of the CPU registers that were specified by the *sample_regs_user* attr field. The number of values is the number of bits set in the *sample_regs_user* bit mask.

size
data[size]
dyn_size
If **PERF_SAMPLE_STACK_USER** is enabled, then the user stack is recorded. This can be used to generate stack backtraces. *size* is the size requested by the user in *sample_stack_user* or else the maximum record size. *data* is the stack data (a raw dump of the memory pointed to by the stack pointer at the time of sampling). *dyn_size* is the amount of data actually dumped (can be less than *size*). Note that *dyn_size* is omitted if *size* is 0.

weight
If **PERF_SAMPLE_WEIGHT** or **PERF_SAMPLE_WEIGHT_STRUCT** is enabled, then a 64-bit value provided by the hardware is recorded that indicates how costly the event was. This allows expensive events to stand out more clearly in profiles.

data_src
If **PERF_SAMPLE_DATA_SRC** is enabled, then a 64-bit value is recorded that is made up of the following fields:

mem_op
Type of opcode, a bitwise combination of:

PERF_MEM_OP_NA Not available
PERF_MEM_OP_LOAD Load instruction
PERF_MEM_OP_STORE Store instruction
PERF_MEM_OP_PFETCH
Prefetch

PERF_MEM_OP_EXEC Executable code

mem_lvl
Memory hierarchy level hit or miss, a bitwise combination of the following, shifted left by **PERF_MEM_LVL_SHIFT**:

PERF_MEM_LVL_NA Not available
PERF_MEM_LVL_HIT Hit
PERF_MEM_LVL_MISS Miss
PERF_MEM_LVL_L1 Level 1 cache
PERF_MEM_LVL_LFB Line fill buffer
PERF_MEM_LVL_L2 Level 2 cache
PERF_MEM_LVL_L3 Level 3 cache
PERF_MEM_LVL_LOC_RAM
Local DRAM
PERF_MEM_LVL_REM_RAM1
Remote DRAM 1 hop
PERF_MEM_LVL_REM_RAM2
Remote DRAM 2 hops
PERF_MEM_LVL_REM_CCE1
Remote cache 1 hop
PERF_MEM_LVL_REM_CCE2
Remote cache 2 hops
PERF_MEM_LVL_IO I/O memory
PERF_MEM_LVL_UNC Uncached memory

mem_snoop
Snoop mode, a bitwise combination of the following, shifted left by **PERF_MEM_SNOOP_SHIFT**:

PERF_MEM_SNOOP_NA
Not available
PERF_MEM_SNOOP_NONE
No snoop
PERF_MEM_SNOOP_HIT
Snoop hit
PERF_MEM_SNOOP_MISS
Snoop miss
PERF_MEM_SNOOP_HITM
Snoop hit modified

mem_lock
Lock instruction, a bitwise combination of the following, shifted left by **PERF_MEM_LOCK_SHIFT**:

PERF_MEM_LOCK_NA Not available
PERF_MEM_LOCK_LOCKED
Locked transaction

mem_dtlb
TLB access hit or miss, a bitwise combination of the following, shifted left by **PERF_MEM_TLB_SHIFT**:

PERF_MEM_TLB_NA Not available
PERF_MEM_TLB_HIT Hit
PERF_MEM_TLB_MISS Miss
PERF_MEM_TLB_L1 Level 1 TLB
PERF_MEM_TLB_L2 Level 2 TLB
PERF_MEM_TLB_WK Hardware walker
PERF_MEM_TLB_OS OS fault handler

transaction
If the **PERF_SAMPLE_TRANSACTION** flag is set, then a 64-bit field is recorded describing the sources of any transactional memory aborts.

The field is a bitwise combination of the following values:

PERF_TXN_ELISION
Abort from an elision type transaction (Intel-CPU-specific).

PERF_TXN_TRANSACTION
Abort from a generic transaction.

PERF_TXN_SYNC
Synchronous abort (related to the reported instruction).

PERF_TXN_ASYNC
Asynchronous abort (not related to the reported instruction).

PERF_TXN_RETRY
Retryable abort (retrying the transaction may have succeeded).

PERF_TXN_CONFLICT
Abort due to memory conflicts with other threads.

PERF_TXN_CAPACITY_WRITE
Abort due to write capacity overflow.

PERF_TXN_CAPACITY_READ
Abort due to read capacity overflow.

In addition, a user-specified abort code can be obtained from the high 32 bits of the field by shifting right by **PERF_TXN_ABORT_SHIFT** and masking with the value **PERF_TXN_ABORT_MASK**.

abi
regs[weight(mask)]
If **PERF_SAMPLE_REGS_INTR** is enabled, then the user CPU registers are recorded.

The *abi* field is one of **PERF_SAMPLE_REGS_ABI_NONE**, **PERF_SAMPLE_REGS_ABI_32**, or **PERF_SAMPLE_REGS_ABI_64**.

The *regs* field is an array of the CPU registers that were specified by the *sample_regs_intr* attr field. The number of values is the number of bits set in the *sample_regs_intr* bit mask.

phys_addr
If the **PERF_SAMPLE_PHYS_ADDR** flag is set, then the 64-bit physical address is recorded.

cgroup
If the **PERF_SAMPLE_CGROUP** flag is set, then the 64-bit cgroup ID (for the perf_event subsystem) is recorded. To get the pathname of the cgroup, the ID should match to one in a **PERF_RECORD_CGROUP**.

data_page_size
If the **PERF_SAMPLE_DATA_PAGE_SIZE** flag is set, then the 64-bit page size value of the **data** address is recorded.

code_page_size
If the **PERF_SAMPLE_CODE_PAGE_SIZE** flag is set, then the 64-bit page size value of the **ip** address is recorded.

size
data[*size*]
If **PERF_SAMPLE_AUX** is enabled, a snapshot of the aux buffer is recorded.

PERF_RECORD_MMAP2
This record includes extended information on *mmap*(2) calls returning executable mappings. The format is similar to that of the **PERF_RECORD_MMAP** record, but includes extra values that allow uniquely identifying shared mappings. Depending on the **PERF_RECORD_MISC_MMAP_BUILD_ID** bit in the header, the extra values have different layout and meanings.

```
struct {
    struct perf_event_header header;
    u32    pid;
    u32    tid;
    u64    addr;
    u64    len;
    u64    pgoff;
    union {
        struct {
            u32    maj;
            u32    min;
            u64    ino;
            u64    ino_generation;
        };
        struct {   /* if PERF_RECORD_MISC_MMAP_BUILD_ID */
            u8     build_id_size;
            u8     __reserved_1;
            u16    __reserved_2;
            u8     build_id[20];
        };
    };
    u32    prot;
    u32    flags;
    char   filename[];
    struct sample_id sample_id;
};
```

pid is the process ID.

tid is the thread ID.

addr is the address of the allocated memory.

len is the length of the allocated memory.

pgoff is the page offset of the allocated memory.

maj is the major ID of the underlying device.

min is the minor ID of the underlying device.

ino is the inode number.

ino_generation
is the inode generation.

build_id_size
is the actual size of *build_id* field (up to 20).

build_id
is a raw data to identify a binary.

prot is the protection information.

flags is the flags information.

filename
is a string describing the backing of the allocated memory.

PERF_RECORD_AUX (since Linux 4.1)
This record reports that new data is available in the separate AUX buffer region.

```
struct {
    struct perf_event_header header;
    u64    aux_offset;
    u64    aux_size;
    u64    flags;
    struct sample_id sample_id;
```

```
};
```

aux_offset
: offset in the AUX mmap region where the new data begins.

aux_size
: size of the data made available.

flags describes the AUX update.

PERF_AUX_FLAG_TRUNCATED
: if set, then the data returned was truncated to fit the available buffer size.

PERF_AUX_FLAG_OVERWRITE
: if set, then the data returned has overwritten previous data.

PERF_RECORD_ITRACE_START (since Linux 4.1)
: This record indicates which process has initiated an instruction trace event, allowing tools to properly correlate the instruction addresses in the AUX buffer with the proper executable.

```
struct {
    struct perf_event_header header;
    u32    pid;
    u32    tid;
};
```

pid process ID of the thread starting an instruction trace.

tid thread ID of the thread starting an instruction trace.

PERF_RECORD_LOST_SAMPLES (since Linux 4.2)
: When using hardware sampling (such as Intel PEBS) this record indicates some number of samples that may have been lost.

```
struct {
    struct perf_event_header header;
    u64    lost;
    struct sample_id sample_id;
};
```

lost the number of potentially lost samples.

PERF_RECORD_SWITCH (since Linux 4.3)
: This record indicates a context switch has happened. The **PERF_RECORD_MISC_SWITCH_OUT** bit in the *misc* field indicates whether it was a context switch into or away from the current process.

```
struct {
    struct perf_event_header header;
    struct sample_id sample_id;
};
```

PERF_RECORD_SWITCH_CPU_WIDE (since Linux 4.3)
: As with **PERF_RECORD_SWITCH** this record indicates a context switch has happened, but it only occurs when sampling in CPU-wide mode and provides additional information on the process being switched to/from. The **PERF_RECORD_MISC_SWITCH_OUT** bit in the *misc* field indicates whether it was a context switch into or away from the current process.

```
struct {
    struct perf_event_header header;
    u32 next_prev_pid;
    u32 next_prev_tid;
    struct sample_id sample_id;
};
```

next_prev_pid
The process ID of the previous (if switching in) or next (if switching out) process on the CPU.

next_prev_tid
The thread ID of the previous (if switching in) or next (if switching out) thread on the CPU.

PERF_RECORD_NAMESPACES (since Linux 4.11)
This record includes various namespace information of a process.

```
struct {
    struct perf_event_header header;
    u32    pid;
    u32    tid;
    u64    nr_namespaces;
    struct { u64 dev, inode } [nr_namespaces];
    struct sample_id sample_id;
};
```

pid is the process ID

tid is the thread ID

nr_namespace
is the number of namespaces in this record

Each namespace has *dev* and *inode* fields and is recorded in the fixed position like below:

NET_NS_INDEX=**0**
Network namespace

UTS_NS_INDEX=**1**
UTS namespace

IPC_NS_INDEX=**2**
IPC namespace

PID_NS_INDEX=**3**
PID namespace

USER_NS_INDEX=**4**
User namespace

MNT_NS_INDEX=**5**
Mount namespace

CGROUP_NS_INDEX=**6**
Cgroup namespace

PERF_RECORD_KSYMBOL (since Linux 5.0)
This record indicates kernel symbol register/unregister events.

```
struct {
    struct perf_event_header header;
    u64    addr;
    u32    len;
    u16    ksym_type;
    u16    flags;
    char   name[];
    struct sample_id sample_id;
};
```

addr is the address of the kernel symbol.

len is the length of the kernel symbol.

ksym_type
is the type of the kernel symbol. Currently the following types are available:

PERF_RECORD_KSYMBOL_TYPE_BPF
The kernel symbol is a BPF function.

flags If the **PERF_RECORD_KSYMBOL_FLAGS_UNREGISTER** is set, then this event is for unregistering the kernel symbol.

PERF_RECORD_BPF_EVENT (since Linux 5.0)
This record indicates BPF program is loaded or unloaded.

```
struct {
    struct perf_event_header header;
    u16 type;
    u16 flags;
    u32 id;
    u8 tag[BPF_TAG_SIZE];
    struct sample_id sample_id;
};
```

type is one of the following values:

PERF_BPF_EVENT_PROG_LOAD
A BPF program is loaded

PERF_BPF_EVENT_PROG_UNLOAD
A BPF program is unloaded

id is the ID of the BPF program.

tag is the tag of the BPF program. Currently, **BPF_TAG_SIZE** is defined as 8.

PERF_RECORD_CGROUP (since Linux 5.7)
This record indicates a new cgroup is created and activated.

```
struct {
    struct perf_event_header header;
    u64    id;
    char   path[];
    struct sample_id sample_id;
};
```

id is the cgroup identifier. This can be also retrieved by *name_to_handle_at*(2) on the cgroup path (as a file handle).

path is the path of the cgroup from the root.

PERF_RECORD_TEXT_POKE (since Linux 5.8)
This record indicates a change in the kernel text. This includes addition and removal of the text and the corresponding length is zero in this case.

```
struct {
    struct perf_event_header header;
    u64    addr;
    u16    old_len;
    u16    new_len;
    u8     bytes[];
    struct sample_id sample_id;
};
```

addr is the address of the change

old_len is the old length

new_len
is the new length

bytes contains old bytes immediately followed by new bytes.

Overflow handling
Events can be set to notify when a threshold is crossed, indicating an overflow. Overflow conditions can be captured by monitoring the event file descriptor with *poll*(2), *select*(2), or *epoll*(7).

Alternatively, the overflow events can be captured via sa signal handler, by enabling I/O signaling on the file descriptor; see the discussion of the **F_SETOWN** and **F_SETSIG** operations in *fcntl*(2).

Overflows are generated only by sampling events (*sample_period* must have a nonzero value).

There are two ways to generate overflow notifications.

The first is to set a *wakeup_events* or *wakeup_watermark* value that will trigger if a certain number of samples or bytes have been written to the mmap ring buffer. In this case, **POLL_IN** is indicated.

The other way is by use of the **PERF_EVENT_IOC_REFRESH** ioctl. This ioctl adds to a counter that decrements each time the event overflows. When nonzero, **POLL_IN** is indicated, but once the counter reaches 0 **POLL_HUP** is indicated and the underlying event is disabled.

Refreshing an event group leader refreshes all siblings and refreshing with a parameter of 0 currently enables infinite refreshes; these behaviors are unsupported and should not be relied on.

Starting with Linux 3.18, **POLL_HUP** is indicated if the event being monitored is attached to a different process and that process exits.

rdpmc instruction

Starting with Linux 3.4 on x86, you can use the *rdpmc* instruction to get low-latency reads without having to enter the kernel. Note that using *rdpmc* is not necessarily faster than other methods for reading event values.

Support for this can be detected with the *cap_usr_rdpmc* field in the mmap page; documentation on how to calculate event values can be found in that section.

Originally, when rdpmc support was enabled, any process (not just ones with an active perf event) could use the rdpmc instruction to access the counters. Starting with Linux 4.0, rdpmc support is only allowed if an event is currently enabled in a process's context. To restore the old behavior, write the value 2 to */sys/devices/cpu/rdpmc*.

perf_event ioctl calls

Various ioctls act on **perf_event_open**() file descriptors:

PERF_EVENT_IOC_ENABLE

This enables the individual event or event group specified by the file descriptor argument.

If the **PERF_IOC_FLAG_GROUP** bit is set in the ioctl argument, then all events in a group are enabled, even if the event specified is not the group leader (but see BUGS).

PERF_EVENT_IOC_DISABLE

This disables the individual counter or event group specified by the file descriptor argument.

Enabling or disabling the leader of a group enables or disables the entire group; that is, while the group leader is disabled, none of the counters in the group will count. Enabling or disabling a member of a group other than the leader affects only that counter; disabling a non-leader stops that counter from counting but doesn't affect any other counter.

If the **PERF_IOC_FLAG_GROUP** bit is set in the ioctl argument, then all events in a group are disabled, even if the event specified is not the group leader (but see BUGS).

PERF_EVENT_IOC_REFRESH

Non-inherited overflow counters can use this to enable a counter for a number of overflows specified by the argument, after which it is disabled. Subsequent calls of this ioctl add the argument value to the current count. An overflow notification with **POLL_IN** set will happen on each overflow until the count reaches 0; when that happens a notification with **POLL_HUP** set is sent and the event is disabled. Using an argument of 0 is considered undefined behavior.

PERF_EVENT_IOC_RESET

Reset the event count specified by the file descriptor argument to zero. This resets only the counts; there is no way to reset the multiplexing *time_enabled* or *time_running* values.

If the **PERF_IOC_FLAG_GROUP** bit is set in the ioctl argument, then all events in a group are reset, even if the event specified is not the group leader (but see BUGS).

PERF_EVENT_IOC_PERIOD
This updates the overflow period for the event.

Since Linux 3.7 (on ARM) and Linux 3.14 (all other architectures), the new period takes effect immediately. On older kernels, the new period did not take effect until after the next overflow.

The argument is a pointer to a 64-bit value containing the desired new period.

Prior to Linux 2.6.36, this ioctl always failed due to a bug in the kernel.

PERF_EVENT_IOC_SET_OUTPUT
This tells the kernel to report event notifications to the specified file descriptor rather than the default one. The file descriptors must all be on the same CPU.

The argument specifies the desired file descriptor, or −1 if output should be ignored.

PERF_EVENT_IOC_SET_FILTER (since Linux 2.6.33)
This adds an ftrace filter to this event.

The argument is a pointer to the desired ftrace filter.

PERF_EVENT_IOC_ID (since Linux 3.12)
This returns the event ID value for the given event file descriptor.

The argument is a pointer to a 64-bit unsigned integer to hold the result.

PERF_EVENT_IOC_SET_BPF (since Linux 4.1)
This allows attaching a Berkeley Packet Filter (BPF) program to an existing kprobe tracepoint event. You need **CAP_PERFMON** (since Linux 5.8) or **CAP_SYS_ADMIN** privileges to use this ioctl.

The argument is a BPF program file descriptor that was created by a previous *bpf*(2) system call.

PERF_EVENT_IOC_PAUSE_OUTPUT (since Linux 4.7)
This allows pausing and resuming the event's ring-buffer. A paused ring-buffer does not prevent generation of samples, but simply discards them. The discarded samples are considered lost, and cause a **PERF_RECORD_LOST** sample to be generated when possible. An overflow signal may still be triggered by the discarded sample even though the ring-buffer remains empty.

The argument is an unsigned 32-bit integer. A nonzero value pauses the ring-buffer, while a zero value resumes the ring-buffer.

PERF_EVENT_MODIFY_ATTRIBUTES (since Linux 4.17)
This allows modifying an existing event without the overhead of closing and reopening a new event. Currently this is supported only for breakpoint events.

The argument is a pointer to a *perf_event_attr* structure containing the updated event settings.

PERF_EVENT_IOC_QUERY_BPF (since Linux 4.16)
This allows querying which Berkeley Packet Filter (BPF) programs are attached to an existing kprobe tracepoint. You can only attach one BPF program per event, but you can have multiple events attached to a tracepoint. Querying this value on one tracepoint event returns the ID of all BPF programs in all events attached to the tracepoint. You need **CAP_PERFMON** (since Linux 5.8) or **CAP_SYS_ADMIN** privileges to use this ioctl.

The argument is a pointer to a structure

```
struct perf_event_query_bpf {
    __u32    ids_len;
    __u32    prog_cnt;
    __u32    ids[0];
};
```

The *ids_len* field indicates the number of ids that can fit in the provided *ids* array. The *prog_cnt* value is filled in by the kernel with the number of attached BPF programs. The *ids* array is filled with the ID of each attached BPF program. If there are more programs than will fit in the array, then the kernel will return **ENOSPC** and *ids_len* will indicate the number of

program IDs that were successfully copied.

Using prctl(2)

A process can enable or disable all currently open event groups using the *prctl*(2) **PR_TASK_PERF_EVENTS_ENABLE** and **PR_TASK_PERF_EVENTS_DISABLE** operations. This applies only to events created locally by the calling process. This does not apply to events created by other processes attached to the calling process or inherited events from a parent process. Only group leaders are enabled and disabled, not any other members of the groups.

perf_event related configuration files

Files in */proc/sys/kernel/*

/proc/sys/kernel/perf_event_paranoid

The */proc/sys/kernel/perf_event_paranoid* file can be set to restrict access to the performance counters.

2 allow only user-space measurements (default since Linux 4.6).
1 allow both kernel and user measurements (default before Linux 4.6).
0 allow access to CPU-specific data but not raw tracepoint samples.
−1 no restrictions.

The existence of the */proc/sys/kernel/perf_event_paranoid* file is the official method for determining if a kernel supports **perf_event_open**().

/proc/sys/kernel/perf_event_max_sample_rate

This sets the maximum sample rate. Setting this too high can allow users to sample at a rate that impacts overall machine performance and potentially lock up the machine. The default value is 100000 (samples per second).

/proc/sys/kernel/perf_event_max_stack

This file sets the maximum depth of stack frame entries reported when generating a call trace.

/proc/sys/kernel/perf_event_mlock_kb

Maximum number of pages an unprivileged user can *mlock*(2). The default is 516 (kB).

Files in */sys/bus/event_source/devices/*

Since Linux 2.6.34, the kernel supports having multiple PMUs available for monitoring. Information on how to program these PMUs can be found under */sys/bus/event_source/devices/*. Each subdirectory corresponds to a different PMU.

/sys/bus/event_source/devices//type* (since Linux 2.6.38)

This contains an integer that can be used in the *type* field of *perf_event_attr* to indicate that you wish to use this PMU.

/sys/bus/event_source/devices/cpu/rdpmc (since Linux 3.4)

If this file is 1, then direct user-space access to the performance counter registers is allowed via the rdpmc instruction. This can be disabled by echoing 0 to the file.

As of Linux 4.0 the behavior has changed, so that 1 now means only allow access to processes with active perf events, with 2 indicating the old allow-anyone-access behavior.

/sys/bus/event_source/devices//format/* (since Linux 3.4)

This subdirectory contains information on the architecture-specific subfields available for programming the various *config* fields in the *perf_event_attr* struct.

The content of each file is the name of the config field, followed by a colon, followed by a series of integer bit ranges separated by commas. For example, the file *event* may contain the value *config1:1,6−10,44* which indicates that event is an attribute that occupies bits 1,6–10, and 44 of *perf_event_attr::config1*.

/sys/bus/event_source/devices//events/* (since Linux 3.4)

This subdirectory contains files with predefined events. The contents are strings describing the event settings expressed in terms of the fields found in the previously mentioned *./format/* directory. These are not necessarily complete lists of all events supported by a PMU, but usually a subset of events deemed useful or interesting.

The content of each file is a list of attribute names separated by commas. Each entry has an optional value (either hex or decimal). If no value is specified, then it is assumed to be

a single-bit field with a value of 1. An example entry may look like this: *event=0x2,inv,ldlat=3*.

/sys/bus/event_source/devices//uevent*
This file is the standard kernel device interface for injecting hotplug events.

/sys/bus/event_source/devices//cpumask* (since Linux 3.7)
The *cpumask* file contains a comma-separated list of integers that indicate a representative CPU number for each socket (package) on the motherboard. This is needed when setting up uncore or northbridge events, as those PMUs present socket-wide events.

RETURN VALUE

On success, **perf_event_open**() returns the new file descriptor. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

The errors returned by **perf_event_open**() can be inconsistent, and may vary across processor architectures and performance monitoring units.

E2BIG Returned if the *perf_event_attr size* value is too small (smaller than **PERF_ATTR_SIZE_VER0**), too big (larger than the page size), or larger than the kernel supports and the extra bytes are not zero. When **E2BIG** is returned, the *perf_event_attr size* field is overwritten by the kernel to be the size of the structure it was expecting.

EACCES
Returned when the requested event requires **CAP_PERFMON** (since Linux 5.8) or **CAP_SYS_ADMIN** permissions (or a more permissive perf_event paranoid setting). Some common cases where an unprivileged process may encounter this error: attaching to a process owned by a different user; monitoring all processes on a given CPU (i.e., specifying the *pid* argument as −1); and not setting *exclude_kernel* when the paranoid setting requires it.

EBADF
Returned if the *group_fd* file descriptor is not valid, or, if **PERF_FLAG_PID_CGROUP** is set, the cgroup file descriptor in *pid* is not valid.

EBUSY (since Linux 4.1)
Returned if another event already has exclusive access to the PMU.

EFAULT
Returned if the *attr* pointer points at an invalid memory address.

EINTR
Returned when trying to mix perf and ftrace handling for a uprobe.

EINVAL
Returned if the specified event is invalid. There are many possible reasons for this. A not-exhaustive list: *sample_freq* is higher than the maximum setting; the *cpu* to monitor does not exist; *read_format* is out of range; *sample_type* is out of range; the *flags* value is out of range; *exclusive* or *pinned* set and the event is not a group leader; the event *config* values are out of range or set reserved bits; the generic event selected is not supported; or there is not enough room to add the selected event.

EMFILE
Each opened event uses one file descriptor. If a large number of events are opened, the per-process limit on the number of open file descriptors will be reached, and no more events can be created.

ENODEV
Returned when the event involves a feature not supported by the current CPU.

ENOENT
Returned if the *type* setting is not valid. This error is also returned for some unsupported generic events.

ENOSPC
Prior to Linux 3.3, if there was not enough room for the event, **ENOSPC** was returned. In Linux 3.3, this was changed to **EINVAL**. **ENOSPC** is still returned if you try to add more breakpoint events than supported by the hardware.

ENOSYS
Returned if **PERF_SAMPLE_STACK_USER** is set in *sample_type* and it is not supported by hardware.

EOPNOTSUPP
Returned if an event requiring a specific hardware feature is requested but there is no hardware support. This includes requesting low-skid events if not supported, branch tracing if it is not available, sampling if no PMU interrupt is available, and branch stacks for software events.

EOVERFLOW (since Linux 4.8)
Returned if **PERF_SAMPLE_CALLCHAIN** is requested and *sample_max_stack* is larger than the maximum specified in */proc/sys/kernel/perf_event_max_stack*.

EPERM
Returned on many (but not all) architectures when an unsupported *exclude_hv*, *exclude_idle*, *exclude_user*, or *exclude_kernel* setting is specified.

It can also happen, as with **EACCES**, when the requested event requires **CAP_PERFMON** (since Linux 5.8) or **CAP_SYS_ADMIN** permissions (or a more permissive perf_event paranoid setting). This includes setting a breakpoint on a kernel address, and (since Linux 3.13) setting a kernel function-trace tracepoint.

ESRCH
Returned if attempting to attach to a process that does not exist.

STANDARDS
Linux.

HISTORY
perf_event_open() was introduced in Linux 2.6.31 but was called **perf_counter_open**(). It was renamed in Linux 2.6.32.

NOTES
The official way of knowing if **perf_event_open**() support is enabled is checking for the existence of the file */proc/sys/kernel/perf_event_paranoid*.

CAP_PERFMON capability (since Linux 5.8) provides secure approach to performance monitoring and observability operations in a system according to the principal of least privilege (POSIX IEEE 1003.1e). Accessing system performance monitoring and observability operations using **CAP_PERFMON** rather than the much more powerful **CAP_SYS_ADMIN** excludes chances to misuse credentials and makes operations more secure. **CAP_SYS_ADMIN** usage for secure system performance monitoring and observability is discouraged in favor of the **CAP_PERFMON** capability.

BUGS
The **F_SETOWN_EX** option to *fcntl*(2) is needed to properly get overflow signals in threads. This was introduced in Linux 2.6.32.

Prior to Linux 2.6.33 (at least for x86), the kernel did not check if events could be scheduled together until read time. The same happens on all known kernels if the NMI watchdog is enabled. This means to see if a given set of events works you have to **perf_event_open**(), start, then read before you know for sure you can get valid measurements.

Prior to Linux 2.6.34, event constraints were not enforced by the kernel. In that case, some events would silently return "0" if the kernel scheduled them in an improper counter slot.

Prior to Linux 2.6.34, there was a bug when multiplexing where the wrong results could be returned.

Kernels from Linux 2.6.35 to Linux 2.6.39 can quickly crash the kernel if "inherit" is enabled and many threads are started.

Prior to Linux 2.6.35, **PERF_FORMAT_GROUP** did not work with attached processes.

There is a bug in the kernel code between Linux 2.6.36 and Linux 3.0 that ignores the "watermark" field and acts as if a wakeup_event was chosen if the union has a nonzero value in it.

From Linux 2.6.31 to Linux 3.4, the **PERF_IOC_FLAG_GROUP** ioctl argument was broken and would repeatedly operate on the event specified rather than iterating across all sibling events in a group.

From Linux 3.4 to Linux 3.11, the mmap *cap_usr_rdpmc* and *cap_usr_time* bits mapped to the same

location. Code should migrate to the new *cap_user_rdpmc* and *cap_user_time* fields instead.

Always double-check your results! Various generalized events have had wrong values. For example, retired branches measured the wrong thing on AMD machines until Linux 2.6.35.

EXAMPLES

The following is a short example that measures the total instruction count of a call to *printf*(3).

```
#include <linux/perf_event.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/ioctl.h>
#include <sys/syscall.h>
#include <unistd.h>

static long
perf_event_open(struct perf_event_attr *hw_event, pid_t pid,
                int cpu, int group_fd, unsigned long flags)
{
    int ret;

    ret = syscall(SYS_perf_event_open, hw_event, pid, cpu,
                  group_fd, flags);
    return ret;
}

int
main(void)
{
    int                     fd;
    long long               count;
    struct perf_event_attr  pe;

    memset(&pe, 0, sizeof(pe));
    pe.type = PERF_TYPE_HARDWARE;
    pe.size = sizeof(pe);
    pe.config = PERF_COUNT_HW_INSTRUCTIONS;
    pe.disabled = 1;
    pe.exclude_kernel = 1;
    pe.exclude_hv = 1;

    fd = perf_event_open(&pe, 0, -1, -1, 0);
    if (fd == -1) {
       fprintf(stderr, "Error opening leader %llx\n", pe.config);
       exit(EXIT_FAILURE);
    }

    ioctl(fd, PERF_EVENT_IOC_RESET, 0);
    ioctl(fd, PERF_EVENT_IOC_ENABLE, 0);

    printf("Measuring instruction count for this printf\n");

    ioctl(fd, PERF_EVENT_IOC_DISABLE, 0);
    read(fd, &count, sizeof(count));

    printf("Used %lld instructions\n", count);

    close(fd);
}
```

NAME

perfmonctl − interface to IA-64 performance monitoring unit

SYNOPSIS

#include <syscall.h>
#include <perfmon.h>

long perfmonctl(int *fd***, int** *cmd***, void** *arg***[.***narg***], int** *narg***);**

Note: There is no glibc wrapper for this system call; see HISTORY.

DESCRIPTION

The IA-64-specific **perfmonctl**() system call provides an interface to the PMU (performance monitoring unit). The PMU consists of PMD (performance monitoring data) registers and PMC (performance monitoring control) registers, which gather hardware statistics.

perfmonctl() applies the operation *cmd* to the input arguments specified by *arg*. The number of arguments is defined by *narg*. The *fd* argument specifies the perfmon context to operate on.

Supported values for *cmd* are:

PFM_CREATE_CONTEXT
perfmonctl(int *fd***, PFM_CREATE_CONTEXT, pfarg_context_t *** *ctxt***, 1);**
Set up a context.

The *fd* parameter is ignored. A new perfmon context is created as specified in *ctxt* and its file descriptor is returned in *ctxt−>ctx_fd*.

The file descriptor can be used in subsequent calls to **perfmonctl**() and can be used to read event notifications (type *pfm_msg_t*) using *read*(2). The file descriptor is pollable using *select*(2), *poll*(2), and *epoll*(7).

The context can be destroyed by calling *close*(2) on the file descriptor.

PFM_WRITE_PMCS
perfmonctl(int *fd***, PFM_WRITE_PMCS, pfarg_reg_t *** *pmcs***, n);**
Set PMC registers.

PFM_WRITE_PMDS
perfmonctl(int *fd***, PFM_WRITE_PMDS, pfarg_reg_t *** *pmds***, n);**
Set PMD registers.

PFM_READ_PMDS
perfmonctl(int *fd***, PFM_READ_PMDS, pfarg_reg_t *** *pmds***, n);**
Read PMD registers.

PFM_START
perfmonctl(int *fd***, PFM_START, NULL, 0);**
Start monitoring.

PFM_STOP
perfmonctl(int *fd***, PFM_STOP, NULL, 0);**
Stop monitoring.

PFM_LOAD_CONTEXT
perfmonctl(int *fd***, PFM_LOAD_CONTEXT, pfarg_load_t *** *largs***, 1);**
Attach the context to a thread.

PFM_UNLOAD_CONTEXT
perfmonctl(int *fd***, PFM_UNLOAD_CONTEXT, NULL, 0);**
Detach the context from a thread.

PFM_RESTART
perfmonctl(int *fd***, PFM_RESTART, NULL, 0);**
Restart monitoring after receiving an overflow notification.

PFM_GET_FEATURES
perfmonctl(int *fd***, PFM_GET_FEATURES, pfarg_features_t *** *arg***, 1);**

PFM_DEBUG

perfmonctl(int *fd***, PFM_DEBUG,** *val***, 0);**
If *val* is nonzero, enable debugging mode, otherwise disable.

PFM_GET_PMC_RESET_VAL

perfmonctl(int *fd***, PFM_GET_PMC_RESET_VAL, pfarg_reg_t ****req***, n);**
Reset PMC registers to default values.

RETURN VALUE

perfmonctl() returns zero when the operation is successful. On error, −1 is returned and *errno* is set to indicate the error.

STANDARDS

Linux on IA-64.

HISTORY

Added in Linux 2.4; removed in Linux 5.10.

This system call was broken for many years, and ultimately removed in Linux 5.10.

glibc does not provide a wrapper for this system call; on kernels where it exists, call it using *syscall*(2).

NAME

personality − set the process execution domain

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/personality.h>

int personality(unsigned long *persona***);**

DESCRIPTION

Linux supports different execution domains, or personalities, for each process. Among other things, execution domains tell Linux how to map signal numbers into signal actions. The execution domain system allows Linux to provide limited support for binaries compiled under other UNIX-like operating systems.

If *persona* is not 0xffffffff, then **personality**() sets the caller's execution domain to the value specified by *persona*. Specifying *persona* as 0xffffffff provides a way of retrieving the current persona without changing it.

A list of the available execution domains can be found in *<sys/personality.h>*. The execution domain is a 32-bit value in which the top three bytes are set aside for flags that cause the kernel to modify the behavior of certain system calls so as to emulate historical or architectural quirks. The least significant byte is a value defining the personality the kernel should assume. The flag values are as follows:

ADDR_COMPAT_LAYOUT (since Linux 2.6.9)
With this flag set, provide legacy virtual address space layout.

ADDR_NO_RANDOMIZE (since Linux 2.6.12)
With this flag set, disable address-space-layout randomization.

ADDR_LIMIT_32BIT (since Linux 2.2)
Limit the address space to 32 bits.

ADDR_LIMIT_3GB (since Linux 2.4.0)
With this flag set, use 0xc0000000 as the offset at which to search a virtual memory chunk on *mmap*(2); otherwise use 0xffffe000. Applies to 32-bit x86 processes only.

FDPIC_FUNCPTRS (since Linux 2.6.11)
User-space function pointers to signal handlers point to descriptors. Applies only to ARM if BINFMT_ELF_FDPIC and SuperH.

MMAP_PAGE_ZERO (since Linux 2.4.0)
Map page 0 as read-only (to support binaries that depend on this SVr4 behavior).

READ_IMPLIES_EXEC (since Linux 2.6.8)
With this flag set, **PROT_READ** implies **PROT_EXEC** for *mmap*(2).

SHORT_INODE (since Linux 2.4.0)
No effect.

STICKY_TIMEOUTS (since Linux 1.2.0)
With this flag set, *select*(2), *pselect*(2), and *ppoll*(2) do not modify the returned timeout argument when interrupted by a signal handler.

UNAME26 (since Linux 3.1)
Have *uname*(2) report a 2.6.(40+x) version number rather than a MAJOR.x version number. Added as a stopgap measure to support broken applications that could not handle the kernel version-numbering switch from Linux 2.6.x to Linux 3.x.

WHOLE_SECONDS (since Linux 1.2.0)
No effect.

The available execution domains are:

PER_BSD (since Linux 1.2.0)
BSD. (No effects.)

PER_HPUX (since Linux 2.4)
Support for 32-bit HP/UX. This support was never complete, and was dropped so that since Linux 4.0, this value has no effect.

PER_IRIX32 (since Linux 2.2)
IRIX 5 32-bit. Never fully functional; support dropped in Linux 2.6.27. Implies **STICKY_TIMEOUTS**.

PER_IRIX64 (since Linux 2.2)
IRIX 6 64-bit. Implies **STICKY_TIMEOUTS**; otherwise no effect.

PER_IRIXN32 (since Linux 2.2)
IRIX 6 new 32-bit. Implies **STICKY_TIMEOUTS**; otherwise no effect.

PER_ISCR4 (since Linux 1.2.0)
Implies **STICKY_TIMEOUTS**; otherwise no effect.

PER_LINUX (since Linux 1.2.0)
Linux.

PER_LINUX32 (since Linux 2.2)
uname(2) returns the name of the 32-bit architecture in the *machine* field ("i686" instead of "x86_64", &c.).

Under ia64 (Itanium), processes with this personality don't have the O_LARGEFILE *open*(2) flag forced.

Under 64-bit ARM, setting this personality is forbidden if *execve*(2)ing a 32-bit process would also be forbidden (cf. the allow_mismatched_32bit_el0 kernel parameter and *Documentation/arm64/asymmetric-32bit.rst*).

PER_LINUX32_3GB (since Linux 2.4)
Same as **PER_LINUX32**, but implies **ADDR_LIMIT_3GB**.

PER_LINUX_32BIT (since Linux 2.0)
Same as **PER_LINUX**, but implies **ADDR_LIMIT_32BIT**.

PER_LINUX_FDPIC (since Linux 2.6.11)
Same as **PER_LINUX**, but implies **FDPIC_FUNCPTRS**.

PER_OSF4 (since Linux 2.4)
OSF/1 v4. No effect since Linux 6.1, which removed a.out binary support. Before, on alpha, would clear top 32 bits of iov_len in the user's buffer for compatibility with old versions of OSF/1 where iov_len was defined as. *int*.

PER_OSR5 (since Linux 2.4)
SCO OpenServer 5. Implies **STICKY_TIMEOUTS** and **WHOLE_SECONDS**; otherwise no effect.

PER_RISCOS (since Linux 2.3.7; macro since Linux 2.3.13)
Acorn RISC OS/Arthur (MIPS). No effect. Up to Linux v4.0, would set the emulation altroot to */usr/gnemul/riscos* (cf. **PER_SUNOS**, below). Before then, up to Linux 2.6.3, just Arthur emulation.

PER_SCOSVR3 (since Linux 1.2.0)
SCO UNIX System V Release 3. Same as **PER_OSR5**, but also implies **SHORT_INODE**.

PER_SOLARIS (since Linux 2.4)
Solaris. Implies **STICKY_TIMEOUTS**; otherwise no effect.

PER_SUNOS (since Linux 2.4.0)
Sun OS. Same as **PER_BSD**, but implies **STICKY_TIMEOUTS**. Prior to Linux 2.6.26, diverted library and dynamic linker searches to */usr/gnemul*. Buggy, largely unmaintained, and almost entirely unused.

PER_SVR3 (since Linux 1.2.0)
AT&T UNIX System V Release 3. Implies **STICKY_TIMEOUTS** and **SHORT_INODE**; otherwise no effect.

PER_SVR4 (since Linux 1.2.0)
AT&T UNIX System V Release 4. Implies **STICKY_TIMEOUTS** and **MMAP_PAGE_ZERO**; otherwise no effect.

PER_UW7 (since Linux 2.4)
UnixWare 7. Implies **STICKY_TIMEOUTS** and **MMAP_PAGE_ZERO**; otherwise no effect.

PER_WYSEV386 (since Linux 1.2.0)
WYSE UNIX System V/386. Implies **STICKY_TIMEOUTS** and **SHORT_INODE**; otherwise no effect.

PER_XENIX (since Linux 1.2.0)
XENIX. Implies **STICKY_TIMEOUTS** and **SHORT_INODE**; otherwise no effect.

RETURN VALUE

On success, the previous *persona* is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
The kernel was unable to change the personality.

NAME

pidfd_getfd − obtain a duplicate of another process's file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_pidfd_getfd, int pidfd, int targetfd,
            unsigned int flags);
```

Note: glibc provides no wrapper for **pidfd_getfd**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **pidfd_getfd**() system call allocates a new file descriptor in the calling process. This new file descriptor is a duplicate of an existing file descriptor, *targetfd*, in the process referred to by the PID file descriptor *pidfd*.

The duplicate file descriptor refers to the same open file description (see *open*(2)) as the original file descriptor in the process referred to by *pidfd*. The two file descriptors thus share file status flags and file offset. Furthermore, operations on the underlying file object (for example, assigning an address to a socket object using *bind*(2)) can equally be performed via the duplicate file descriptor.

The close-on-exec flag (**FD_CLOEXEC**; see *fcntl*(2)) is set on the file descriptor returned by **pidfd_getfd**().

The *flags* argument is reserved for future use. Currently, it must be specified as 0.

Permission to duplicate another process's file descriptor is governed by a ptrace access mode **PTRACE_MODE_ATTACH_REALCREDS** check (see *ptrace*(2)).

RETURN VALUE

On success, **pidfd_getfd**() returns a file descriptor (a nonnegative integer). On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF
: *pidfd* is not a valid PID file descriptor.

EBADF
: *targetfd* is not an open file descriptor in the process referred to by *pidfd*.

EINVAL
: *flags* is not 0.

EMFILE
: The per-process limit on the number of open file descriptors has been reached (see the description of **RLIMIT_NOFILE** in *getrlimit*(2)).

ENFILE
: The system-wide limit on the total number of open files has been reached.

EPERM
: The calling process did not have **PTRACE_MODE_ATTACH_REALCREDS** permissions (see *ptrace*(2)) over the process referred to by *pidfd*.

ESRCH
: The process referred to by *pidfd* does not exist (i.e., it has terminated and been waited on).

STANDARDS

Linux.

HISTORY

Linux 5.6.

NOTES

For a description of PID file descriptors, see *pidfd_open*(2).

The effect of **pidfd_getfd**() is similar to the use of **SCM_RIGHTS** messages described in *unix*(7), but

differs in the following respects:

- In order to pass a file descriptor using an **SCM_RIGHTS** message, the two processes must first establish a UNIX domain socket connection.
- The use of **SCM_RIGHTS** requires cooperation on the part of the process whose file descriptor is being copied. By contrast, no such cooperation is necessary when using **pidfd_getfd**().
- The ability to use **pidfd_getfd**() is restricted by a **PTRACE_MODE_ATTACH_REALCREDS** ptrace access mode check.

clone3(2), *dup*(2), *kcmp*(2), *pidfd_open*(2)

NAME

pidfd_open − obtain a file descriptor that refers to a process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_pidfd_open, pid_t *pid***, unsigned int** *flags***);**

Note: glibc provides no wrapper for **pidfd_open**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **pidfd_open**() system call creates a file descriptor that refers to the process whose PID is specified in *pid*. The file descriptor is returned as the function result; the close-on-exec flag is set on the file descriptor.

The *flags* argument either has the value 0, or contains the following flag:

PIDFD_NONBLOCK (since Linux 5.10)
: Return a nonblocking file descriptor. If the process referred to by the file descriptor has not yet terminated, then an attempt to wait on the file descriptor using *waitid*(2) will immediately return the error **EAGAIN** rather than blocking.

RETURN VALUE

On success, **pidfd_open**() returns a file descriptor (a nonnegative integer). On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EINVAL
: *flags* is not valid.

EINVAL
: *pid* is not valid.

EMFILE
: The per-process limit on the number of open file descriptors has been reached (see the description of **RLIMIT_NOFILE** in *getrlimit*(2)).

ENFILE
: The system-wide limit on the total number of open files has been reached.

ENODEV
: The anonymous inode filesystem is not available in this kernel.

ENOMEM
: Insufficient kernel memory was available.

ESRCH
: The process specified by *pid* does not exist.

STANDARDS

Linux.

HISTORY

Linux 5.3.

NOTES

The following code sequence can be used to obtain a file descriptor for the child of *fork*(2):

```
pid = fork();
if (pid > 0) {     /* If parent */
    pidfd = pidfd_open(pid, 0);
    ...
}
```

Even if the child has already terminated by the time of the **pidfd_open**() call, its PID will not have been recycled and the returned file descriptor will refer to the resulting zombie process. Note, however, that this is guaranteed only if the following conditions hold true:

- the disposition of **SIGCHLD** has not been explicitly set to **SIG_IGN** (see *sigaction*(2));
- the **SA_NOCLDWAIT** flag was not specified while establishing a handler for **SIGCHLD** or while setting the disposition of that signal to **SIG_DFL** (see *sigaction*(2)); and
- the zombie process was not reaped elsewhere in the program (e.g., either by an asynchronously executed signal handler or by *wait*(2) or similar in another thread).

If any of these conditions does not hold, then the child process (along with a PID file descriptor that refers to it) should instead be created using *clone*(2) with the **CLONE_PIDFD** flag.

Use cases for PID file descriptors

A PID file descriptor returned by **pidfd_open**() (or by *clone*(2) with the **CLONE_PID** flag) can be used for the following purposes:

- The *pidfd_send_signal*(2) system call can be used to send a signal to the process referred to by a PID file descriptor.
- A PID file descriptor can be monitored using *poll*(2), *select*(2), and *epoll*(7). When the process that it refers to terminates, these interfaces indicate the file descriptor as readable. Note, however, that in the current implementation, nothing can be read from the file descriptor (**read**(2) on the file descriptor fails with the error **EINVAL**).
- If the PID file descriptor refers to a child of the calling process, then it can be waited on using *waitid*(2).
- The *pidfd_getfd*(2) system call can be used to obtain a duplicate of a file descriptor of another process referred to by a PID file descriptor.
- A PID file descriptor can be used as the argument of *setns*(2) in order to move into one or more of the same namespaces as the process referred to by the file descriptor.
- A PID file descriptor can be used as the argument of *process_madvise*(2) in order to provide advice on the memory usage patterns of the process referred to by the file descriptor.

The **pidfd_open**() system call is the preferred way of obtaining a PID file descriptor for an already existing process. The alternative is to obtain a file descriptor by opening a */proc/*pid directory. However, the latter technique is possible only if the *proc*(5) filesystem is mounted; furthermore, the file descriptor obtained in this way is *not* pollable and can't be waited on with *waitid*(2).

EXAMPLES

The program below opens a PID file descriptor for the process whose PID is specified as its command-line argument. It then uses *poll*(2) to monitor the file descriptor for process exit, as indicated by an **EPOLLIN** event.

Program source

```
#define _GNU_SOURCE
#include <poll.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/syscall.h>
#include <unistd.h>

static int
pidfd_open(pid_t pid, unsigned int flags)
{
    return syscall(SYS_pidfd_open, pid, flags);
}

int
main(int argc, char *argv[])
{
    int            pidfd, ready;
    struct pollfd  pollfd;
```

```
        if (argc != 2) {
            fprintf(stderr, "Usage: %s <pid>\n", argv[0]);
            exit(EXIT_SUCCESS);
        }

        pidfd = pidfd_open(atoi(argv[1]), 0);
        if (pidfd == -1) {
            perror("pidfd_open");
            exit(EXIT_FAILURE);
        }

        pollfd.fd = pidfd;
        pollfd.events = POLLIN;

        ready = poll(&pollfd, 1, -1);
        if (ready == -1) {
            perror("poll");
            exit(EXIT_FAILURE);
        }

        printf("Events (%#x): POLLIN is %sset\n", pollfd.revents,
               (pollfd.revents & POLLIN) ? "" : "not ");

        close(pidfd);
        exit(EXIT_SUCCESS);
    }
```

SEE ALSO

clone(2), *kill*(2), *pidfd_getfd*(2), *pidfd_send_signal*(2), *poll*(2), *process_madvise*(2), *select*(2), *setns*(2), *waitid*(2), *epoll*(7)

NAME

pidfd_send_signal − send a signal to a process specified by a file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/signal.h>      /* Definition of SIG* constants */
#include <signal.h>            /* Definition of SI_* constants */
#include <sys/syscall.h>       /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_pidfd_send_signal, int pidfd, int sig,
            siginfo_t *_Nullable info, unsigned int flags);
```

Note: glibc provides no wrapper for **pidfd_send_signal**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **pidfd_send_signal**() system call sends the signal *sig* to the target process referred to by *pidfd*, a PID file descriptor that refers to a process.

If the *info* argument points to a *siginfo_t* buffer, that buffer should be populated as described in *rt_sigqueueinfo*(2).

If the *info* argument is a null pointer, this is equivalent to specifying a pointer to a *siginfo_t* buffer whose fields match the values that are implicitly supplied when a signal is sent using *kill*(2):

- *si_signo* is set to the signal number;
- *si_errno* is set to 0;
- *si_code* is set to **SI_USER**;
- *si_pid* is set to the caller's PID; and
- *si_uid* is set to the caller's real user ID.

The calling process must either be in the same PID namespace as the process referred to by *pidfd*, or be in an ancestor of that namespace.

The *flags* argument is reserved for future use; currently, this argument must be specified as 0.

RETURN VALUE

On success, **pidfd_send_signal**() returns 0. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF
: *pidfd* is not a valid PID file descriptor.

EINVAL
: *sig* is not a valid signal.

EINVAL
: The calling process is not in a PID namespace from which it can send a signal to the target process.

EINVAL
: *flags* is not 0.

EPERM
: The calling process does not have permission to send the signal to the target process.

EPERM
: *pidfd* doesn't refer to the calling process, and *info.si_code* is invalid (see *rt_sigqueueinfo*(2)).

ESRCH
: The target process does not exist (i.e., it has terminated and been waited on).

STANDARDS

Linux.

HISTORY

Linux 5.1.

NOTES

PID file descriptors

The *pidfd* argument is a PID file descriptor, a file descriptor that refers to process. Such a file descriptor can be obtained in any of the following ways:

- by opening a */proc/* pid directory;
- using *pidfd_open*(2); or
- via the PID file descriptor that is returned by a call to *clone*(2) or *clone3*(2) that specifies the **CLONE_PIDFD** flag.

The **pidfd_send_signal**() system call allows the avoidance of race conditions that occur when using traditional interfaces (such as *kill*(2)) to signal a process. The problem is that the traditional interfaces specify the target process via a process ID (PID), with the result that the sender may accidentally send a signal to the wrong process if the originally intended target process has terminated and its PID has been recycled for another process. By contrast, a PID file descriptor is a stable reference to a specific process; if that process terminates, **pidfd_send_signal**() fails with the error **ESRCH**.

EXAMPLES

```
#define _GNU_SOURCE
#include <fcntl.h>
#include <limits.h>
#include <signal.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/syscall.h>
#include <unistd.h>

static int
pidfd_send_signal(int pidfd, int sig, siginfo_t *info,
                  unsigned int flags)
{
    return syscall(SYS_pidfd_send_signal, pidfd, sig, info, flags);
}

int
main(int argc, char *argv[])
{
    int        pidfd, sig;
    char       path[PATH_MAX];
    siginfo_t  info;

    if (argc != 3) {
        fprintf(stderr, "Usage: %s <pid> <signal>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    sig = atoi(argv[2]);

    /* Obtain a PID file descriptor by opening the /proc/PID directory
       of the target process. */

    snprintf(path, sizeof(path), "/proc/%s", argv[1]);

    pidfd = open(path, O_RDONLY);
    if (pidfd == -1) {
        perror("open");
        exit(EXIT_FAILURE);
    }
```

```
        /* Populate a 'siginfo_t' structure for use with
           pidfd_send_signal(). */

        memset(&info, 0, sizeof(info));
        info.si_code = SI_QUEUE;
        info.si_signo = sig;
        info.si_errno = 0;
        info.si_uid = getuid();
        info.si_pid = getpid();
        info.si_value.sival_int = 1234;

        /* Send the signal. */

        if (pidfd_send_signal(pidfd, sig, &info, 0) == -1) {
            perror("pidfd_send_signal");
            exit(EXIT_FAILURE);
        }

        exit(EXIT_SUCCESS);
    }
```

NAME

pipe, pipe2 − create pipe

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int pipe(int pipefd[2]);

#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <fcntl.h>          /* Definition of O_* constants */
#include <unistd.h>

int pipe2(int pipefd[2], int flags);

/* On Alpha, IA-64, MIPS, SuperH, and SPARC/SPARC64, pipe() has the
   following prototype; see VERSIONS */

#include <unistd.h>

struct fd_pair {
    long fd[2];
};
struct fd_pair pipe(void);
```

DESCRIPTION

pipe() creates a pipe, a unidirectional data channel that can be used for interprocess communication. The array *pipefd* is used to return two file descriptors referring to the ends of the pipe. *pipefd[0]* refers to the read end of the pipe. *pipefd[1]* refers to the write end of the pipe. Data written to the write end of the pipe is buffered by the kernel until it is read from the read end of the pipe. For further details, see *pipe*(7).

If *flags* is 0, then **pipe2**() is the same as **pipe**(). The following values can be bitwise ORed in *flags* to obtain different behavior:

O_CLOEXEC
: Set the close-on-exec (**FD_CLOEXEC**) flag on the two new file descriptors. See the description of the same flag in *open*(2) for reasons why this may be useful.

O_DIRECT (since Linux 3.4)
: Create a pipe that performs I/O in "packet" mode. Each *write*(2) to the pipe is dealt with as a separate packet, and *read*(2)s from the pipe will read one packet at a time. Note the following points:

  - Writes of greater than **PIPE_BUF** bytes (see *pipe*(7)) will be split into multiple packets. The constant **PIPE_BUF** is defined in <*limits.h*>.
  - If a *read*(2) specifies a buffer size that is smaller than the next packet, then the requested number of bytes are read, and the excess bytes in the packet are discarded. Specifying a buffer size of **PIPE_BUF** will be sufficient to read the largest possible packets (see the previous point).
  - Zero-length packets are not supported. (A *read*(2) that specifies a buffer size of zero is a no-op, and returns 0.)

  Older kernels that do not support this flag will indicate this via an **EINVAL** error.

  Since Linux 4.5, it is possible to change the **O_DIRECT** setting of a pipe file descriptor using *fcntl*(2).

O_NONBLOCK
: Set the **O_NONBLOCK** file status flag on the open file descriptions referred to by the new file descriptors. Using this flag saves extra calls to *fcntl*(2) to achieve the same result.

O_NOTIFICATION_PIPE
: Since Linux 5.8, general notification mechanism is built on the top of the pipe where kernel splices notification messages into pipes opened by user space. The owner of the pipe has to tell the kernel which sources of events to watch and filters can also be applied to select which

subevents should be placed into the pipe.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, *errno* is set to indicate the error, and *pipefd* is left unchanged.

On Linux (and other systems), **pipe**() does not modify *pipefd* on failure. A requirement standardizing this behavior was added in POSIX.1-2008 TC2. The Linux-specific **pipe2**() system call likewise does not modify *pipefd* on failure.

ERRORS

EFAULT
pipefd is not valid.

EINVAL
(**pipe2**()) Invalid value in *flags*.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENFILE
The user hard limit on memory that can be allocated for pipes has been reached and the caller is not privileged; see *pipe*(7).

ENOPKG
(**pipe2**()) **O_NOTIFICATION_PIPE** was passed in *flags* and support for notifications (**CONFIG_WATCH_QUEUE**) is not compiled into the kernel.

VERSIONS

The System V ABI on some architectures allows the use of more than one register for returning multiple values; several architectures (namely, Alpha, IA-64, MIPS, SuperH, and SPARC/SPARC64) (ab)use this feature in order to implement the **pipe**() system call in a functional manner: the call doesn't take any arguments and returns a pair of file descriptors as the return value on success. The glibc **pipe**() wrapper function transparently deals with this. See *syscall*(2) for information regarding registers used for storing second file descriptor.

STANDARDS

pipe() POSIX.1-2008.

pipe2() Linux.

HISTORY

pipe() POSIX.1-2001.

pipe2() Linux 2.6.27, glibc 2.9.

EXAMPLES

The following program creates a pipe, and then *fork*(2)s to create a child process; the child inherits a duplicate set of file descriptors that refer to the same pipe. After the *fork*(2), each process closes the file descriptors that it doesn't need for the pipe (see *pipe*(7)). The parent then writes the string contained in the program's command-line argument to the pipe, and the child reads this string a byte at a time from the pipe and echoes it on standard output.

Program source

```
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/wait.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int    pipefd[2];
    char   buf;
```

```
        pid_t  cpid;

        if (argc != 2) {
            fprintf(stderr, "Usage: %s <string>\n", argv[0]);
            exit(EXIT_FAILURE);
        }

        if (pipe(pipefd) == -1) {
            perror("pipe");
            exit(EXIT_FAILURE);
        }

        cpid = fork();
        if (cpid == -1) {
            perror("fork");
            exit(EXIT_FAILURE);
        }

        if (cpid == 0) {    /* Child reads from pipe */
            close(pipefd[1]);          /* Close unused write end */

            while (read(pipefd[0], &buf, 1) > 0)
                write(STDOUT_FILENO, &buf, 1);

            write(STDOUT_FILENO, "\n", 1);
            close(pipefd[0]);
            _exit(EXIT_SUCCESS);

        } else {            /* Parent writes argv[1] to pipe */
            close(pipefd[0]);          /* Close unused read end */
            write(pipefd[1], argv[1], strlen(argv[1]));
            close(pipefd[1]);          /* Reader will see EOF */
            wait(NULL);                /* Wait for child */
            exit(EXIT_SUCCESS);
        }
    }
```

NAME

pivot_root − change the root mount

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_pivot_root, const char **new_root*, const char **put_old*);

Note: glibc provides no wrapper for **pivot_root**(), necessitating the use of *syscall*(2).

DESCRIPTION

pivot_root() changes the root mount in the mount namespace of the calling process. More precisely, it moves the root mount to the directory *put_old* and makes *new_root* the new root mount. The calling process must have the **CAP_SYS_ADMIN** capability in the user namespace that owns the caller's mount namespace.

pivot_root() changes the root directory and the current working directory of each process or thread in the same mount namespace to *new_root* if they point to the old root directory. (See also NOTES.) On the other hand, **pivot_root**() does not change the caller's current working directory (unless it is on the old root directory), and thus it should be followed by a **chdir("/")** call.

The following restrictions apply:

- *new_root* and *put_old* must be directories.
- *new_root* and *put_old* must not be on the same mount as the current root.
- *put_old* must be at or underneath *new_root*; that is, adding some nonnegative number of "/.." suffixes to the pathname pointed to by *put_old* must yield the same directory as *new_root*.
- *new_root* must be a path to a mount point, but can't be *"/"*. A path that is not already a mount point can be converted into one by bind mounting the path onto itself.
- The propagation type of the parent mount of *new_root* and the parent mount of the current root directory must not be **MS_SHARED**; similarly, if *put_old* is an existing mount point, its propagation type must not be **MS_SHARED**. These restrictions ensure that **pivot_root**() never propagates any changes to another mount namespace.
- The current root directory must be a mount point.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

pivot_root() may fail with any of the same errors as *stat*(2). Additionally, it may fail with the following errors:

EBUSY
new_root or *put_old* is on the current root mount. (This error covers the pathological case where *new_root* is *"/"*.)

EINVAL
new_root is not a mount point.

EINVAL
put_old is not at or underneath *new_root*.

EINVAL
The current root directory is not a mount point (because of an earlier *chroot*(2)).

EINVAL
The current root is on the rootfs (initial ramfs) mount; see NOTES.

EINVAL
Either the mount point at *new_root*, or the parent mount of that mount point, has propagation type **MS_SHARED**.

EINVAL
put_old is a mount point and has the propagation type **MS_SHARED**.

ENOTDIR
new_root or *put_old* is not a directory.

EPERM
The calling process does not have the **CAP_SYS_ADMIN** capability.

STANDARDS
Linux.

HISTORY
Linux 2.3.41.

NOTES
A command-line interface for this system call is provided by *pivot_root*(8)

pivot_root() allows the caller to switch to a new root filesystem while at the same time placing the old root mount at a location under *new_root* from where it can subsequently be unmounted. (The fact that it moves all processes that have a root directory or current working directory on the old root directory to the new root frees the old root directory of users, allowing the old root mount to be unmounted more easily.)

One use of **pivot_root**() is during system startup, when the system mounts a temporary root filesystem (e.g., an *initrd*(4)), then mounts the real root filesystem, and eventually turns the latter into the root directory of all relevant processes and threads. A modern use is to set up a root filesystem during the creation of a container.

The fact that **pivot_root**() modifies process root and current working directories in the manner noted in DESCRIPTION is necessary in order to prevent kernel threads from keeping the old root mount busy with their root and current working directories, even if they never access the filesystem in any way.

The rootfs (initial ramfs) cannot be **pivot_root**()ed. The recommended method of changing the root filesystem in this case is to delete everything in rootfs, overmount rootfs with the new root, attach *stdin*/*stdout*/*stderr* to the new */dev/console*, and exec the new *init*(1)Helper programs for this process exist; see *switch_root*(8)

pivot_root(".", ".")
new_root and *put_old* may be the same directory. In particular, the following sequence allows a pivot-root operation without needing to create and remove a temporary directory:

```
chdir(new_root);
pivot_root(".", ".");
umount2(".", MNT_DETACH);
```

This sequence succeeds because the **pivot_root**() call stacks the old root mount point on top of the new root mount point at `/`. At that point, the calling process's root directory and current working directory refer to the new root mount point (*new_root*). During the subsequent **umount**() call, resolution of *"."* starts with *new_root* and then moves up the list of mounts stacked at `/`, with the result that old root mount point is unmounted.

Historical notes
For many years, this manual page carried the following text:

> **pivot_root**() may or may not change the current root and the current working directory of any processes or threads which use the old root directory. The caller of **pivot_root**() must ensure that processes with root or current working directory at the old root operate correctly in either case. An easy way to ensure this is to change their root and current working directory to *new_root* before invoking **pivot_root**().

This text, written before the system call implementation was even finalized in the kernel, was probably intended to warn users at that time that the implementation might change before final release. However, the behavior stated in DESCRIPTION has remained consistent since this system call was first implemented and will not change now.

EXAMPLES

The program below demonstrates the use of **pivot_root**() inside a mount namespace that is created using *clone*(2). After pivoting to the root directory named in the program's first command-line argument, the child created by *clone*(2) then executes the program named in the remaining command-line arguments.

We demonstrate the program by creating a directory that will serve as the new root filesystem and placing a copy of the (statically linked) *busybox*(1) executable in that directory.

```
$ mkdir /tmp/rootfs
$ ls -id /tmp/rootfs    # Show inode number of new root directory
319459 /tmp/rootfs
$ cp $(which busybox) /tmp/rootfs
$ PS1='bbsh$ ' sudo ./pivot_root_demo /tmp/rootfs /busybox sh
bbsh$ PATH=/
bbsh$ busybox ln busybox ln
bbsh$ ln busybox echo
bbsh$ ln busybox ls
bbsh$ ls
busybox  echo     ln       ls
bbsh$ ls -id /          # Compare with inode number above
319459 /
bbsh$ echo 'hello world'
hello world
```

NAME

pkey_alloc, pkey_free − allocate or free a protection key

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sys/mman.h>

int pkey_alloc(unsigned int flags, unsigned int access_rights);
int pkey_free(int pkey);
```

DESCRIPTION

pkey_alloc() allocates a protection key (pkey) and allows it to be passed to *pkey_mprotect*(2).

The **pkey_alloc**() *flags* is reserved for future use and currently must always be specified as 0.

The **pkey_alloc**() *access_rights* argument may contain zero or more disable operations:

PKEY_DISABLE_ACCESS
: Disable all data access to memory covered by the returned protection key.

PKEY_DISABLE_WRITE
: Disable write access to memory covered by the returned protection key.

pkey_free() frees a protection key and makes it available for later allocations. After a protection key has been freed, it may no longer be used in any protection-key-related operations.

An application should not call **pkey_free**() on any protection key which has been assigned to an address range by *pkey_mprotect*(2) and which is still in use. The behavior in this case is undefined and may result in an error.

RETURN VALUE

On success, **pkey_alloc**() returns a positive protection key value. On success, **pkey_free**() returns zero. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
: *pkey*, *flags*, or *access_rights* is invalid.

ENOSPC
: (**pkey_alloc**()) All protection keys available for the current process have been allocated. The number of keys available is architecture-specific and implementation-specific and may be reduced by kernel-internal use of certain keys. There are currently 15 keys available to user programs on x86.

  This error will also be returned if the processor or operating system does not support protection keys. Applications should always be prepared to handle this error, since factors outside of the application's control can reduce the number of available pkeys.

STANDARDS

Linux.

HISTORY

Linux 4.9, glibc 2.27.

NOTES

pkey_alloc() is always safe to call regardless of whether or not the operating system supports protection keys. It can be used in lieu of any other mechanism for detecting pkey support and will simply fail with the error **ENOSPC** if the operating system has no pkey support.

The kernel guarantees that the contents of the hardware rights register (PKRU) will be preserved only for allocated protection keys. Any time a key is unallocated (either before the first call returning that key from **pkey_alloc**() or after it is freed via *pkey_free*()), the kernel may make arbitrary changes to the parts of the rights register affecting access to that key.

EXAMPLES

See *pkeys*(7).

NAME

poll, ppoll − wait for some event on a file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <poll.h>

int poll(struct pollfd * fds, nfds_t nfds, int timeout);

#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <poll.h>

int ppoll(struct pollfd * fds, nfds_t nfds,
      const struct timespec *_Nullable tmo_p,
      const sigset_t *_Nullable sigmask);
```

DESCRIPTION

poll() performs a similar task to *select*(2): it waits for one of a set of file descriptors to become ready to perform I/O. The Linux-specific *epoll*(7) API performs a similar task, but offers features beyond those found in **poll**().

The set of file descriptors to be monitored is specified in the *fds* argument, which is an array of structures of the following form:

```
struct pollfd {
    int   fd;         /* file descriptor */
    short events;     /* requested events */
    short revents;    /* returned events */
};
```

The caller should specify the number of items in the *fds* array in *nfds*.

The field *fd* contains a file descriptor for an open file. If this field is negative, then the corresponding *events* field is ignored and the *revents* field returns zero. (This provides an easy way of ignoring a file descriptor for a single **poll**() call: simply set the *fd* field to its bitwise complement.)

The field *events* is an input parameter, a bit mask specifying the events the application is interested in for the file descriptor *fd*. This field may be specified as zero, in which case the only events that can be returned in *revents* are **POLLHUP**, **POLLERR**, and **POLLNVAL** (see below).

The field *revents* is an output parameter, filled by the kernel with the events that actually occurred. The bits returned in *revents* can include any of those specified in *events*, or one of the values **POLLERR**, **POLLHUP**, or **POLLNVAL**. (These three bits are meaningless in the *events* field, and will be set in the *revents* field whenever the corresponding condition is true.)

If none of the events requested (and no error) has occurred for any of the file descriptors, then **poll**() blocks until one of the events occurs.

The *timeout* argument specifies the number of milliseconds that **poll**() should block waiting for a file descriptor to become ready. The call will block until either:

- a file descriptor becomes ready;
- the call is interrupted by a signal handler; or
- the timeout expires.

Being "ready" means that the requested operation will not block; thus, **poll**()ing regular files, block devices, and other files with no reasonable polling semantic *always* returns instantly as ready to read and write.

Note that the *timeout* interval will be rounded up to the system clock granularity, and kernel scheduling delays mean that the blocking interval may overrun by a small amount. Specifying a negative value in *timeout* means an infinite timeout. Specifying a *timeout* of zero causes **poll**() to return immediately, even if no file descriptors are ready.

The bits that may be set/returned in *events* and *revents* are defined in <*poll.h*>:

POLLIN
There is data to read.

POLLPRI
There is some exceptional condition on the file descriptor. Possibilities include:

- There is out-of-band data on a TCP socket (see *tcp*(7)).
- A pseudoterminal master in packet mode has seen a state change on the slave (see *ioctl_tty*(2)).
- A *cgroup.events* file has been modified (see *cgroups*(7)).

POLLOUT
Writing is now possible, though a write larger than the available space in a socket or pipe will still block (unless **O_NONBLOCK** is set).

POLLRDHUP (since Linux 2.6.17)
Stream socket peer closed connection, or shut down writing half of connection. The **_GNU_SOURCE** feature test macro must be defined (before including *any* header files) in order to obtain this definition.

POLLERR
Error condition (only returned in *revents*; ignored in *events*). This bit is also set for a file descriptor referring to the write end of a pipe when the read end has been closed.

POLLHUP
Hang up (only returned in *revents*; ignored in *events*). Note that when reading from a channel such as a pipe or a stream socket, this event merely indicates that the peer closed its end of the channel. Subsequent reads from the channel will return 0 (end of file) only after all outstanding data in the channel has been consumed.

POLLNVAL
Invalid request: *fd* not open (only returned in *revents*; ignored in *events*).

When compiling with **_XOPEN_SOURCE** defined, one also has the following, which convey no further information beyond the bits listed above:

POLLRDNORM
Equivalent to **POLLIN**.

POLLRDBAND
Priority band data can be read (generally unused on Linux).

POLLWRNORM
Equivalent to **POLLOUT**.

POLLWRBAND
Priority data may be written.

Linux also knows about, but does not use **POLLMSG**.

ppoll()

The relationship between **poll**() and **ppoll**() is analogous to the relationship between *select*(2) and *pselect*(2): like *pselect*(2), **ppoll**() allows an application to safely wait until either a file descriptor becomes ready or until a signal is caught.

Other than the difference in the precision of the *timeout* argument, the following **ppoll**() call:

```
ready = ppoll(&fds, nfds, tmo_p, &sigmask);
```

is nearly equivalent to *atomically* executing the following calls:

```
sigset_t origmask;
int timeout;

timeout = (tmo_p == NULL) ? -1 :
          (tmo_p->tv_sec * 1000 + tmo_p->tv_nsec / 1000000);
pthread_sigmask(SIG_SETMASK, &sigmask, &origmask);
ready = poll(&fds, nfds, timeout);
pthread_sigmask(SIG_SETMASK, &origmask, NULL);
```

The above code segment is described as *nearly* equivalent because whereas a negative *timeout* value for **poll**() is interpreted as an infinite timeout, a negative value expressed in **tmo_p* results in an error from **ppoll**().

See the description of *pselect*(2) for an explanation of why **ppoll**() is necessary.

If the *sigmask* argument is specified as NULL, then no signal mask manipulation is performed (and thus **ppoll**() differs from **poll**() only in the precision of the *timeout* argument).

The *tmo_p* argument specifies an upper limit on the amount of time that **ppoll**() will block. This argument is a pointer to a *timespec*(3) structure.

If *tmo_p* is specified as NULL, then **ppoll**() can block indefinitely.

RETURN VALUE

On success, **poll**() returns a nonnegative value which is the number of elements in the *pollfds* whose *revents* fields have been set to a nonzero value (indicating an event or an error). A return value of zero indicates that the system call timed out before any file descriptors became ready.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
: *fds* points outside the process's accessible address space. The array given as argument was not contained in the calling program's address space.

EINTR
: A signal occurred before any requested event; see *signal*(7).

EINVAL
: The *nfds* value exceeds the **RLIMIT_NOFILE** value.

EINVAL
: (**ppoll**()) The timeout value expressed in **tmo_p* is invalid (negative).

ENOMEM
: Unable to allocate memory for kernel data structures.

VERSIONS

On some other UNIX systems, **poll**() can fail with the error **EAGAIN** if the system fails to allocate kernel-internal resources, rather than **ENOMEM** as Linux does. POSIX permits this behavior. Portable programs may wish to check for **EAGAIN** and loop, just as with **EINTR**.

Some implementations define the nonstandard constant **INFTIM** with the value −1 for use as a *timeout* for **poll**(). This constant is not provided in glibc.

C library/kernel differences

The Linux **ppoll**() system call modifies its *tmo_p* argument. However, the glibc wrapper function hides this behavior by using a local variable for the timeout argument that is passed to the system call. Thus, the glibc **ppoll**() function does not modify its *tmo_p* argument.

The raw **ppoll**() system call has a fifth argument, *size_t sigsetsize*, which specifies the size in bytes of the *sigmask* argument. The glibc **ppoll**() wrapper function specifies this argument as a fixed value (equal to *sizeof(kernel_sigset_t)*). See *sigprocmask*(2) for a discussion on the differences between the kernel and the libc notion of the sigset.

STANDARDS

poll() POSIX.1-2008.

ppoll() Linux.

HISTORY

poll() POSIX.1-2001. Linux 2.1.23.

On older kernels that lack this system call, the glibc **poll**() wrapper function provides emulation using *select*(2).

ppoll() Linux 2.6.16, glibc 2.4.

NOTES

The operation of **poll**() and **ppoll**() is not affected by the **O_NONBLOCK** flag.

For a discussion of what may happen if a file descriptor being monitored by **poll**() is closed in another thread, see *select*(2).

BUGS

See the discussion of spurious readiness notifications under the BUGS section of *select*(2).

EXAMPLES

The program below opens each of the files named in its command-line arguments and monitors the resulting file descriptors for readiness to read (**POLLIN**). The program loops, repeatedly using **poll**() to monitor the file descriptors, printing the number of ready file descriptors on return. For each ready file descriptor, the program:

- displays the returned *revents* field in a human-readable form;
- if the file descriptor is readable, reads some data from it, and displays that data on standard output; and
- if the file descriptor was not readable, but some other event occurred (presumably **POLLHUP**), closes the file descriptor.

Suppose we run the program in one terminal, asking it to open a FIFO:

```
$ mkfifo myfifo
$ ./poll_input myfifo
```

In a second terminal window, we then open the FIFO for writing, write some data to it, and close the FIFO:

```
$ echo aaaaabbbbbccccc > myfifo
```

In the terminal where we are running the program, we would then see:

```
Opened "myfifo" on fd 3
About to poll()
Ready: 1
  fd=3; events: POLLIN POLLHUP
    read 10 bytes: aaaaabbbbb
About to poll()
Ready: 1
  fd=3; events: POLLIN POLLHUP
    read 6 bytes: ccccc

About to poll()
Ready: 1
  fd=3; events: POLLHUP
    closing fd 3
All file descriptors closed; bye
```

In the above output, we see that **poll**() returned three times:

- On the first return, the bits returned in the *revents* field were **POLLIN**, indicating that the file descriptor is readable, and **POLLHUP**, indicating that the other end of the FIFO has been closed. The program then consumed some of the available input.
- The second return from **poll**() also indicated **POLLIN** and **POLLHUP**; the program then consumed the last of the available input.
- On the final return, **poll**() indicated only **POLLHUP** on the FIFO, at which point the file descriptor was closed and the program terminated.

NAME

posix_fadvise − predeclare an access pattern for file data

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <fcntl.h>

int posix_fadvise(int fd, off_t offset, off_t len, int advice);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

posix_fadvise():
_POSIX_C_SOURCE >= 200112L

DESCRIPTION

Programs can use **posix_fadvise**() to announce an intention to access file data in a specific pattern in the future, thus allowing the kernel to perform appropriate optimizations.

The *advice* applies to a (not necessarily existent) region starting at *offset* and extending for *len* bytes (or until the end of the file if *len* is 0) within the file referred to by *fd*. The *advice* is not binding; it merely constitutes an expectation on behalf of the application.

Permissible values for *advice* include:

POSIX_FADV_NORMAL
: Indicates that the application has no advice to give about its access pattern for the specified data. If no advice is given for an open file, this is the default assumption.

POSIX_FADV_SEQUENTIAL
: The application expects to access the specified data sequentially (with lower offsets read before higher ones).

POSIX_FADV_RANDOM
: The specified data will be accessed in random order.

POSIX_FADV_NOREUSE
: The specified data will be accessed only once.

  Before Linux 2.6.18, **POSIX_FADV_NOREUSE** had the same semantics as **POSIX_FADV_WILLNEED**. This was probably a bug; since Linux 2.6.18, this flag is a no-op.

POSIX_FADV_WILLNEED
: The specified data will be accessed in the near future.

  POSIX_FADV_WILLNEED initiates a nonblocking read of the specified region into the page cache. The amount of data read may be decreased by the kernel depending on virtual memory load. (A few megabytes will usually be fully satisfied, and more is rarely useful.)

POSIX_FADV_DONTNEED
: The specified data will not be accessed in the near future.

  POSIX_FADV_DONTNEED attempts to free cached pages associated with the specified region. This is useful, for example, while streaming large files. A program may periodically request the kernel to free cached data that has already been used, so that more useful cached pages are not discarded instead.

  Requests to discard partial pages are ignored. It is preferable to preserve needed data than discard unneeded data. If the application requires that data be considered for discarding, then *offset* and *len* must be page-aligned.

  The implementation *may* attempt to write back dirty pages in the specified region, but this is not guaranteed. Any unwritten dirty pages will not be freed. If the application wishes to ensure that dirty pages will be released, it should call *fsync*(2) or *fdatasync*(2) first.

RETURN VALUE

On success, zero is returned. On error, an error number is returned.

ERRORS

EBADF
The *fd* argument was not a valid file descriptor.

EINVAL
An invalid value was specified for *advice*.

ESPIPE
The specified file descriptor refers to a pipe or FIFO. (**ESPIPE** is the error specified by POSIX, but before Linux 2.6.16, Linux returned **EINVAL** in this case.)

VERSIONS

Under Linux, **POSIX_FADV_NORMAL** sets the readahead window to the default size for the backing device; **POSIX_FADV_SEQUENTIAL** doubles this size, and **POSIX_FADV_RANDOM** disables file readahead entirely. These changes affect the entire file, not just the specified region (but other open file handles to the same file are unaffected).

C library/kernel differences

The name of the wrapper function in the C library is **posix_fadvise**(). The underlying system call is called **fadvise64**() (or, on some architectures, *fadvise64_64*()); the difference between the two is that the former system call assumes that the type of the *len* argument is *size_t*, while the latter expects *loff_t* there.

Architecture-specific variants

Some architectures require 64-bit arguments to be aligned in a suitable pair of registers (see *syscall*(2) for further detail). On such architectures, the call signature of **posix_fadvise**() shown in the SYNOPSIS would force a register to be wasted as padding between the *fd* and *offset* arguments. Therefore, these architectures define a version of the system call that orders the arguments suitably, but is otherwise exactly the same as **posix_fadvise**().

For example, since Linux 2.6.14, ARM has the following system call:

```
long arm_fadvise64_64(int fd, int advice,
                      loff_t offset, loff_t len);
```

These architecture-specific details are generally hidden from applications by the glibc **posix_fadvise**() wrapper function, which invokes the appropriate architecture-specific system call.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

Kernel support first appeared in Linux 2.5.60; the underlying system call is called **fadvise64**(). Library support has been provided since glibc 2.2, via the wrapper function **posix_fadvise**().

Since Linux 3.18, support for the underlying system call is optional, depending on the setting of the **CONFIG_ADVISE_SYSCALLS** configuration option.

The type of the *len* argument was changed from *size_t* to *off_t* in POSIX.1-2001 TC1.

NOTES

The contents of the kernel buffer cache can be cleared via the */proc/sys/vm/drop_caches* interface described in *proc*(5).

One can obtain a snapshot of which pages of a file are resident in the buffer cache by opening a file, mapping it with *mmap*(2), and then applying *mincore*(2) to the mapping.

BUGS

Before Linux 2.6.6, if *len* was specified as 0, then this was interpreted literally as "zero bytes", rather than as meaning "all bytes through to the end of the file".

NAME

prctl − operations on a process or thread

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/prctl.h>

int prctl(int *op***, ...**
/* **unsigned long** *arg2***, unsigned long** *arg3***,**
unsigned long *arg4***, unsigned long** *arg5* */ **);**

DESCRIPTION

prctl() manipulates various aspects of the behavior of the calling thread or process.

Note that careless use of some **prctl**() operations can confuse the user-space run-time environment, so these operations should be used with care.

prctl() is called with a first argument describing what to do (with values defined in *<linux/prctl.h>*), and further arguments with a significance depending on the first one. The first argument can be:

PR_CAP_AMBIENT (since Linux 4.3)
Reads or changes the ambient capability set of the calling thread, according to the value of *arg2*, which must be one of the following:

PR_CAP_AMBIENT_RAISE
The capability specified in *arg3* is added to the ambient set. The specified capability must already be present in both the permitted and the inheritable sets of the process. This operation is not permitted if the **SECBIT_NO_CAP_AMBIENT_RAISE** securebit is set.

PR_CAP_AMBIENT_LOWER
The capability specified in *arg3* is removed from the ambient set.

PR_CAP_AMBIENT_IS_SET
The **prctl**() call returns 1 if the capability in *arg3* is in the ambient set and 0 if it is not.

PR_CAP_AMBIENT_CLEAR_ALL
All capabilities will be removed from the ambient set. This operation requires setting *arg3* to zero.

In all of the above operations, *arg4* and *arg5* must be specified as 0.

Higher-level interfaces layered on top of the above operations are provided in the *libcap*(3) library in the form of *cap_get_ambient*(3), *cap_set_ambient*(3), and *cap_reset_ambient*(3)

PR_CAPBSET_READ (since Linux 2.6.25)
Return (as the function result) 1 if the capability specified in *arg2* is in the calling thread's capability bounding set, or 0 if it is not. (The capability constants are defined in *<linux/capability.h>*.) The capability bounding set dictates whether the process can receive the capability through a file's permitted capability set on a subsequent call to *execve*(2).

If the capability specified in *arg2* is not valid, then the call fails with the error **EINVAL**.

A higher-level interface layered on top of this operation is provided in the *libcap*(3) library in the form of *cap_get_bound*(3)

PR_CAPBSET_DROP (since Linux 2.6.25)
If the calling thread has the **CAP_SETPCAP** capability within its user namespace, then drop the capability specified by *arg2* from the calling thread's capability bounding set. Any children of the calling thread will inherit the newly reduced bounding set.

The call fails with the error: **EPERM** if the calling thread does not have the **CAP_SETPCAP**; **EINVAL** if *arg2* does not represent a valid capability; or **EINVAL** if file capabilities are not enabled in the kernel, in which case bounding sets are not supported.

A higher-level interface layered on top of this operation is provided in the *libcap*(3) library in the form of *cap_drop_bound*(3)

PR_SET_CHILD_SUBREAPER (since Linux 3.4)
If *arg2* is nonzero, set the "child subreaper" attribute of the calling process; if *arg2* is zero, unset the attribute.

A subreaper fulfills the role of *init*(1) for its descendant processes. When a process becomes orphaned (i.e., its immediate parent terminates), then that process will be reparented to the nearest still living ancestor subreaper. Subsequently, calls to *getppid*(2) in the orphaned process will now return the PID of the subreaper process, and when the orphan terminates, it is the subreaper process that will receive a **SIGCHLD** signal and will be able to *wait*(2) on the process to discover its termination status.

The setting of the "child subreaper" attribute is not inherited by children created by *fork*(2) and *clone*(2). The setting is preserved across *execve*(2).

Establishing a subreaper process is useful in session management frameworks where a hierarchical group of processes is managed by a subreaper process that needs to be informed when one of the processes—for example, a double-forked daemon—terminates (perhaps so that it can restart that process). Some *init*(1) frameworks (e.g., *systemd*(1)) employ a subreaper process for similar reasons.

PR_GET_CHILD_SUBREAPER (since Linux 3.4)
Return the "child subreaper" setting of the caller, in the location pointed to by *(int *) arg2*.

PR_SET_DUMPABLE (since Linux 2.3.20)
Set the state of the "dumpable" attribute, which determines whether core dumps are produced for the calling process upon delivery of a signal whose default behavior is to produce a core dump.

Up to and including Linux 2.6.12, *arg2* must be either 0 (**SUID_DUMP_DISABLE**, process is not dumpable) or 1 (**SUID_DUMP_USER**, process is dumpable). Between Linux 2.6.13 and Linux 2.6.17, the value 2 was also permitted, which caused any binary which normally would not be dumped to be dumped readable by root only; for security reasons, this feature has been removed. (See also the description of */proc/sys/fs/suid_dumpable* in *proc*(5).)

Normally, the "dumpable" attribute is set to 1. However, it is reset to the current value contained in the file */proc/sys/fs/suid_dumpable* (which by default has the value 0), in the following circumstances:

- The process's effective user or group ID is changed.
- The process's filesystem user or group ID is changed (see *credentials*(7)).
- The process executes (**execve**(2)) a set-user-ID or set-group-ID program, resulting in a change of either the effective user ID or the effective group ID.
- The process executes (**execve**(2)) a program that has file capabilities (see *capabilities*(7)), but only if the permitted capabilities gained exceed those already permitted for the process.

Processes that are not dumpable can not be attached via *ptrace*(2) **PTRACE_ATTACH**; see *ptrace*(2) for further details.

If a process is not dumpable, the ownership of files in the process's */proc/*pid directory is affected as described in *proc*(5).

PR_GET_DUMPABLE (since Linux 2.3.20)
Return (as the function result) the current state of the calling process's dumpable attribute.

PR_SET_ENDIAN (since Linux 2.6.18, PowerPC only)
Set the endian-ness of the calling process to the value given in *arg2*, which should be one of the following: **PR_ENDIAN_BIG**, **PR_ENDIAN_LITTLE**, or **PR_ENDIAN_PPC_LITTLE** (PowerPC pseudo little endian).

PR_GET_ENDIAN (since Linux 2.6.18, PowerPC only)
Return the endian-ness of the calling process, in the location pointed to by *(int *) arg2*.

PR_SET_FP_MODE (since Linux 4.0, only on MIPS)
On the MIPS architecture, user-space code can be built using an ABI which permits linking with code that has more restrictive floating-point (FP) requirements. For example, user-space

code may be built to target the O32 FPXX ABI and linked with code built for either one of the more restrictive FP32 or FP64 ABIs. When more restrictive code is linked in, the overall requirement for the process is to use the more restrictive floating-point mode.

Because the kernel has no means of knowing in advance which mode the process should be executed in, and because these restrictions can change over the lifetime of the process, the **PR_SET_FP_MODE** operation is provided to allow control of the floating-point mode from user space.

The *(unsigned int) arg2* argument is a bit mask describing the floating-point mode used:

PR_FP_MODE_FR
When this bit is *unset* (so called **FR=0** or **FR0** mode), the 32 floating-point registers are 32 bits wide, and 64-bit registers are represented as a pair of registers (even- and odd- numbered, with the even-numbered register containing the lower 32 bits, and the odd-numbered register containing the higher 32 bits).

When this bit is *set* (on supported hardware), the 32 floating-point registers are 64 bits wide (so called **FR=1** or **FR1** mode). Note that modern MIPS implementations (MIPS R6 and newer) support **FR=1** mode only.

Applications that use the O32 FP32 ABI can operate only when this bit is *unset* (**FR=0**; or they can be used with FRE enabled, see below). Applications that use the O32 FP64 ABI (and the O32 FP64A ABI, which exists to provide the ability to operate with existing FP32 code; see below) can operate only when this bit is *set* (**FR=1**). Applications that use the O32 FPXX ABI can operate with either **FR=0** or **FR=1**.

PR_FP_MODE_FRE
Enable emulation of 32-bit floating-point mode. When this mode is enabled, it emulates 32-bit floating-point operations by raising a reserved-instruction exception on every instruction that uses 32-bit formats and the kernel then handles the instruction in software. (The problem lies in the discrepancy of handling odd-numbered registers which are the high 32 bits of 64-bit registers with even numbers in **FR=0** mode and the lower 32-bit parts of odd-numbered 64-bit registers in **FR=1** mode.) Enabling this bit is necessary when code with the O32 FP32 ABI should operate with code with compatible the O32 FPXX or O32 FP64A ABIs (which require **FR=1** FPU mode) or when it is executed on newer hardware (MIPS R6 onwards) which lacks **FR=0** mode support when a binary with the FP32 ABI is used.

Note that this mode makes sense only when the FPU is in 64-bit mode (**FR=1**).

Note that the use of emulation inherently has a significant performance hit and should be avoided if possible.

In the N32/N64 ABI, 64-bit floating-point mode is always used, so FPU emulation is not required and the FPU always operates in **FR=1** mode.

This operation is mainly intended for use by the dynamic linker (**ld.so**(8)).

The arguments *arg3*, *arg4*, and *arg5* are ignored.

PR_GET_FP_MODE (since Linux 4.0, only on MIPS)
Return (as the function result) the current floating-point mode (see the description of **PR_SET_FP_MODE** for details).

On success, the call returns a bit mask which represents the current floating-point mode.

The arguments *arg2*, *arg3*, *arg4*, and *arg5* are ignored.

PR_SET_FPEMU (since Linux 2.4.18, 2.5.9, only on ia64)
Set floating-point emulation control bits to *arg2*. Pass **PR_FPEMU_NOPRINT** to silently emulate floating-point operation accesses, or **PR_FPEMU_SIGFPE** to not emulate floating-point operations and send **SIGFPE** instead.

PR_GET_FPEMU (since Linux 2.4.18, 2.5.9, only on ia64)
Return floating-point emulation control bits, in the location pointed to by *(int *) arg2*.

PR_SET_FPEXC (since Linux 2.4.21, 2.5.32, only on PowerPC)
Set floating-point exception mode to *arg2*. Pass **PR_FP_EXC_SW_ENABLE** to use FPEXC for FP exception enables, **PR_FP_EXC_DIV** for floating-point divide by zero, **PR_FP_EXC_OVF** for floating-point overflow, **PR_FP_EXC_UND** for floating-point underflow, **PR_FP_EXC_RES** for floating-point inexact result, **PR_FP_EXC_INV** for floating-point invalid operation, **PR_FP_EXC_DISABLED** for FP exceptions disabled, **PR_FP_EXC_NONRECOV** for async nonrecoverable exception mode, **PR_FP_EXC_ASYNC** for async recoverable exception mode, **PR_FP_EXC_PRECISE** for precise exception mode.

PR_GET_FPEXC (since Linux 2.4.21, 2.5.32, only on PowerPC)
Return floating-point exception mode, in the location pointed to by *(int *) arg2*.

PR_SET_IO_FLUSHER (since Linux 5.6)
If a user process is involved in the block layer or filesystem I/O path, and can allocate memory while processing I/O requests it must set *arg2* to 1. This will put the process in the IO_FLUSHER state, which allows it special treatment to make progress when allocating memory. If *arg2* is 0, the process will clear the IO_FLUSHER state, and the default behavior will be used.

The calling process must have the **CAP_SYS_RESOURCE** capability.

arg3, *arg4*, and *arg5* must be zero.

The IO_FLUSHER state is inherited by a child process created via *fork*(2) and is preserved across *execve*(2).

Examples of IO_FLUSHER applications are FUSE daemons, SCSI device emulation daemons, and daemons that perform error handling like multipath path recovery applications.

PR_GET_IO_FLUSHER (Since Linux 5.6)
Return (as the function result) the IO_FLUSHER state of the caller. A value of 1 indicates that the caller is in the IO_FLUSHER state; 0 indicates that the caller is not in the IO_FLUSHER state.

The calling process must have the **CAP_SYS_RESOURCE** capability.

arg2, *arg3*, *arg4*, and *arg5* must be zero.

PR_SET_KEEPCAPS (since Linux 2.2.18)
Set the state of the calling thread's "keep capabilities" flag. The effect of this flag is described in *capabilities*(7). *arg2* must be either 0 (clear the flag) or 1 (set the flag). The "keep capabilities" value will be reset to 0 on subsequent calls to *execve*(2).

PR_GET_KEEPCAPS (since Linux 2.2.18)
Return (as the function result) the current state of the calling thread's "keep capabilities" flag. See *capabilities*(7) for a description of this flag.

PR_MCE_KILL (since Linux 2.6.32)
Set the machine check memory corruption kill policy for the calling thread. If *arg2* is **PR_MCE_KILL_CLEAR**, clear the thread memory corruption kill policy and use the system-wide default. (The system-wide default is defined by */proc/sys/vm/memory_failure_early_kill*; see *proc*(5).) If *arg2* is **PR_MCE_KILL_SET**, use a thread-specific memory corruption kill policy. In this case, *arg3* defines whether the policy is *early kill* (**PR_MCE_KILL_EARLY**), *late kill* (**PR_MCE_KILL_LATE**), or the system-wide default (**PR_MCE_KILL_DEFAULT**). Early kill means that the thread receives a **SIGBUS** signal as soon as hardware memory corruption is detected inside its address space. In late kill mode, the process is killed only when it accesses a corrupted page. See *sigaction*(2) for more information on the **SIGBUS** signal. The policy is inherited by children. The remaining unused **prctl**() arguments must be zero for future compatibility.

PR_MCE_KILL_GET (since Linux 2.6.32)
Return (as the function result) the current per-process machine check kill policy. All unused **prctl**() arguments must be zero.

PR_SET_MM (since Linux 3.3)
Modify certain kernel memory map descriptor fields of the calling process. Usually these fields are set by the kernel and dynamic loader (see *ld.so*(8) for more information) and a regular application should not use this feature. However, there are cases, such as self-modifying programs, where a program might find it useful to change its own memory map.

The calling process must have the **CAP_SYS_RESOURCE** capability. The value in *arg2* is one of the options below, while *arg3* provides a new value for the option. The *arg4* and *arg5* arguments must be zero if unused.

Before Linux 3.10, this feature is available only if the kernel is built with the **CONFIG_CHECKPOINT_RESTORE** option enabled.

PR_SET_MM_START_CODE
Set the address above which the program text can run. The corresponding memory area must be readable and executable, but not writable or shareable (see *mprotect*(2) and *mmap*(2) for more information).

PR_SET_MM_END_CODE
Set the address below which the program text can run. The corresponding memory area must be readable and executable, but not writable or shareable.

PR_SET_MM_START_DATA
Set the address above which initialized and uninitialized (bss) data are placed. The corresponding memory area must be readable and writable, but not executable or shareable.

PR_SET_MM_END_DATA
Set the address below which initialized and uninitialized (bss) data are placed. The corresponding memory area must be readable and writable, but not executable or shareable.

PR_SET_MM_START_STACK
Set the start address of the stack. The corresponding memory area must be readable and writable.

PR_SET_MM_START_BRK
Set the address above which the program heap can be expanded with *brk*(2) call. The address must be greater than the ending address of the current program data segment. In addition, the combined size of the resulting heap and the size of the data segment can't exceed the **RLIMIT_DATA** resource limit (see *setrlimit*(2)).

PR_SET_MM_BRK
Set the current *brk*(2) value. The requirements for the address are the same as for the **PR_SET_MM_START_BRK** option.

The following options are available since Linux 3.5.

PR_SET_MM_ARG_START
Set the address above which the program command line is placed.

PR_SET_MM_ARG_END
Set the address below which the program command line is placed.

PR_SET_MM_ENV_START
Set the address above which the program environment is placed.

PR_SET_MM_ENV_END
Set the address below which the program environment is placed.

The address passed with **PR_SET_MM_ARG_START**, **PR_SET_MM_ARG_END**, **PR_SET_MM_ENV_START**, and **PR_SET_MM_ENV_END** should belong to a process stack area. Thus, the corresponding memory area must be readable, writable, and (depending on the kernel configuration) have the **MAP_GROWSDOWN** attribute set (see *mmap*(2)).

PR_SET_MM_AUXV
Set a new auxiliary vector. The *arg3* argument should provide the address of the vector. The *arg4* is the size of the vector.

PR_SET_MM_EXE_FILE
Supersede the */proc/*pid*/exe* symbolic link with a new one pointing to a new executable file identified by the file descriptor provided in *arg3* argument. The file descriptor should be obtained with a regular *open*(2) call.

To change the symbolic link, one needs to unmap all existing executable memory areas, including those created by the kernel itself (for example the kernel usually creates at least one executable memory area for the ELF *.text* section).

In Linux 4.9 and earlier, the **PR_SET_MM_EXE_FILE** operation can be performed only once in a process's lifetime; attempting to perform the operation a second time results in the error **EPERM**. This restriction was enforced for security reasons that were subsequently deemed specious, and the restriction was removed in Linux 4.10 because some user-space applications needed to perform this operation more than once.

The following options are available since Linux 3.18.

PR_SET_MM_MAP
Provides one-shot access to all the addresses by passing in a *struct prctl_mm_map* (as defined in <*linux/prctl.h*>). The *arg4* argument should provide the size of the struct.

This feature is available only if the kernel is built with the **CONFIG_CHECKPOINT_RESTORE** option enabled.

PR_SET_MM_MAP_SIZE
Returns the size of the *struct prctl_mm_map* the kernel expects. This allows user space to find a compatible struct. The *arg4* argument should be a pointer to an unsigned int.

This feature is available only if the kernel is built with the **CONFIG_CHECKPOINT_RESTORE** option enabled.

PR_SET_VMA (since Linux 5.17)
Sets an attribute specified in *arg2* for virtual memory areas starting from the address specified in *arg3* and spanning the size specified in *arg4*. *arg5* specifies the value of the attribute to be set.

Note that assigning an attribute to a virtual memory area might prevent it from being merged with adjacent virtual memory areas due to the difference in that attribute's value.

Currently, *arg2* must be one of:

PR_SET_VMA_ANON_NAME
Set a name for anonymous virtual memory areas. *arg5* should be a pointer to a null-terminated string containing the name. The name length including null byte cannot exceed 80 bytes. If *arg5* is NULL, the name of the appropriate anonymous virtual memory areas will be reset. The name can contain only printable ascii characters (including space), except '[', ']', '\', '$', and '`'.

PR_MPX_ENABLE_MANAGEMENT
PR_MPX_DISABLE_MANAGEMENT (since Linux 3.19, removed in Linux 5.4; only on x86)
Enable or disable kernel management of Memory Protection eXtensions (MPX) bounds tables. The *arg2*, *arg3*, *arg4*, and *arg5* arguments must be zero.

MPX is a hardware-assisted mechanism for performing bounds checking on pointers. It consists of a set of registers storing bounds information and a set of special instruction prefixes that tell the CPU on which instructions it should do bounds enforcement. There is a limited number of these registers and when there are more pointers than registers, their contents must be "spilled" into a set of tables. These tables are called "bounds tables" and the MPX **prctl**() operations control whether the kernel manages their allocation and freeing.

When management is enabled, the kernel will take over allocation and freeing of the bounds tables. It does this by trapping the #BR exceptions that result at first use of missing bounds

tables and instead of delivering the exception to user space, it allocates the table and populates the bounds directory with the location of the new table. For freeing, the kernel checks to see if bounds tables are present for memory which is not allocated, and frees them if so.

Before enabling MPX management using **PR_MPX_ENABLE_MANAGEMENT**, the application must first have allocated a user-space buffer for the bounds directory and placed the location of that directory in the *bndcfgu* register.

These calls fail if the CPU or kernel does not support MPX. Kernel support for MPX is enabled via the **CONFIG_X86_INTEL_MPX** configuration option. You can check whether the CPU supports MPX by looking for the *mpx* CPUID bit, like with the following command:

```
cat /proc/cpuinfo | grep ' mpx '
```

A thread may not switch in or out of long (64-bit) mode while MPX is enabled.

All threads in a process are affected by these calls.

The child of a *fork*(2) inherits the state of MPX management. During *execve*(2), MPX management is reset to a state as if **PR_MPX_DISABLE_MANAGEMENT** had been called.

For further information on Intel MPX, see the kernel source file *Documentation/x86/intel_mpx.txt*.

Due to a lack of toolchain support, **PR_MPX_ENABLE_MANAGEMENT** and **PR_MPX_DISABLE_MANAGEMENT** are not supported in Linux 5.4 and later.

PR_SET_NAME (since Linux 2.6.9)
Set the name of the calling thread, using the value in the location pointed to by *(char *) arg2*. The name can be up to 16 bytes long, including the terminating null byte. (If the length of the string, including the terminating null byte, exceeds 16 bytes, the string is silently truncated.) This is the same attribute that can be set via *pthread_setname_np*(3) and retrieved using *pthread_getname_np*(3). The attribute is likewise accessible via */proc/self/task/*tid*/comm* (see *proc*(5)), where *tid* is the thread ID of the calling thread, as returned by *gettid*(2).

PR_GET_NAME (since Linux 2.6.11)
Return the name of the calling thread, in the buffer pointed to by *(char *) arg2*. The buffer should allow space for up to 16 bytes; the returned string will be null-terminated.

PR_SET_NO_NEW_PRIVS (since Linux 3.5)
Set the calling thread's *no_new_privs* attribute to the value in *arg2*. With *no_new_privs* set to 1, *execve*(2) promises not to grant privileges to do anything that could not have been done without the *execve*(2) call (for example, rendering the set-user-ID and set-group-ID mode bits, and file capabilities non-functional). Once set, the *no_new_privs* attribute cannot be unset. The setting of this attribute is inherited by children created by *fork*(2) and *clone*(2), and preserved across *execve*(2).

Since Linux 4.10, the value of a thread's *no_new_privs* attribute can be viewed via the *NoNewPrivs* field in the */proc/*pid*/status* file.

For more information, see the kernel source file *Documentation/user-space−api/no_new_privs.rst* (or *Documentation/prctl/no_new_privs.txt* before Linux 4.13). See also *seccomp*(2).

PR_GET_NO_NEW_PRIVS (since Linux 3.5)
Return (as the function result) the value of the *no_new_privs* attribute for the calling thread. A value of 0 indicates the regular *execve*(2) behavior. A value of 1 indicates *execve*(2) will operate in the privilege-restricting mode described above.

PR_PAC_RESET_KEYS (since Linux 5.0, only on arm64)
Securely reset the thread's pointer authentication keys to fresh random values generated by the kernel.

The set of keys to be reset is specified by *arg2*, which must be a logical OR of zero or more of the following:

PR_PAC_APIAKEY
instruction authentication key A

PR_PAC_APIBKEY
instruction authentication key B

PR_PAC_APDAKEY
data authentication key A

PR_PAC_APDBKEY
data authentication key B

PR_PAC_APGAKEY
generic authentication "A" key.

(Yes folks, there really is no generic B key.)

As a special case, if *arg2* is zero, then all the keys are reset. Since new keys could be added in future, this is the recommended way to completely wipe the existing keys when establishing a clean execution context. Note that there is no need to use **PR_PAC_RESET_KEYS** in preparation for calling *execve*(2), since *execve*(2) resets all the pointer authentication keys.

The remaining arguments *arg3*, *arg4*, and *arg5* must all be zero.

If the arguments are invalid, and in particular if *arg2* contains set bits that are unrecognized or that correspond to a key not available on this platform, then the call fails with error **EINVAL**.

Warning: Because the compiler or run-time environment may be using some or all of the keys, a successful **PR_PAC_RESET_KEYS** may crash the calling process. The conditions for using it safely are complex and system-dependent. Don't use it unless you know what you are doing.

For more information, see the kernel source file *Documentation/arm64/pointer−authentication.rst* (or *Documentation/arm64/pointer−authentication.txt* before Linux 5.3).

PR_SET_PDEATHSIG (since Linux 2.1.57)
Set the parent-death signal of the calling process to *arg2* (either a signal value in the range [**1**, *NSIG − 1*], or **0** to clear). This is the signal that the calling process will get when its parent dies.

Warning: the "parent" in this case is considered to be the *thread* that created this process. In other words, the signal will be sent when that thread terminates (via, for example, *pthread_exit*(3)), rather than after all of the threads in the parent process terminate.

The parent-death signal is sent upon subsequent termination of the parent thread and also upon termination of each subreaper process (see the description of **PR_SET_CHILD_SUBREAPER** above) to which the caller is subsequently reparented. If the parent thread and all ancestor subreapers have already terminated by the time of the **PR_SET_PDEATHSIG** operation, then no parent-death signal is sent to the caller.

The parent-death signal is process-directed (see *signal*(7)) and, if the child installs a handler using the *sigaction*(2) **SA_SIGINFO** flag, the *si_pid* field of the *siginfo_t* argument of the handler contains the PID of the terminating parent process.

The parent-death signal setting is cleared for the child of a *fork*(2). It is also (since Linux 2.4.36 / 2.6.23) cleared when executing a set-user-ID or set-group-ID binary, or a binary that has associated capabilities (see *capabilities*(7)); otherwise, this value is preserved across *execve*(2). The parent-death signal setting is also cleared upon changes to any of the following thread credentials: effective user ID, effective group ID, filesystem user ID, or filesystem group ID.

PR_GET_PDEATHSIG (since Linux 2.3.15)
Return the current value of the parent process death signal, in the location pointed to by *(int *) arg2*.

PR_SET_PTRACER (since Linux 3.4)
This is meaningful only when the Yama LSM is enabled and in mode 1 ("restricted ptrace", visible via */proc/sys/kernel/yama/ptrace_scope*). When a "ptracer process ID" is passed in *arg2*, the caller is declaring that the ptracer process can *ptrace*(2) the calling process as if it were a direct process ancestor. Each **PR_SET_PTRACER** operation replaces the previous "ptracer process ID". Employing **PR_SET_PTRACER** with *arg2* set to 0 clears the caller's

"ptracer process ID". If *arg2* is **PR_SET_PTRACER_ANY**, the ptrace restrictions introduced by Yama are effectively disabled for the calling process.

For further information, see the kernel source file *Documentation/admin−guide/LSM/Yama.rst* (or *Documentation/security/Yama.txt* before Linux 4.13).

PR_SET_SECCOMP (since Linux 2.6.23)
Set the secure computing (seccomp) mode for the calling thread, to limit the available system calls. The more recent *seccomp*(2) system call provides a superset of the functionality of **PR_SET_SECCOMP**, and is the preferred interface for new applications.

The seccomp mode is selected via *arg2*. (The seccomp constants are defined in <*linux/seccomp.h*>.) The following values can be specified:

SECCOMP_MODE_STRICT (since Linux 2.6.23)
See the description of **SECCOMP_SET_MODE_STRICT** in *seccomp*(2).

This operation is available only if the kernel is configured with **CONFIG_SECCOMP** enabled.

SECCOMP_MODE_FILTER (since Linux 3.5)
The allowed system calls are defined by a pointer to a Berkeley Packet Filter passed in *arg3*. This argument is a pointer to *struct sock_fprog*; it can be designed to filter arbitrary system calls and system call arguments. See the description of **SECCOMP_SET_MODE_FILTER** in *seccomp*(2).

This operation is available only if the kernel is configured with **CONFIG_SECCOMP_FILTER** enabled.

For further details on seccomp filtering, see *seccomp*(2).

PR_GET_SECCOMP (since Linux 2.6.23)
Return (as the function result) the secure computing mode of the calling thread. If the caller is not in secure computing mode, this operation returns 0; if the caller is in strict secure computing mode, then the **prctl**() call will cause a **SIGKILL** signal to be sent to the process. If the caller is in filter mode, and this system call is allowed by the seccomp filters, it returns 2; otherwise, the process is killed with a **SIGKILL** signal.

This operation is available only if the kernel is configured with **CONFIG_SECCOMP** enabled.

Since Linux 3.8, the *Seccomp* field of the */proc/*pid*/status* file provides a method of obtaining the same information, without the risk that the process is killed; see *proc*(5).

PR_SET_SECUREBITS (since Linux 2.6.26)
Set the "securebits" flags of the calling thread to the value supplied in *arg2*. See *capabilities*(7).

PR_GET_SECUREBITS (since Linux 2.6.26)
Return (as the function result) the "securebits" flags of the calling thread. See *capabilities*(7).

PR_GET_SPECULATION_CTRL (since Linux 4.17)
Return (as the function result) the state of the speculation misfeature specified in *arg2*. Currently, the only permitted value for this argument is **PR_SPEC_STORE_BYPASS** (otherwise the call fails with the error **ENODEV**).

The return value uses bits 0-3 with the following meaning:

PR_SPEC_PRCTL
Mitigation can be controlled per thread by **PR_SET_SPECULATION_CTRL**.

PR_SPEC_ENABLE
The speculation feature is enabled, mitigation is disabled.

PR_SPEC_DISABLE
The speculation feature is disabled, mitigation is enabled.

PR_SPEC_FORCE_DISABLE
Same as **PR_SPEC_DISABLE** but cannot be undone.

PR_SPEC_DISABLE_NOEXEC (since Linux 5.1)
Same as **PR_SPEC_DISABLE**, but the state will be cleared on *execve*(2).

If all bits are 0, then the CPU is not affected by the speculation misfeature.

If **PR_SPEC_PRCTL** is set, then per-thread control of the mitigation is available. If not set, **prctl**() for the speculation misfeature will fail.

The *arg3*, *arg4*, and *arg5* arguments must be specified as 0; otherwise the call fails with the error **EINVAL**.

PR_SET_SPECULATION_CTRL (since Linux 4.17)
Sets the state of the speculation misfeature specified in *arg2*. The speculation-misfeature settings are per-thread attributes.

Currently, *arg2* must be one of:

PR_SPEC_STORE_BYPASS
Set the state of the speculative store bypass misfeature.

PR_SPEC_INDIRECT_BRANCH (since Linux 4.20)
Set the state of the indirect branch speculation misfeature.

If *arg2* does not have one of the above values, then the call fails with the error **ENODEV**.

The *arg3* argument is used to hand in the control value, which is one of the following:

PR_SPEC_ENABLE
The speculation feature is enabled, mitigation is disabled.

PR_SPEC_DISABLE
The speculation feature is disabled, mitigation is enabled.

PR_SPEC_FORCE_DISABLE
Same as **PR_SPEC_DISABLE**, but cannot be undone. A subsequent **prctl**(*arg2*, **PR_SPEC_ENABLE**) with the same value for *arg2* will fail with the error **EPERM**.

PR_SPEC_DISABLE_NOEXEC (since Linux 5.1)
Same as **PR_SPEC_DISABLE**, but the state will be cleared on *execve*(2). Currently only supported for *arg2* equal to **PR_SPEC_STORE_BYPASS.**

Any unsupported value in *arg3* will result in the call failing with the error **ERANGE**.

The *arg4* and *arg5* arguments must be specified as 0; otherwise the call fails with the error **EINVAL**.

The speculation feature can also be controlled by the **spec_store_bypass_disable** boot parameter. This parameter may enforce a read-only policy which will result in the **prctl**() call failing with the error **ENXIO**. For further details, see the kernel source file *Documentation/admin−guide/kernel−parameters.txt*.

PR_SVE_SET_VL (since Linux 4.15, only on arm64)
Configure the thread's SVE vector length, as specified by *(int) arg2*. Arguments *arg3*, *arg4*, and *arg5* are ignored.

The bits of *arg2* corresponding to **PR_SVE_VL_LEN_MASK** must be set to the desired vector length in bytes. This is interpreted as an upper bound: the kernel will select the greatest available vector length that does not exceed the value specified. In particular, specifying **SVE_VL_MAX** (defined in *<asm/sigcontext.h>)* for the **PR_SVE_VL_LEN_MASK** bits requests the maximum supported vector length.

In addition, the other bits of *arg2* must be set to one of the following combinations of flags:

0
Perform the change immediately. At the next *execve*(2) in the thread, the vector length will be reset to the value configured in */proc/sys/abi/sve_default_vector_length*.

PR_SVE_VL_INHERIT
Perform the change immediately. Subsequent *execve*(2) calls will preserve the new vector length.

PR_SVE_SET_VL_ONEXEC
Defer the change, so that it is performed at the next *execve*(2) in the thread. Further *execve*(2) calls will reset the vector length to the value configured in */proc/sys/abi/sve_default_vector_length*.

PR_SVE_SET_VL_ONEXEC | PR_SVE_VL_INHERIT
Defer the change, so that it is performed at the next *execve*(2) in the thread. Further *execve*(2) calls will preserve the new vector length.

In all cases, any previously pending deferred change is canceled.

The call fails with error **EINVAL** if SVE is not supported on the platform, if *arg2* is unrecognized or invalid, or the value in the bits of *arg2* corresponding to **PR_SVE_VL_LEN_MASK** is outside the range **SVE_VL_MIN**..**SVE_VL_MAX** or is not a multiple of 16.

On success, a nonnegative value is returned that describes the *selected* configuration. If **PR_SVE_SET_VL_ONEXEC** was included in *arg2*, then the configuration described by the return value will take effect at the next *execve*(2). Otherwise, the configuration is already in effect when the **PR_SVE_SET_VL** call returns. In either case, the value is encoded in the same way as the return value of **PR_SVE_GET_VL**. Note that there is no explicit flag in the return value corresponding to **PR_SVE_SET_VL_ONEXEC**.

The configuration (including any pending deferred change) is inherited across *fork*(2) and *clone*(2).

For more information, see the kernel source file *Documentation/arm64/sve.rst* (or *Documentation/arm64/sve.txt* before Linux 5.3).

Warning: Because the compiler or run-time environment may be using SVE, using this call without the **PR_SVE_SET_VL_ONEXEC** flag may crash the calling process. The conditions for using it safely are complex and system-dependent. Don't use it unless you really know what you are doing.

PR_SVE_GET_VL (since Linux 4.15, only on arm64)
Get the thread's current SVE vector length configuration.

Arguments *arg2*, *arg3*, *arg4*, and *arg5* are ignored.

Provided that the kernel and platform support SVE, this operation always succeeds, returning a nonnegative value that describes the *current* configuration. The bits corresponding to **PR_SVE_VL_LEN_MASK** contain the currently configured vector length in bytes. The bit corresponding to **PR_SVE_VL_INHERIT** indicates whether the vector length will be inherited across *execve*(2).

Note that there is no way to determine whether there is a pending vector length change that has not yet taken effect.

For more information, see the kernel source file *Documentation/arm64/sve.rst* (or *Documentation/arm64/sve.txt* before Linux 5.3).

PR_SET_SYSCALL_USER_DISPATCH (since Linux 5.11, x86 only)
Configure the Syscall User Dispatch mechanism for the calling thread. This mechanism allows an application to selectively intercept system calls so that they can be handled within the application itself. Interception takes the form of a thread-directed **SIGSYS** signal that is delivered to the thread when it makes a system call. If intercepted, the system call is not executed by the kernel.

To enable this mechanism, *arg2* should be set to **PR_SYS_DISPATCH_ON**. Once enabled, further system calls will be selectively intercepted, depending on a control variable provided by user space. In this case, *arg3* and *arg4* respectively identify the *offset* and *length* of a single contiguous memory region in the process address space from where system calls are always allowed to be executed, regardless of the control variable. (Typically, this area would include the area of memory containing the C library.)

arg5 points to a char-sized variable that is a fast switch to allow/block system call execution without the overhead of doing another system call to re-configure Syscall User Dispatch. This control variable can either be set to **SYSCALL_DISPATCH_FILTER_BLOCK** to block system calls from executing or to **SYSCALL_DISPATCH_FILTER_ALLOW** to

temporarily allow them to be executed. This value is checked by the kernel on every system call entry, and any unexpected value will raise an uncatchable **SIGSYS** at that time, killing the application.

When a system call is intercepted, the kernel sends a thread-directed **SIGSYS** signal to the triggering thread. Various fields will be set in the *siginfo_t* structure (see *sigaction*(2)) associated with the signal:

- *si_signo* will contain **SIGSYS**.
- *si_call_addr* will show the address of the system call instruction.
- *si_syscall* and *si_arch* will indicate which system call was attempted.
- *si_code* will contain **SYS_USER_DISPATCH**.
- *si_errno* will be set to 0.

The program counter will be as though the system call happened (i.e., the program counter will not point to the system call instruction).

When the signal handler returns to the kernel, the system call completes immediately and returns to the calling thread, without actually being executed. If necessary (i.e., when emulating the system call on user space.), the signal handler should set the system call return value to a sane value, by modifying the register context stored in the *ucontext* argument of the signal handler. See *sigaction*(2), *sigreturn*(2), and *getcontext*(3) for more information.

If *arg2* is set to **PR_SYS_DISPATCH_OFF**, Syscall User Dispatch is disabled for that thread. the remaining arguments must be set to 0.

The setting is not preserved across *fork*(2), *clone*(2), or *execve*(2).

For more information, see the kernel source file *Documentation/admin−guide/syscall−user−dispatch.rst*

PR_SET_TAGGED_ADDR_CTRL (since Linux 5.4, only on arm64)
Controls support for passing tagged user-space addresses to the kernel (i.e., addresses where bits 56—63 are not all zero).

The level of support is selected by *arg2*, which can be one of the following:

0 Addresses that are passed for the purpose of being dereferenced by the kernel must be untagged.

PR_TAGGED_ADDR_ENABLE
Addresses that are passed for the purpose of being dereferenced by the kernel may be tagged, with the exceptions summarized below.

The remaining arguments *arg3*, *arg4*, and *arg5* must all be zero.

On success, the mode specified in *arg2* is set for the calling thread and the return value is 0. If the arguments are invalid, the mode specified in *arg2* is unrecognized, or if this feature is unsupported by the kernel or disabled via */proc/sys/abi/tagged_addr_disabled*, the call fails with the error **EINVAL**.

In particular, if **prctl**(**PR_SET_TAGGED_ADDR_CTRL**, 0, 0, 0, 0) fails with **EINVAL**, then all addresses passed to the kernel must be untagged.

Irrespective of which mode is set, addresses passed to certain interfaces must always be untagged:

- *brk*(2), *mmap*(2), *shmat*(2), *shmdt*(2), and the *new_address* argument of *mremap*(2).

  (Prior to Linux 5.6 these accepted tagged addresses, but the behaviour may not be what you expect. Don't rely on it.)
- 'polymorphic' interfaces that accept pointers to arbitrary types cast to a *void* * or other generic type, specifically **prctl**(), *ioctl*(2), and in general *setsockopt*(2) (only certain specific *setsockopt*(2) options allow tagged addresses).

This list of exclusions may shrink when moving from one kernel version to a later kernel version. While the kernel may make some guarantees for backwards compatibility reasons, for

the purposes of new software the effect of passing tagged addresses to these interfaces is unspecified.

The mode set by this call is inherited across *fork*(2) and *clone*(2). The mode is reset by *execve*(2) to 0 (i.e., tagged addresses not permitted in the user/kernel ABI).

For more information, see the kernel source file *Documentation/arm64/tagged−address−abi.rst*.

Warning: This call is primarily intended for use by the run-time environment. A successful **PR_SET_TAGGED_ADDR_CTRL** call elsewhere may crash the calling process. The conditions for using it safely are complex and system-dependent. Don't use it unless you know what you are doing.

PR_GET_TAGGED_ADDR_CTRL (since Linux 5.4, only on arm64)
Returns the current tagged address mode for the calling thread.

Arguments *arg2*, *arg3*, *arg4*, and *arg5* must all be zero.

If the arguments are invalid or this feature is disabled or unsupported by the kernel, the call fails with **EINVAL**. In particular, if **prctl**(**PR_GET_TAGGED_ADDR_CTRL**, 0, 0, 0, 0) fails with **EINVAL**, then this feature is definitely either unsupported, or disabled via */proc/sys/abi/tagged_addr_disabled*. In this case, all addresses passed to the kernel must be untagged.

Otherwise, the call returns a nonnegative value describing the current tagged address mode, encoded in the same way as the *arg2* argument of **PR_SET_TAGGED_ADDR_CTRL**.

For more information, see the kernel source file *Documentation/arm64/tagged−address−abi.rst*.

PR_TASK_PERF_EVENTS_DISABLE (since Linux 2.6.31)
Disable all performance counters attached to the calling process, regardless of whether the counters were created by this process or another process. Performance counters created by the calling process for other processes are unaffected. For more information on performance counters, see the Linux kernel source file *tools/perf/design.txt*.

Originally called **PR_TASK_PERF_COUNTERS_DISABLE**; renamed (retaining the same numerical value) in Linux 2.6.32.

PR_TASK_PERF_EVENTS_ENABLE (since Linux 2.6.31)
The converse of **PR_TASK_PERF_EVENTS_DISABLE**; enable performance counters attached to the calling process.

Originally called **PR_TASK_PERF_COUNTERS_ENABLE**; renamed in Linux 2.6.32.

PR_SET_THP_DISABLE (since Linux 3.15)
Set the state of the "THP disable" flag for the calling thread. If *arg2* has a nonzero value, the flag is set, otherwise it is cleared. Setting this flag provides a method for disabling transparent huge pages for jobs where the code cannot be modified, and using a malloc hook with *madvise*(2) is not an option (i.e., statically allocated data). The setting of the "THP disable" flag is inherited by a child created via *fork*(2) and is preserved across *execve*(2).

PR_GET_THP_DISABLE (since Linux 3.15)
Return (as the function result) the current setting of the "THP disable" flag for the calling thread: either 1, if the flag is set, or 0, if it is not.

PR_GET_TID_ADDRESS (since Linux 3.5)
Return the *clear_child_tid* address set by *set_tid_address*(2) and the *clone*(2) **CLONE_CHILD_CLEARTID** flag, in the location pointed to by *(int **) arg2*. This feature is available only if the kernel is built with the **CONFIG_CHECKPOINT_RESTORE** option enabled. Note that since the **prctl**() system call does not have a compat implementation for the AMD64 x32 and MIPS n32 ABIs, and the kernel writes out a pointer using the kernel's pointer size, this operation expects a user-space buffer of 8 (not 4) bytes on these ABIs.

PR_SET_TIMERSLACK (since Linux 2.6.28)
Each thread has two associated timer slack values: a "default" value, and a "current" value. This operation sets the "current" timer slack value for the calling thread. *arg2* is an unsigned

long value, then maximum "current" value is ULONG_MAX and the minimum "current" value is 1. If the nanosecond value supplied in *arg2* is greater than zero, then the "current" value is set to this value. If *arg2* is equal to zero, the "current" timer slack is reset to the thread's "default" timer slack value.

The "current" timer slack is used by the kernel to group timer expirations for the calling thread that are close to one another; as a consequence, timer expirations for the thread may be up to the specified number of nanoseconds late (but will never expire early). Grouping timer expirations can help reduce system power consumption by minimizing CPU wake-ups.

The timer expirations affected by timer slack are those set by *select*(2), *pselect*(2), *poll*(2), *ppoll*(2), *epoll_wait*(2), *epoll_pwait*(2), *clock_nanosleep*(2), *nanosleep*(2), and *futex*(2) (and thus the library functions implemented via futexes, including *pthread_cond_timedwait*(3), *pthread_mutex_timedlock*(3), *pthread_rwlock_timedrdlock*(3), *pthread_rwlock_timedwrlock*(3), and *sem_timedwait*(3)).

Timer slack is not applied to threads that are scheduled under a real-time scheduling policy (see *sched_setscheduler*(2)).

When a new thread is created, the two timer slack values are made the same as the "current" value of the creating thread. Thereafter, a thread can adjust its "current" timer slack value via **PR_SET_TIMERSLACK**. The "default" value can't be changed. The timer slack values of *init* (PID 1), the ancestor of all processes, are 50,000 nanoseconds (50 microseconds). The timer slack value is inherited by a child created via *fork*(2), and is preserved across *execve*(2).

Since Linux 4.6, the "current" timer slack value of any process can be examined and changed via the file */proc/*pid*/timerslack_ns*. See *proc*(5).

PR_GET_TIMERSLACK (since Linux 2.6.28)
Return (as the function result) the "current" timer slack value of the calling thread.

PR_SET_TIMING (since Linux 2.6.0)
Set whether to use (normal, traditional) statistical process timing or accurate timestamp-based process timing, by passing **PR_TIMING_STATISTICAL** or **PR_TIMING_TIMESTAMP** to *arg2*. **PR_TIMING_TIMESTAMP** is not currently implemented (attempting to set this mode will yield the error **EINVAL**).

PR_GET_TIMING (since Linux 2.6.0)
Return (as the function result) which process timing method is currently in use.

PR_SET_TSC (since Linux 2.6.26, x86 only)
Set the state of the flag determining whether the timestamp counter can be read by the process. Pass **PR_TSC_ENABLE** to *arg2* to allow it to be read, or **PR_TSC_SIGSEGV** to generate a **SIGSEGV** when the process tries to read the timestamp counter.

PR_GET_TSC (since Linux 2.6.26, x86 only)
Return the state of the flag determining whether the timestamp counter can be read, in the location pointed to by *(int *) arg2*.

PR_SET_UNALIGN
(Only on: ia64, since Linux 2.3.48; parisc, since Linux 2.6.15; PowerPC, since Linux 2.6.18; Alpha, since Linux 2.6.22; sh, since Linux 2.6.34; tile, since Linux 3.12) Set unaligned access control bits to *arg2*. Pass **PR_UNALIGN_NOPRINT** to silently fix up unaligned user accesses, or **PR_UNALIGN_SIGBUS** to generate **SIGBUS** on unaligned user access. Alpha also supports an additional flag with the value of 4 and no corresponding named constant, which instructs kernel to not fix up unaligned accesses (it is analogous to providing the **UAC_NOFIX** flag in **SSI_NVPAIRS** operation of the **setsysinfo**() system call on Tru64).

PR_GET_UNALIGN
(See **PR_SET_UNALIGN** for information on versions and architectures.) Return unaligned access control bits, in the location pointed to by *(unsigned int *) arg2*.

PR_GET_AUXV (since Linux 6.4)
Get the auxiliary vector (auxv) into the buffer pointed to by *(void *) arg2*, whose length is given by *arg3*. If the buffer is not long enough for the full auxiliary vector, the copy will be truncated. Return (as the function result) the full length of the auxiliary vector. *arg4* and *arg5*

must be 0.

PR_SET_MDWE (since Linux 6.3)
Set the calling process' Memory-Deny-Write-Execute protection mask. Once protection bits are set, they can not be changed. *arg2* must be a bit mask of:

PR_MDWE_REFUSE_EXEC_GAIN
New memory mapping protections can't be writable and executable. Non-executable mappings can't become executable.

PR_MDWE_NO_INHERIT (since Linux 6.6)
Do not propagate MDWE protection to child processes on *fork*(2). Setting this bit requires setting **PR_MDWE_REFUSE_EXEC_GAIN** too.

PR_GET_MDWE (since Linux 6.3)
Return (as the function result) the Memory-Deny-Write-Execute protection mask of the calling process. (See **PR_SET_MDWE** for information on the protection mask bits.)

RETURN VALUE

On success, **PR_CAP_AMBIENT**+**PR_CAP_AMBIENT_IS_SET**, **PR_CAPBSET_READ**, **PR_GET_DUMPABLE**, **PR_GET_FP_MODE**, **PR_GET_IO_FLUSHER**, **PR_GET_KEEPCAPS**, **PR_MCE_KILL_GET**, **PR_GET_NO_NEW_PRIVS**, **PR_GET_SECUREBITS**, **PR_GET_SPECULATION_CTRL**, **PR_SVE_GET_VL**, **PR_SVE_SET_VL**, **PR_GET_TAGGED_ADDR_CTRL**, **PR_GET_THP_DISABLE**, **PR_GET_TIMING**, **PR_GET_TIMERSLACK**, **PR_GET_AUXV**, and (if it returns) **PR_GET_SECCOMP** return the nonnegative values described above. All other *op* values return 0 on success. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
op is **PR_SET_SECCOMP** and *arg2* is **SECCOMP_MODE_FILTER**, but the process does not have the **CAP_SYS_ADMIN** capability or has not set the *no_new_privs* attribute (see the discussion of **PR_SET_NO_NEW_PRIVS** above).

EACCES
op is **PR_SET_MM**, and *arg3* is **PR_SET_MM_EXE_FILE**, the file is not executable.

EBADF
op is **PR_SET_MM**, *arg3* is **PR_SET_MM_EXE_FILE**, and the file descriptor passed in *arg4* is not valid.

EBUSY
op is **PR_SET_MM**, *arg3* is **PR_SET_MM_EXE_FILE**, and this the second attempt to change the */proc/*pid*/exe* symbolic link, which is prohibited.

EFAULT
arg2 is an invalid address.

EFAULT
op is **PR_SET_SECCOMP**, *arg2* is **SECCOMP_MODE_FILTER**, the system was built with **CONFIG_SECCOMP_FILTER**, and *arg3* is an invalid address.

EFAULT
op is **PR_SET_SYSCALL_USER_DISPATCH** and *arg5* has an invalid address.

EINVAL
The value of *op* is not recognized, or not supported on this system.

EINVAL
op is **PR_MCE_KILL** or **PR_MCE_KILL_GET** or **PR_SET_MM**, and unused **prctl**() arguments were not specified as zero.

EINVAL
arg2 is not valid value for this *op*.

EINVAL
op is **PR_SET_SECCOMP** or **PR_GET_SECCOMP**, and the kernel was not configured with **CONFIG_SECCOMP**.

EINVAL
op is **PR_SET_SECCOMP**, *arg2* is **SECCOMP_MODE_FILTER**, and the kernel was not configured with **CONFIG_SECCOMP_FILTER**.

EINVAL
op is **PR_SET_MM**, and one of the following is true

- *arg4* or *arg5* is nonzero;
- *arg3* is greater than **TASK_SIZE** (the limit on the size of the user address space for this architecture);
- *arg2* is **PR_SET_MM_START_CODE**, **PR_SET_MM_END_CODE**, **PR_SET_MM_START_DATA**, **PR_SET_MM_END_DATA**, or **PR_SET_MM_START_STACK**, and the permissions of the corresponding memory area are not as required;
- *arg2* is **PR_SET_MM_START_BRK** or **PR_SET_MM_BRK**, and *arg3* is less than or equal to the end of the data segment or specifies a value that would cause the **RLIMIT_DATA** resource limit to be exceeded.

EINVAL
op is **PR_SET_PTRACER** and *arg2* is not 0, **PR_SET_PTRACER_ANY**, or the PID of an existing process.

EINVAL
op is **PR_SET_PDEATHSIG** and *arg2* is not a valid signal number.

EINVAL
op is **PR_SET_DUMPABLE** and *arg2* is neither **SUID_DUMP_DISABLE** nor **SUID_DUMP_USER**.

EINVAL
op is **PR_SET_TIMING** and *arg2* is not **PR_TIMING_STATISTICAL**.

EINVAL
op is **PR_SET_NO_NEW_PRIVS** and *arg2* is not equal to 1 or *arg3*, *arg4*, or *arg5* is nonzero.

EINVAL
op is **PR_GET_NO_NEW_PRIVS** and *arg2*, *arg3*, *arg4*, or *arg5* is nonzero.

EINVAL
op is **PR_SET_THP_DISABLE** and *arg3*, *arg4*, or *arg5* is nonzero.

EINVAL
op is **PR_GET_THP_DISABLE** and *arg2*, *arg3*, *arg4*, or *arg5* is nonzero.

EINVAL
op is **PR_CAP_AMBIENT** and an unused argument (*arg4*, *arg5*, or, in the case of **PR_CAP_AMBIENT_CLEAR_ALL**, *arg3*) is nonzero; or *arg2* has an invalid value; or *arg2* is **PR_CAP_AMBIENT_LOWER**, **PR_CAP_AMBIENT_RAISE**, or **PR_CAP_AMBIENT_IS_SET** and *arg3* does not specify a valid capability.

EINVAL
op was **PR_GET_SPECULATION_CTRL** or **PR_SET_SPECULATION_CTRL** and unused arguments to **prctl**() are not 0.

EINVAL
op is **PR_PAC_RESET_KEYS** and the arguments are invalid or unsupported. See the description of **PR_PAC_RESET_KEYS** above for details.

EINVAL
op is **PR_SVE_SET_VL** and the arguments are invalid or unsupported, or SVE is not available on this platform. See the description of **PR_SVE_SET_VL** above for details.

EINVAL
op is **PR_SVE_GET_VL** and SVE is not available on this platform.

EINVAL
op is **PR_SET_SYSCALL_USER_DISPATCH** and one of the following is true:

- *arg2* is **PR_SYS_DISPATCH_OFF** and the remaining arguments are not 0;
- *arg2* is **PR_SYS_DISPATCH_ON** and the memory range specified is outside the address space of the process.
- *arg2* is invalid.

EINVAL
op is **PR_SET_TAGGED_ADDR_CTRL** and the arguments are invalid or unsupported. See the description of **PR_SET_TAGGED_ADDR_CTRL** above for details.

EINVAL
op is **PR_GET_TAGGED_ADDR_CTRL** and the arguments are invalid or unsupported. See the description of **PR_GET_TAGGED_ADDR_CTRL** above for details.

ENODEV
op was **PR_SET_SPECULATION_CTRL** the kernel or CPU does not support the requested speculation misfeature.

ENXIO
op was **PR_MPX_ENABLE_MANAGEMENT** or **PR_MPX_DISABLE_MANAGEMENT** and the kernel or the CPU does not support MPX management. Check that the kernel and processor have MPX support.

ENXIO
op was **PR_SET_SPECULATION_CTRL** implies that the control of the selected speculation misfeature is not possible. See **PR_GET_SPECULATION_CTRL** for the bit fields to determine which option is available.

EOPNOTSUPP
op is **PR_SET_FP_MODE** and *arg2* has an invalid or unsupported value.

EPERM
op is **PR_SET_SECUREBITS**, and the caller does not have the **CAP_SETPCAP** capability, or tried to unset a "locked" flag, or tried to set a flag whose corresponding locked flag was set (see *capabilities*(7)).

EPERM
op is **PR_SET_SPECULATION_CTRL** wherein the speculation was disabled with **PR_SPEC_FORCE_DISABLE** and caller tried to enable it again.

EPERM
op is **PR_SET_KEEPCAPS**, and the caller's **SECBIT_KEEP_CAPS_LOCKED** flag is set (see *capabilities*(7)).

EPERM
op is **PR_CAPBSET_DROP**, and the caller does not have the **CAP_SETPCAP** capability.

EPERM
op is **PR_SET_MM**, and the caller does not have the **CAP_SYS_RESOURCE** capability.

EPERM
op is **PR_CAP_AMBIENT** and *arg2* is **PR_CAP_AMBIENT_RAISE**, but either the capability specified in *arg3* is not present in the process's permitted and inheritable capability sets, or the **PR_CAP_AMBIENT_LOWER** securebit has been set.

ERANGE
op was **PR_SET_SPECULATION_CTRL** and *arg3* is not **PR_SPEC_ENABLE**, **PR_SPEC_DISABLE**, **PR_SPEC_FORCE_DISABLE**, nor **PR_SPEC_DISABLE_NOEXEC**.

VERSIONS

IRIX has a **prctl**() system call (also introduced in Linux 2.1.44 as irix_prctl on the MIPS architecture), with prototype

```
ptrdiff_t prctl(int op, int arg2, int arg3);
```

and operations to get the maximum number of processes per user, get the maximum number of processors the calling process can use, find out whether a specified process is currently blocked, get or set the maximum stack size, and so on.

STANDARDS

Linux.

HISTORY

Linux 2.1.57, glibc 2.0.6

SEE ALSO

signal(2), *core*(5)

NAME

pread, pwrite − read from or write to a file descriptor at a given offset

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

ssize_t pread(int fd, void buf[.count], size_t count,
              off_t offset);
ssize_t pwrite(int fd, const void buf[.count], size_t count,
               off_t offset);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

pread(), **pwrite**():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L

DESCRIPTION

pread() reads up to *count* bytes from file descriptor *fd* at offset *offset* (from the start of the file) into the buffer starting at *buf*. The file offset is not changed.

pwrite() writes up to *count* bytes from the buffer starting at *buf* to the file descriptor *fd* at offset *offset*. The file offset is not changed.

The file referenced by *fd* must be capable of seeking.

RETURN VALUE

On success, **pread**() returns the number of bytes read (a return of zero indicates end of file) and **pwrite**() returns the number of bytes written.

Note that it is not an error for a successful call to transfer fewer bytes than requested (see *read*(2) and *write*(2)).

On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

pread() can fail and set *errno* to any error specified for *read*(2) or *lseek*(2). **pwrite**() can fail and set *errno* to any error specified for *write*(2) or *lseek*(2).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

Added in Linux 2.1.60; the entries in the i386 system call table were added in Linux 2.1.69. C library support (including emulation using *lseek*(2) on older kernels without the system calls) was added in glibc 2.1.

C library/kernel differences

On Linux, the underlying system calls were renamed in Linux 2.6: **pread**() became **pread64**(), and **pwrite**() became **pwrite64**(). The system call numbers remained the same. The glibc **pread**() and **pwrite**() wrapper functions transparently deal with the change.

On some 32-bit architectures, the calling signature for these system calls differ, for the reasons described in *syscall*(2).

NOTES

The **pread**() and **pwrite**() system calls are especially useful in multithreaded applications. They allow multiple threads to perform I/O on the same file descriptor without being affected by changes to the file offset by other threads.

BUGS

POSIX requires that opening a file with the **O_APPEND** flag should have no effect on the location at which **pwrite**() writes data. However, on Linux, if a file is opened with **O_APPEND**, **pwrite**() appends data to the end of the file, regardless of the value of *offset*.

SEE ALSO

lseek(2), *read*(2), *readv*(2), *write*(2)

NAME

process_madvise − give advice about use of memory to a process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/mman.h>

ssize_t process_madvise(int *pidfd***, const struct iovec** *iovec***[.***n***],**
size_t *n***, int** *advice***, unsigned int** *flags***);**

DESCRIPTION

The **process_madvise**() system call is used to give advice or directions to the kernel about the address ranges of another process or of the calling process. It provides the advice for the address ranges described by *iovec* and *n*. The goal of such advice is to improve system or application performance.

The *pidfd* argument is a PID file descriptor (see *pidfd_open*(2)) that specifies the process to which the advice is to be applied.

The pointer *iovec* points to an array of *iovec* structures, described in *iovec*(3type).

n specifies the number of elements in the array of *iovec* structures. This value must be less than or equal to **IOV_MAX** (defined in <*limits.h*> or accessible via the call *sysconf(_SC_IOV_MAX)*).

The *advice* argument is one of the following values:

MADV_COLD
See *madvise*(2).

MADV_COLLAPSE
See *madvise*(2).

MADV_PAGEOUT
See *madvise*(2).

MADV_WILLNEED
See *madvise*(2).

The *flags* argument is reserved for future use; currently, this argument must be specified as 0.

The *n* and *iovec* arguments are checked before applying any advice. If *n* is too big, or *iovec* is invalid, then an error will be returned immediately and no advice will be applied.

The advice might be applied to only a part of *iovec* if one of its elements points to an invalid memory region in the remote process. No further elements will be processed beyond that point. (See the discussion regarding partial advice in RETURN VALUE.)

Starting in Linux 5.12, permission to apply advice to another process is governed by ptrace access mode **PTRACE_MODE_READ_FSCREDS** check (see *ptrace*(2)); in addition, because of the performance implications of applying the advice, the caller must have the **CAP_SYS_NICE** capability (see *capabilities*(7)).

RETURN VALUE

On success, **process_madvise**() returns the number of bytes advised. This return value may be less than the total number of requested bytes, if an error occurred after some *iovec* elements were already processed. The caller should check the return value to determine whether a partial advice occurred.

On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF
pidfd is not a valid PID file descriptor.

EFAULT
The memory described by *iovec* is outside the accessible address space of the process referred to by *pidfd*.

EINVAL
flags is not 0.

EINVAL
The sum of the *iov_len* values of *iovec* overflows a *ssize_t* value.

EINVAL
n is too large.

ENOMEM
Could not allocate memory for internal copies of the *iovec* structures.

EPERM
The caller does not have permission to access the address space of the process *pidfd*.

ESRCH
The target process does not exist (i.e., it has terminated and been waited on).

See *madvise*(2) for *advice*-specific errors.

STANDARDS

Linux.

HISTORY

Linux 5.10. glibc 2.36.

Support for this system call is optional, depending on the setting of the **CONFIG_ADVISE_SYSCALLS** configuration option.

When this system call first appeared in Linux 5.10, permission to apply advice to another process was entirely governed by ptrace access mode **PTRACE_MODE_ATTACH_FSCREDS** check (see *ptrace*(2)). This requirement was relaxed in Linux 5.12 so that the caller didn't require full control over the target process.

SEE ALSO

madvise(2), *pidfd_open*(2), *process_vm_readv*(2), *process_vm_write*(2)

NAME

process_vm_readv, process_vm_writev − transfer data between process address spaces

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/uio.h>

ssize_t process_vm_readv(pid_t pid,
                         const struct iovec *local_iov,
                         unsigned long liovcnt,
                         const struct iovec *remote_iov,
                         unsigned long riovcnt,
                         unsigned long flags);
ssize_t process_vm_writev(pid_t pid,
                         const struct iovec *local_iov,
                         unsigned long liovcnt,
                         const struct iovec *remote_iov,
                         unsigned long riovcnt,
                         unsigned long flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

process_vm_readv(), **process_vm_writev**():
_GNU_SOURCE

DESCRIPTION

These system calls transfer data between the address space of the calling process ("the local process") and the process identified by *pid* ("the remote process"). The data moves directly between the address spaces of the two processes, without passing through kernel space.

The **process_vm_readv**() system call transfers data from the remote process to the local process. The data to be transferred is identified by *remote_iov* and *riovcnt*: *remote_iov* is a pointer to an array describing address ranges in the process *pid*, and *riovcnt* specifies the number of elements in *remote_iov*. The data is transferred to the locations specified by *local_iov* and *liovcnt*: *local_iov* is a pointer to an array describing address ranges in the calling process, and *liovcnt* specifies the number of elements in *local_iov*.

The **process_vm_writev**() system call is the converse of **process_vm_readv**()—it transfers data from the local process to the remote process. Other than the direction of the transfer, the arguments *liovcnt*, *local_iov*, *riovcnt*, and *remote_iov* have the same meaning as for **process_vm_readv**().

The *local_iov* and *remote_iov* arguments point to an array of *iovec* structures, described in *iovec*(3type).

Buffers are processed in array order. This means that **process_vm_readv**() completely fills *local_iov[0]* before proceeding to *local_iov[1]*, and so on. Likewise, *remote_iov[0]* is completely read before proceeding to *remote_iov[1]*, and so on.

Similarly, **process_vm_writev**() writes out the entire contents of *local_iov[0]* before proceeding to *local_iov[1]*, and it completely fills *remote_iov[0]* before proceeding to *remote_iov[1]*.

The lengths of *remote_iov[i].iov_len* and *local_iov[i].iov_len* do not have to be the same. Thus, it is possible to split a single local buffer into multiple remote buffers, or vice versa.

The *flags* argument is currently unused and must be set to 0.

The values specified in the *liovcnt* and *riovcnt* arguments must be less than or equal to **IOV_MAX** (defined in <*limits.h*> or accessible via the call *sysconf(_SC_IOV_MAX)*).

The count arguments and *local_iov* are checked before doing any transfers. If the counts are too big, or *local_iov* is invalid, or the addresses refer to regions that are inaccessible to the local process, none of the vectors will be processed and an error will be returned immediately.

Note, however, that these system calls do not check the memory regions in the remote process until just before doing the read/write. Consequently, a partial read/write (see RETURN VALUE) may result if one of the *remote_iov* elements points to an invalid memory region in the remote process. No further

reads/writes will be attempted beyond that point. Keep this in mind when attempting to read data of unknown length (such as C strings that are null-terminated) from a remote process, by avoiding spanning memory pages (typically 4 KiB) in a single remote *iovec* element. (Instead, split the remote read into two *remote_iov* elements and have them merge back into a single write *local_iov* entry. The first read entry goes up to the page boundary, while the second starts on the next page boundary.)

Permission to read from or write to another process is governed by a ptrace access mode **PTRACE_MODE_ATTACH_REALCREDS** check; see *ptrace*(2).

RETURN VALUE

On success, **process_vm_readv**() returns the number of bytes read and **process_vm_writev**() returns the number of bytes written. This return value may be less than the total number of requested bytes, if a partial read/write occurred. (Partial transfers apply at the granularity of *iovec* elements. These system calls won't perform a partial transfer that splits a single *iovec* element.) The caller should check the return value to determine whether a partial read/write occurred.

On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
The memory described by *local_iov* is outside the caller's accessible address space.

EFAULT
The memory described by *remote_iov* is outside the accessible address space of the process *pid*.

EINVAL
The sum of the *iov_len* values of either *local_iov* or *remote_iov* overflows a *ssize_t* value.

EINVAL
flags is not 0.

EINVAL
liovcnt or *riovcnt* is too large.

ENOMEM
Could not allocate memory for internal copies of the *iovec* structures.

EPERM
The caller does not have permission to access the address space of the process *pid*.

ESRCH
No process with ID *pid* exists.

STANDARDS

Linux.

HISTORY

Linux 3.2, glibc 2.15.

NOTES

The data transfers performed by **process_vm_readv**() and **process_vm_writev**() are not guaranteed to be atomic in any way.

These system calls were designed to permit fast message passing by allowing messages to be exchanged with a single copy operation (rather than the double copy that would be required when using, for example, shared memory or pipes).

EXAMPLES

The following code sample demonstrates the use of **process_vm_readv**(). It reads 20 bytes at the address 0x10000 from the process with PID 10 and writes the first 10 bytes into *buf1* and the second 10 bytes into *buf2*.

```
#define _GNU_SOURCE
#include <stdlib.h>
#include <sys/types.h>
#include <sys/uio.h>

int
```

```
main(void)
{
    char          buf1[10];
    char          buf2[10];
    pid_t         pid = 10;    /* PID of remote process */
    ssize_t       nread;
    struct iovec  local[2];
    struct iovec  remote[1];

    local[0].iov_base = buf1;
    local[0].iov_len = 10;
    local[1].iov_base = buf2;
    local[1].iov_len = 10;
    remote[0].iov_base = (void *) 0x10000;
    remote[0].iov_len = 20;

    nread = process_vm_readv(pid, local, 2, remote, 1, 0);
    if (nread != 20)
        exit(EXIT_FAILURE);

    exit(EXIT_SUCCESS);
}
```

SEE ALSO

readv(2), *writev*(2)

NAME

ptrace − process trace

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/ptrace.h>

long ptrace(enum __ptrace_request *op***, pid_t** *pid***,**
void ****addr*, void ****data***);**

DESCRIPTION

The **ptrace**() system call provides a means by which one process (the "tracer") may observe and control the execution of another process (the "tracee"), and examine and change the tracee's memory and registers. It is primarily used to implement breakpoint debugging and system call tracing.

A tracee first needs to be attached to the tracer. Attachment and subsequent commands are per thread: in a multithreaded process, every thread can be individually attached to a (potentially different) tracer, or left not attached and thus not debugged. Therefore, "tracee" always means "(one) thread", never "a (possibly multithreaded) process". Ptrace commands are always sent to a specific tracee using a call of the form

```
ptrace(PTRACE_foo, pid, ...)
```

where *pid* is the thread ID of the corresponding Linux thread.

(Note that in this page, a "multithreaded process" means a thread group consisting of threads created using the *clone*(2) **CLONE_THREAD** flag.)

A process can initiate a trace by calling *fork*(2) and having the resulting child do a **PTRACE_TRACEME**, followed (typically) by an *execve*(2). Alternatively, one process may commence tracing another process using **PTRACE_ATTACH** or **PTRACE_SEIZE**.

While being traced, the tracee will stop each time a signal is delivered, even if the signal is being ignored. (An exception is **SIGKILL**, which has its usual effect.) The tracer will be notified at its next call to *waitpid*(2) (or one of the related "wait" system calls); that call will return a *status* value containing information that indicates the cause of the stop in the tracee. While the tracee is stopped, the tracer can use various ptrace operations to inspect and modify the tracee. The tracer then causes the tracee to continue, optionally ignoring the delivered signal (or even delivering a different signal instead).

If the **PTRACE_O_TRACEEXEC** option is not in effect, all successful calls to *execve*(2) by the traced process will cause it to be sent a **SIGTRAP** signal, giving the parent a chance to gain control before the new program begins execution.

When the tracer is finished tracing, it can cause the tracee to continue executing in a normal, untraced mode via **PTRACE_DETACH**.

The value of *op* determines the operation to be performed:

PTRACE_TRACEME

Indicate that this process is to be traced by its parent. A process probably shouldn't make this operation if its parent isn't expecting to trace it. (*pid*, *addr*, and *data* are ignored.)

The **PTRACE_TRACEME** operation is used only by the tracee; the remaining operations are used only by the tracer. In the following operations, *pid* specifies the thread ID of the tracee to be acted on. For operations other than **PTRACE_ATTACH**, **PTRACE_SEIZE**, **PTRACE_INTERRUPT**, and **PTRACE_KILL**, the tracee must be stopped.

PTRACE_PEEKTEXT
PTRACE_PEEKDATA

Read a word at the address *addr* in the tracee's memory, returning the word as the result of the **ptrace**() call. Linux does not have separate text and data address spaces, so these two operations are currently equivalent. (*data* is ignored; but see NOTES.)

PTRACE_PEEKUSER

Read a word at offset *addr* in the tracee's USER area, which holds the registers and other information about the process (see <*sys/user.h*>). The word is returned as the result of the **ptrace**() call. Typically, the offset must be word-aligned, though this might vary by

architecture. See NOTES. (*data* is ignored; but see NOTES.)

PTRACE_POKETEXT
PTRACE_POKEDATA
Copy the word *data* to the address *addr* in the tracee's memory. As for **PTRACE_PEEKTEXT** and **PTRACE_PEEKDATA**, these two operations are currently equivalent.

PTRACE_POKEUSER
Copy the word *data* to offset *addr* in the tracee's USER area. As for **PTRACE_PEEKUSER**, the offset must typically be word-aligned. In order to maintain the integrity of the kernel, some modifications to the USER area are disallowed.

PTRACE_GETREGS
PTRACE_GETFPREGS
Copy the tracee's general-purpose or floating-point registers, respectively, to the address *data* in the tracer. See <*sys/user.h*> for information on the format of this data. (*addr* is ignored.) Note that SPARC systems have the meaning of *data* and *addr* reversed; that is, *data* is ignored and the registers are copied to the address *addr*. **PTRACE_GETREGS** and **PTRACE_GETFPREGS** are not present on all architectures.

PTRACE_GETREGSET (since Linux 2.6.34)
Read the tracee's registers. *addr* specifies, in an architecture-dependent way, the type of registers to be read. **NT_PRSTATUS** (with numerical value 1) usually results in reading of general-purpose registers. If the CPU has, for example, floating-point and/or vector registers, they can be retrieved by setting *addr* to the corresponding **NT_foo** constant. *data* points to a **struct iovec**, which describes the destination buffer's location and length. On return, the kernel modifies **iov.len** to indicate the actual number of bytes returned.

PTRACE_SETREGS
PTRACE_SETFPREGS
Modify the tracee's general-purpose or floating-point registers, respectively, from the address *data* in the tracer. As for **PTRACE_POKEUSER**, some general-purpose register modifications may be disallowed. (*addr* is ignored.) Note that SPARC systems have the meaning of *data* and *addr* reversed; that is, *data* is ignored and the registers are copied from the address *addr*. **PTRACE_SETREGS** and **PTRACE_SETFPREGS** are not present on all architectures.

PTRACE_SETREGSET (since Linux 2.6.34)
Modify the tracee's registers. The meaning of *addr* and *data* is analogous to **PTRACE_GETREGSET**.

PTRACE_GETSIGINFO (since Linux 2.3.99-pre6)
Retrieve information about the signal that caused the stop. Copy a *siginfo_t* structure (see *sigaction*(2)) from the tracee to the address *data* in the tracer. (*addr* is ignored.)

PTRACE_SETSIGINFO (since Linux 2.3.99-pre6)
Set signal information: copy a *siginfo_t* structure from the address *data* in the tracer to the tracee. This will affect only signals that would normally be delivered to the tracee and were caught by the tracer. It may be difficult to tell these normal signals from synthetic signals generated by **ptrace**() itself. (*addr* is ignored.)

PTRACE_PEEKSIGINFO (since Linux 3.10)
Retrieve *siginfo_t* structures without removing signals from a queue. *addr* points to a *ptrace_peeksiginfo_args* structure that specifies the ordinal position from which copying of signals should start, and the number of signals to copy. *siginfo_t* structures are copied into the buffer pointed to by *data*. The return value contains the number of copied signals (zero indicates that there is no signal corresponding to the specified ordinal position). Within the returned *siginfo* structures, the *si_code* field includes information (**__SI_CHLD**, **__SI_FAULT**, etc.) that are not otherwise exposed to user space.

```
struct ptrace_peeksiginfo_args {
    u64 off;    /* Ordinal position in queue at which
                   to start copying signals */
    u32 flags;  /* PTRACE_PEEKSIGINFO_SHARED or 0 */
    s32 nr;     /* Number of signals to copy */
```

```
};
```

Currently, there is only one flag, **PTRACE_PEEKSIGINFO_SHARED**, for dumping signals from the process-wide signal queue. If this flag is not set, signals are read from the per-thread queue of the specified thread.

PTRACE_GETSIGMASK (since Linux 3.11)
Place a copy of the mask of blocked signals (see *sigprocmask*(2)) in the buffer pointed to by *data*, which should be a pointer to a buffer of type *sigset_t*. The *addr* argument contains the size of the buffer pointed to by *data* (i.e., *sizeof(sigset_t)*).

PTRACE_SETSIGMASK (since Linux 3.11)
Change the mask of blocked signals (see *sigprocmask*(2)) to the value specified in the buffer pointed to by *data*, which should be a pointer to a buffer of type *sigset_t*. The *addr* argument contains the size of the buffer pointed to by *data* (i.e., *sizeof(sigset_t)*).

PTRACE_SETOPTIONS (since Linux 2.4.6; see BUGS for caveats)
Set ptrace options from *data*. (*addr* is ignored.) *data* is interpreted as a bit mask of options, which are specified by the following flags:

PTRACE_O_EXITKILL (since Linux 3.8)
Send a **SIGKILL** signal to the tracee if the tracer exits. This option is useful for ptrace jailers that want to ensure that tracees can never escape the tracer's control.

PTRACE_O_TRACECLONE (since Linux 2.5.46)
Stop the tracee at the next *clone*(2) and automatically start tracing the newly cloned process, which will start with a **SIGSTOP**, or **PTRACE_EVENT_STOP** if **PTRACE_SEIZE** was used. A *waitpid*(2) by the tracer will return a *status* value such that

status>>8 == (SIGTRAP | (PTRACE_EVENT_CLONE<<8))

The PID of the new process can be retrieved with **PTRACE_GETEVENTMSG**.

This option may not catch *clone*(2) calls in all cases. If the tracee calls *clone*(2) with the **CLONE_VFORK** flag, **PTRACE_EVENT_VFORK** will be delivered instead if **PTRACE_O_TRACEVFORK** is set; otherwise if the tracee calls *clone*(2) with the exit signal set to **SIGCHLD**, **PTRACE_EVENT_FORK** will be delivered if **PTRACE_O_TRACEFORK** is set.

PTRACE_O_TRACEEXEC (since Linux 2.5.46)
Stop the tracee at the next *execve*(2). A *waitpid*(2) by the tracer will return a *status* value such that

status>>8 == (SIGTRAP | (PTRACE_EVENT_EXEC<<8))

If the execing thread is not a thread group leader, the thread ID is reset to thread group leader's ID before this stop. Since Linux 3.0, the former thread ID can be retrieved with **PTRACE_GETEVENTMSG**.

PTRACE_O_TRACEEXIT (since Linux 2.5.60)
Stop the tracee at exit. A *waitpid*(2) by the tracer will return a *status* value such that

status>>8 == (SIGTRAP | (PTRACE_EVENT_EXIT<<8))

The tracee's exit status can be retrieved with **PTRACE_GETEVENTMSG**.

The tracee is stopped early during process exit, when registers are still available, allowing the tracer to see where the exit occurred, whereas the normal exit notification is done after the process is finished exiting. Even though context is available, the tracer cannot prevent the exit from happening at this point.

PTRACE_O_TRACEFORK (since Linux 2.5.46)
Stop the tracee at the next *fork*(2) and automatically start tracing the newly forked process, which will start with a **SIGSTOP**, or **PTRACE_EVENT_STOP** if **PTRACE_SEIZE** was used. A *waitpid*(2) by the tracer will return a *status* value such that

status>>8 == (SIGTRAP | (PTRACE_EVENT_FORK<<8))

The PID of the new process can be retrieved with **PTRACE_GETEVENTMSG**.

PTRACE_O_TRACESYSGOOD (since Linux 2.4.6)
When delivering system call traps, set bit 7 in the signal number (i.e., deliver *SIGTRAP|0x80*). This makes it easy for the tracer to distinguish normal traps from those caused by a system call.

PTRACE_O_TRACEVFORK (since Linux 2.5.46)
Stop the tracee at the next *vfork*(2) and automatically start tracing the newly vforked process, which will start with a **SIGSTOP**, or **PTRACE_EVENT_STOP** if **PTRACE_SEIZE** was used. A *waitpid*(2) by the tracer will return a *status* value such that

status>>8 == (SIGTRAP | (PTRACE_EVENT_VFORK<<8))

The PID of the new process can be retrieved with **PTRACE_GETEVENTMSG**.

PTRACE_O_TRACEVFORKDONE (since Linux 2.5.60)
Stop the tracee at the completion of the next *vfork*(2). A *waitpid*(2) by the tracer will return a *status* value such that

status>>8 == (SIGTRAP | (PTRACE_EVENT_VFORK_DONE<<8))

The PID of the new process can (since Linux 2.6.18) be retrieved with **PTRACE_GETEVENTMSG**.

PTRACE_O_TRACESECCOMP (since Linux 3.5)
Stop the tracee when a *seccomp*(2) **SECCOMP_RET_TRACE** rule is triggered. A *waitpid*(2) by the tracer will return a *status* value such that

status>>8 == (SIGTRAP | (PTRACE_EVENT_SECCOMP<<8))

While this triggers a **PTRACE_EVENT** stop, it is similar to a syscall-enter-stop. For details, see the note on **PTRACE_EVENT_SECCOMP** below. The seccomp event message data (from the **SECCOMP_RET_DATA** portion of the seccomp filter rule) can be retrieved with **PTRACE_GETEVENTMSG**.

PTRACE_O_SUSPEND_SECCOMP (since Linux 4.3)
Suspend the tracee's seccomp protections. This applies regardless of mode, and can be used when the tracee has not yet installed seccomp filters. That is, a valid use case is to suspend a tracee's seccomp protections before they are installed by the tracee, let the tracee install the filters, and then clear this flag when the filters should be resumed. Setting this option requires that the tracer have the **CAP_SYS_ADMIN** capability, not have any seccomp protections installed, and not have **PTRACE_O_SUSPEND_SECCOMP** set on itself.

PTRACE_GETEVENTMSG (since Linux 2.5.46)
Retrieve a message (as an *unsigned long*) about the ptrace event that just happened, placing it at the address *data* in the tracer. For **PTRACE_EVENT_EXIT**, this is the tracee's exit status. For **PTRACE_EVENT_FORK**, **PTRACE_EVENT_VFORK**, **PTRACE_EVENT_VFORK_DONE**, and **PTRACE_EVENT_CLONE**, this is the PID of the new process. For **PTRACE_EVENT_SECCOMP**, this is the *seccomp*(2) filter's **SECCOMP_RET_DATA** associated with the triggered rule. (*addr* is ignored.)

PTRACE_CONT
Restart the stopped tracee process. If *data* is nonzero, it is interpreted as the number of a signal to be delivered to the tracee; otherwise, no signal is delivered. Thus, for example, the tracer can control whether a signal sent to the tracee is delivered or not. (*addr* is ignored.)

PTRACE_SYSCALL
PTRACE_SINGLESTEP
Restart the stopped tracee as for **PTRACE_CONT**, but arrange for the tracee to be stopped at the next entry to or exit from a system call, or after execution of a single instruction, respectively. (The tracee will also, as usual, be stopped upon receipt of a signal.) From the tracer's perspective, the tracee will appear to have been stopped by receipt of a **SIGTRAP**. So, for **PTRACE_SYSCALL**, for example, the idea is to inspect the arguments to the system call at

the first stop, then do another **PTRACE_SYSCALL** and inspect the return value of the system call at the second stop. The *data* argument is treated as for **PTRACE_CONT**. (*addr* is ignored.)

PTRACE_SET_SYSCALL (since Linux 2.6.16)
When in syscall-enter-stop, change the number of the system call that is about to be executed to the number specified in the *data* argument. The *addr* argument is ignored. This operation is currently supported only on arm (and arm64, though only for backwards compatibility), but most other architectures have other means of accomplishing this (usually by changing the register that the userland code passed the system call number in).

PTRACE_SYSEMU
PTRACE_SYSEMU_SINGLESTEP (since Linux 2.6.14)
For **PTRACE_SYSEMU**, continue and stop on entry to the next system call, which will not be executed. See the documentation on syscall-stops below. For **PTRACE_SYSEMU_SINGLESTEP**, do the same but also singlestep if not a system call. This call is used by programs like User Mode Linux that want to emulate all the tracee's system calls. The *data* argument is treated as for **PTRACE_CONT**. The *addr* argument is ignored. These operations are currently supported only on x86.

PTRACE_LISTEN (since Linux 3.4)
Restart the stopped tracee, but prevent it from executing. The resulting state of the tracee is similar to a process which has been stopped by a **SIGSTOP** (or other stopping signal). See the "group-stop" subsection for additional information. **PTRACE_LISTEN** works only on tracees attached by **PTRACE_SEIZE**.

PTRACE_KILL
Send the tracee a **SIGKILL** to terminate it. (*addr* and *data* are ignored.)

This operation is deprecated; do not use it! Instead, send a **SIGKILL** directly using *kill*(2) or *tgkill*(2). The problem with **PTRACE_KILL** is that it requires the tracee to be in signal-delivery-stop, otherwise it may not work (i.e., may complete successfully but won't kill the tracee). By contrast, sending a **SIGKILL** directly has no such limitation.

PTRACE_INTERRUPT (since Linux 3.4)
Stop a tracee. If the tracee is running or sleeping in kernel space and **PTRACE_SYSCALL** is in effect, the system call is interrupted and syscall-exit-stop is reported. (The interrupted system call is restarted when the tracee is restarted.) If the tracee was already stopped by a signal and **PTRACE_LISTEN** was sent to it, the tracee stops with **PTRACE_EVENT_STOP** and *WSTOPSIG(status)* returns the stop signal. If any other ptrace-stop is generated at the same time (for example, if a signal is sent to the tracee), this ptrace-stop happens. If none of the above applies (for example, if the tracee is running in user space), it stops with **PTRACE_EVENT_STOP** with *WSTOPSIG(status)* == **SIGTRAP**. **PTRACE_INTERRUPT** only works on tracees attached by **PTRACE_SEIZE**.

PTRACE_ATTACH
Attach to the process specified in *pid*, making it a tracee of the calling process. The tracee is sent a **SIGSTOP**, but will not necessarily have stopped by the completion of this call; use *waitpid*(2) to wait for the tracee to stop. See the "Attaching and detaching" subsection for additional information. (*addr* and *data* are ignored.)

Permission to perform a **PTRACE_ATTACH** is governed by a ptrace access mode **PTRACE_MODE_ATTACH_REALCREDS** check; see below.

PTRACE_SEIZE (since Linux 3.4)
Attach to the process specified in *pid*, making it a tracee of the calling process. Unlike **PTRACE_ATTACH**, **PTRACE_SEIZE** does not stop the process. Group-stops are reported as **PTRACE_EVENT_STOP** and *WSTOPSIG(status)* returns the stop signal. Automatically attached children stop with **PTRACE_EVENT_STOP** and *WSTOPSIG(status)* returns **SIGTRAP** instead of having **SIGSTOP** signal delivered to them. *execve*(2) does not deliver an extra **SIGTRAP**. Only a **PTRACE_SEIZE**d process can accept **PTRACE_INTERRUPT** and **PTRACE_LISTEN** commands. The "seized" behavior just described is inherited by children that are automatically attached using **PTRACE_O_TRACEFORK**, **PTRACE_O_TRACEVFORK**, and **PTRACE_O_TRACECLONE**. *addr* must be zero.

data contains a bit mask of ptrace options to activate immediately.

Permission to perform a **PTRACE_SEIZE** is governed by a ptrace access mode **PTRACE_MODE_ATTACH_REALCREDS** check; see below.

PTRACE_SECCOMP_GET_FILTER (since Linux 4.4)
This operation allows the tracer to dump the tracee's classic BPF filters.

addr is an integer specifying the index of the filter to be dumped. The most recently installed filter has the index 0. If *addr* is greater than the number of installed filters, the operation fails with the error **ENOENT**.

data is either a pointer to a *struct sock_filter* array that is large enough to store the BPF program, or NULL if the program is not to be stored.

Upon success, the return value is the number of instructions in the BPF program. If *data* was NULL, then this return value can be used to correctly size the *struct sock_filter* array passed in a subsequent call.

This operation fails with the error **EACCES** if the caller does not have the **CAP_SYS_ADMIN** capability or if the caller is in strict or filter seccomp mode. If the filter referred to by *addr* is not a classic BPF filter, the operation fails with the error **EMEDIUMTYPE**.

This operation is available if the kernel was configured with both the **CONFIG_SECCOMP_FILTER** and the **CONFIG_CHECKPOINT_RESTORE** options.

PTRACE_DETACH
Restart the stopped tracee as for **PTRACE_CONT**, but first detach from it. Under Linux, a tracee can be detached in this way regardless of which method was used to initiate tracing. (*addr* is ignored.)

PTRACE_GET_THREAD_AREA (since Linux 2.6.0)
This operation performs a similar task to *get_thread_area*(2). It reads the TLS entry in the GDT whose index is given in *addr*, placing a copy of the entry into the *struct user_desc* pointed to by *data*. (By contrast with *get_thread_area*(2), the *entry_number* of the *struct user_desc* is ignored.)

PTRACE_SET_THREAD_AREA (since Linux 2.6.0)
This operation performs a similar task to *set_thread_area*(2). It sets the TLS entry in the GDT whose index is given in *addr*, assigning it the data supplied in the *struct user_desc* pointed to by *data*. (By contrast with *set_thread_area*(2), the *entry_number* of the *struct user_desc* is ignored; in other words, this ptrace operation can't be used to allocate a free TLS entry.)

PTRACE_GET_SYSCALL_INFO (since Linux 5.3)
Retrieve information about the system call that caused the stop. The information is placed into the buffer pointed by the *data* argument, which should be a pointer to a buffer of type *struct ptrace_syscall_info*. The *addr* argument contains the size of the buffer pointed to by the *data* argument (i.e., *sizeof(struct ptrace_syscall_info)*). The return value contains the number of bytes available to be written by the kernel. If the size of the data to be written by the kernel exceeds the size specified by the *addr* argument, the output data is truncated.

The *ptrace_syscall_info* structure contains the following fields:

```
struct ptrace_syscall_info {
    __u8 op;        /* Type of system call stop */
    __u32 arch;     /* AUDIT_ARCH_* value; see seccomp(2) */
    __u64 instruction_pointer; /* CPU instruction pointer */
    __u64 stack_pointer;    /* CPU stack pointer */
    union {
        struct {    /* op == PTRACE_SYSCALL_INFO_ENTRY */
            __u64 nr;       /* System call number */
            __u64 args[6];  /* System call arguments */
        } entry;
        struct {    /* op == PTRACE_SYSCALL_INFO_EXIT */
            __s64 rval;     /* System call return value */
            __u8 is_error;  /* System call error flag;
```

```
                                    Boolean: does rval contain
                                    an error value (-ERRCODE) or
                                    a nonerror return value? */
                } exit;
                struct {    /* op == PTRACE_SYSCALL_INFO_SECCOMP */
                    __u64 nr;       /* System call number */
                    __u64 args[6];  /* System call arguments */
                    __u32 ret_data; /* SECCOMP_RET_DATA portion
                                       of SECCOMP_RET_TRACE
                                       return value */
                } seccomp;
            };
        };
```

The *op*, *arch*, *instruction_pointer*, and *stack_pointer* fields are defined for all kinds of ptrace system call stops. The rest of the structure is a union; one should read only those fields that are meaningful for the kind of system call stop specified by the *op* field.

The *op* field has one of the following values (defined in <*linux/ptrace.h*>) indicating what type of stop occurred and which part of the union is filled:

PTRACE_SYSCALL_INFO_ENTRY
: The *entry* component of the union contains information relating to a system call entry stop.

PTRACE_SYSCALL_INFO_EXIT
: The *exit* component of the union contains information relating to a system call exit stop.

PTRACE_SYSCALL_INFO_SECCOMP
: The *seccomp* component of the union contains information relating to a **PTRACE_EVENT_SECCOMP** stop.

PTRACE_SYSCALL_INFO_NONE
: No component of the union contains relevant information.

In case of system call entry or exit stops, the data returned by **PTRACE_GET_SYSCALL_INFO** is limited to type **PTRACE_SYSCALL_INFO_NONE** unless **PTRACE_O_TRACESYSGOOD** option is set before the corresponding system call stop has occurred.

Death under ptrace

When a (possibly multithreaded) process receives a killing signal (one whose disposition is set to **SIG_DFL** and whose default action is to kill the process), all threads exit. Tracees report their death to their tracer(s). Notification of this event is delivered via *waitpid*(2).

Note that the killing signal will first cause signal-delivery-stop (on one tracee only), and only after it is injected by the tracer (or after it was dispatched to a thread which isn't traced), will death from the signal happen on *all* tracees within a multithreaded process. (The term "signal-delivery-stop" is explained below.)

SIGKILL does not generate signal-delivery-stop and therefore the tracer can't suppress it. **SIGKILL** kills even within system calls (syscall-exit-stop is not generated prior to death by **SIGKILL**). The net effect is that **SIGKILL** always kills the process (all its threads), even if some threads of the process are ptraced.

When the tracee calls *_exit*(2), it reports its death to its tracer. Other threads are not affected.

When any thread executes *exit_group*(2), every tracee in its thread group reports its death to its tracer.

If the **PTRACE_O_TRACEEXIT** option is on, **PTRACE_EVENT_EXIT** will happen before actual death. This applies to exits via *exit*(2), *exit_group*(2), and signal deaths (except **SIGKILL**, depending on the kernel version; see BUGS below), and when threads are torn down on *execve*(2) in a multithreaded process.

The tracer cannot assume that the ptrace-stopped tracee exists. There are many scenarios when the tracee may die while stopped (such as **SIGKILL**). Therefore, the tracer must be prepared to handle an

ESRCH error on any ptrace operation. Unfortunately, the same error is returned if the tracee exists but is not ptrace-stopped (for commands which require a stopped tracee), or if it is not traced by the process which issued the ptrace call. The tracer needs to keep track of the stopped/running state of the tracee, and interpret **ESRCH** as "tracee died unexpectedly" only if it knows that the tracee has been observed to enter ptrace-stop. Note that there is no guarantee that *waitpid(WNOHANG)* will reliably report the tracee's death status if a ptrace operation returned **ESRCH**. *waitpid(WNOHANG)* may return 0 instead. In other words, the tracee may be "not yet fully dead", but already refusing ptrace operations.

The tracer can't assume that the tracee *always* ends its life by reporting *WIFEXITED(status)* or *WIFSIGNALED(status)*; there are cases where this does not occur. For example, if a thread other than thread group leader does an *execve*(2), it disappears; its PID will never be seen again, and any subsequent ptrace stops will be reported under the thread group leader's PID.

Stopped states

A tracee can be in two states: running or stopped. For the purposes of ptrace, a tracee which is blocked in a system call (such as *read*(2), *pause*(2), etc.) is nevertheless considered to be running, even if the tracee is blocked for a long time. The state of the tracee after **PTRACE_LISTEN** is somewhat of a gray area: it is not in any ptrace-stop (ptrace commands won't work on it, and it will deliver *waitpid*(2) notifications), but it also may be considered "stopped" because it is not executing instructions (is not scheduled), and if it was in group-stop before **PTRACE_LISTEN**, it will not respond to signals until **SIGCONT** is received.

There are many kinds of states when the tracee is stopped, and in ptrace discussions they are often conflated. Therefore, it is important to use precise terms.

In this manual page, any stopped state in which the tracee is ready to accept ptrace commands from the tracer is called *ptrace-stop*. Ptrace-stops can be further subdivided into *signal-delivery-stop*, *group-stop*, *syscall-stop*, *PTRACE_EVENT stops*, and so on. These stopped states are described in detail below.

When the running tracee enters ptrace-stop, it notifies its tracer using *waitpid*(2) (or one of the other "wait" system calls). Most of this manual page assumes that the tracer waits with:

```
pid = waitpid(pid_or_minus_1, &status, __WALL);
```

Ptrace-stopped tracees are reported as returns with *pid* greater than 0 and *WIFSTOPPED(status)* true.

The **__WALL** flag does not include the **WSTOPPED** and **WEXITED** flags, but implies their functionality.

Setting the **WCONTINUED** flag when calling *waitpid*(2) is not recommended: the "continued" state is per-process and consuming it can confuse the real parent of the tracee.

Use of the **WNOHANG** flag may cause *waitpid*(2) to return 0 ("no wait results available yet") even if the tracer knows there should be a notification. Example:

```
errno = 0;
ptrace(PTRACE_CONT, pid, 0L, 0L);
if (errno == ESRCH) {
    /* tracee is dead */
    r = waitpid(tracee, &status, __WALL | WNOHANG);
    /* r can still be 0 here! */
}
```

The following kinds of ptrace-stops exist: signal-delivery-stops, group-stops, **PTRACE_EVENT** stops, syscall-stops. They all are reported by *waitpid*(2) with *WIFSTOPPED(status)* true. They may be differentiated by examining the value *status>>8*, and if there is ambiguity in that value, by querying **PTRACE_GETSIGINFO**. (Note: the *WSTOPSIG(status)* macro can't be used to perform this examination, because it returns the value *(status>>8) & 0xff*.)

Signal-delivery-stop

When a (possibly multithreaded) process receives any signal except **SIGKILL**, the kernel selects an arbitrary thread which handles the signal. (If the signal is generated with *tgkill*(2), the target thread can be explicitly selected by the caller.) If the selected thread is traced, it enters signal-delivery-stop. At this point, the signal is not yet delivered to the process, and can be suppressed by the tracer. If the

tracer doesn't suppress the signal, it passes the signal to the tracee in the next ptrace restart operation. This second step of signal delivery is called *signal injection* in this manual page. Note that if the signal is blocked, signal-delivery-stop doesn't happen until the signal is unblocked, with the usual exception that **SIGSTOP** can't be blocked.

Signal-delivery-stop is observed by the tracer as *waitpid*(2) returning with *WIFSTOPPED(status)* true, with the signal returned by *WSTOPSIG(status)*. If the signal is **SIGTRAP**, this may be a different kind of ptrace-stop; see the "Syscall-stops" and "execve" sections below for details. If *WSTOPSIG(status)* returns a stopping signal, this may be a group-stop; see below.

Signal injection and suppression

After signal-delivery-stop is observed by the tracer, the tracer should restart the tracee with the call

```
ptrace(PTRACE_restart, pid, 0, sig)
```

where **PTRACE_restart** is one of the restarting ptrace operations. If *sig* is 0, then a signal is not delivered. Otherwise, the signal *sig* is delivered. This operation is called *signal injection* in this manual page, to distinguish it from signal-delivery-stop.

The *sig* value may be different from the *WSTOPSIG(status)* value: the tracer can cause a different signal to be injected.

Note that a suppressed signal still causes system calls to return prematurely. In this case, system calls will be restarted: the tracer will observe the tracee to reexecute the interrupted system call (or *restart_syscall*(2) system call for a few system calls which use a different mechanism for restarting) if the tracer uses **PTRACE_SYSCALL**. Even system calls (such as *poll*(2)) which are not restartable after signal are restarted after signal is suppressed; however, kernel bugs exist which cause some system calls to fail with **EINTR** even though no observable signal is injected to the tracee.

Restarting ptrace commands issued in ptrace-stops other than signal-delivery-stop are not guaranteed to inject a signal, even if *sig* is nonzero. No error is reported; a nonzero *sig* may simply be ignored. Ptrace users should not try to "create a new signal" this way: use *tgkill*(2) instead.

The fact that signal injection operations may be ignored when restarting the tracee after ptrace stops that are not signal-delivery-stops is a cause of confusion among ptrace users. One typical scenario is that the tracer observes group-stop, mistakes it for signal-delivery-stop, restarts the tracee with

```
ptrace(PTRACE_restart, pid, 0, stopsig)
```

with the intention of injecting *stopsig*, but *stopsig* gets ignored and the tracee continues to run.

The **SIGCONT** signal has a side effect of waking up (all threads of) a group-stopped process. This side effect happens before signal-delivery-stop. The tracer can't suppress this side effect (it can only suppress signal injection, which only causes the **SIGCONT** handler to not be executed in the tracee, if such a handler is installed). In fact, waking up from group-stop may be followed by signal-delivery-stop for signal(s) *other than* **SIGCONT**, if they were pending when **SIGCONT** was delivered. In other words, **SIGCONT** may be not the first signal observed by the tracee after it was sent.

Stopping signals cause (all threads of) a process to enter group-stop. This side effect happens after signal injection, and therefore can be suppressed by the tracer.

In Linux 2.4 and earlier, the **SIGSTOP** signal can't be injected.

PTRACE_GETSIGINFO can be used to retrieve a *siginfo_t* structure which corresponds to the delivered signal. **PTRACE_SETSIGINFO** may be used to modify it. If **PTRACE_SETSIGINFO** has been used to alter *siginfo_t*, the *si_signo* field and the *sig* parameter in the restarting command must match, otherwise the result is undefined.

Group-stop

When a (possibly multithreaded) process receives a stopping signal, all threads stop. If some threads are traced, they enter a group-stop. Note that the stopping signal will first cause signal-delivery-stop (on one tracee only), and only after it is injected by the tracer (or after it was dispatched to a thread which isn't traced), will group-stop be initiated on *all* tracees within the multithreaded process. As usual, every tracee reports its group-stop separately to the corresponding tracer.

Group-stop is observed by the tracer as *waitpid*(2) returning with *WIFSTOPPED(status)* true, with the stopping signal available via *WSTOPSIG(status)*. The same result is returned by some other classes of ptrace-stops, therefore the recommended practice is to perform the call

```
ptrace(PTRACE_GETSIGINFO, pid, 0, &siginfo)
```

The call can be avoided if the signal is not **SIGSTOP**, **SIGTSTP**, **SIGTTIN**, or **SIGTTOU**; only these four signals are stopping signals. If the tracer sees something else, it can't be a group-stop. Otherwise, the tracer needs to call **PTRACE_GETSIGINFO**. If **PTRACE_GETSIGINFO** fails with **EINVAL**, then it is definitely a group-stop. (Other failure codes are possible, such as **ESRCH** ("no such process") if a **SIGKILL** killed the tracee.)

If tracee was attached using **PTRACE_SEIZE**, group-stop is indicated by **PTRACE_EVENT_STOP**: *status>>16 == PTRACE_EVENT_STOP*. This allows detection of group-stops without requiring an extra **PTRACE_GETSIGINFO** call.

As of Linux 2.6.38, after the tracer sees the tracee ptrace-stop and until it restarts or kills it, the tracee will not run, and will not send notifications (except **SIGKILL** death) to the tracer, even if the tracer enters into another *waitpid*(2) call.

The kernel behavior described in the previous paragraph causes a problem with transparent handling of stopping signals. If the tracer restarts the tracee after group-stop, the stopping signal is effectively ignored—the tracee doesn't remain stopped, it runs. If the tracer doesn't restart the tracee before entering into the next *waitpid*(2), future **SIGCONT** signals will not be reported to the tracer; this would cause the **SIGCONT** signals to have no effect on the tracee.

Since Linux 3.4, there is a method to overcome this problem: instead of **PTRACE_CONT**, a **PTRACE_LISTEN** command can be used to restart a tracee in a way where it does not execute, but waits for a new event which it can report via *waitpid*(2) (such as when it is restarted by a **SIGCONT**).

PTRACE_EVENT stops

If the tracer sets **PTRACE_O_TRACE_*** options, the tracee will enter ptrace-stops called **PTRACE_EVENT** stops.

PTRACE_EVENT stops are observed by the tracer as *waitpid*(2) returning with *WIFSTOPPED(status)*, and *WSTOPSIG(status)* returns **SIGTRAP** (or for **PTRACE_EVENT_STOP**, returns the stopping signal if tracee is in a group-stop). An additional bit is set in the higher byte of the status word: the value *status>>8* will be

```
((PTRACE_EVENT_foo<<8) | SIGTRAP).
```

The following events exist:

PTRACE_EVENT_VFORK
: Stop before return from *vfork*(2) or *clone*(2) with the **CLONE_VFORK** flag. When the tracee is continued after this stop, it will wait for child to exit/exec before continuing its execution (in other words, the usual behavior on *vfork*(2)).

PTRACE_EVENT_FORK
: Stop before return from *fork*(2) or *clone*(2) with the exit signal set to **SIGCHLD**.

PTRACE_EVENT_CLONE
: Stop before return from *clone*(2).

PTRACE_EVENT_VFORK_DONE
: Stop before return from *vfork*(2) or *clone*(2) with the **CLONE_VFORK** flag, but after the child unblocked this tracee by exiting or execing.

For all four stops described above, the stop occurs in the parent (i.e., the tracee), not in the newly created thread. **PTRACE_GETEVENTMSG** can be used to retrieve the new thread's ID.

PTRACE_EVENT_EXEC
: Stop before return from *execve*(2). Since Linux 3.0, **PTRACE_GETEVENTMSG** returns the former thread ID.

PTRACE_EVENT_EXIT
: Stop before exit (including death from *exit_group*(2)), signal death, or exit caused by *execve*(2) in a multithreaded process. **PTRACE_GETEVENTMSG** returns the exit status. Registers can be examined (unlike when "real" exit happens). The tracee is still alive; it needs to be **PTRACE_CONT**ed or **PTRACE_DETACH**ed to finish exiting.

PTRACE_EVENT_STOP
Stop induced by **PTRACE_INTERRUPT** command, or group-stop, or initial ptrace-stop when a new child is attached (only if attached using **PTRACE_SEIZE**).

PTRACE_EVENT_SECCOMP
Stop triggered by a *seccomp*(2) rule on tracee syscall entry when **PTRACE_O_TRACESECCOMP** has been set by the tracer. The seccomp event message data (from the **SECCOMP_RET_DATA** portion of the seccomp filter rule) can be retrieved with **PTRACE_GETEVENTMSG**. The semantics of this stop are described in detail in a separate section below.

PTRACE_GETSIGINFO on **PTRACE_EVENT** stops returns **SIGTRAP** in *si_signo*, with *si_code* set to *(event<<8) | SIGTRAP*.

Syscall-stops
If the tracee was restarted by **PTRACE_SYSCALL** or **PTRACE_SYSEMU**, the tracee enters syscall-enter-stop just prior to entering any system call (which will not be executed if the restart was using **PTRACE_SYSEMU**, regardless of any change made to registers at this point or how the tracee is restarted after this stop). No matter which method caused the syscall-entry-stop, if the tracer restarts the tracee with **PTRACE_SYSCALL**, the tracee enters syscall-exit-stop when the system call is finished, or if it is interrupted by a signal. (That is, signal-delivery-stop never happens between syscall-enter-stop and syscall-exit-stop; it happens *after* syscall-exit-stop.). If the tracee is continued using any other method (including **PTRACE_SYSEMU**), no syscall-exit-stop occurs. Note that all mentions **PTRACE_SYSEMU** apply equally to **PTRACE_SYSEMU_SINGLESTEP**.

However, even if the tracee was continued using **PTRACE_SYSCALL**, it is not guaranteed that the next stop will be a syscall-exit-stop. Other possibilities are that the tracee may stop in a **PTRACE_EVENT** stop (including seccomp stops), exit (if it entered *_exit*(2) or *exit_group*(2)), be killed by **SIGKILL**, or die silently (if it is a thread group leader, the *execve*(2) happened in another thread, and that thread is not traced by the same tracer; this situation is discussed later).

Syscall-enter-stop and syscall-exit-stop are observed by the tracer as *waitpid*(2) returning with *WIFSTOPPED(status)* true, and *WSTOPSIG(status)* giving **SIGTRAP**. If the **PTRACE_O_TRACESYSGOOD** option was set by the tracer, then *WSTOPSIG(status)* will give the value *(SIGTRAP | 0x80)*.

Syscall-stops can be distinguished from signal-delivery-stop with **SIGTRAP** by querying **PTRACE_GETSIGINFO** for the following cases:

si_code <= 0
SIGTRAP was delivered as a result of a user-space action, for example, a system call (**tgkill**(2), *kill*(2), *sigqueue*(3), etc.), expiration of a POSIX timer, change of state on a POSIX message queue, or completion of an asynchronous I/O operation.

si_code == SI_KERNEL (0x80)
SIGTRAP was sent by the kernel.

si_code == SIGTRAP or *si_code* == (SIGTRAP|0x80)
This is a syscall-stop.

However, syscall-stops happen very often (twice per system call), and performing **PTRACE_GETSIGINFO** for every syscall-stop may be somewhat expensive.

Some architectures allow the cases to be distinguished by examining registers. For example, on x86, *rax* == −**ENOSYS** in syscall-enter-stop. Since **SIGTRAP** (like any other signal) always happens *after* syscall-exit-stop, and at this point *rax* almost never contains −**ENOSYS**, the **SIGTRAP** looks like "syscall-stop which is not syscall-enter-stop"; in other words, it looks like a "stray syscall-exit-stop" and can be detected this way. But such detection is fragile and is best avoided.

Using the **PTRACE_O_TRACESYSGOOD** option is the recommended method to distinguish syscall-stops from other kinds of ptrace-stops, since it is reliable and does not incur a performance penalty.

Syscall-enter-stop and syscall-exit-stop are indistinguishable from each other by the tracer. The tracer needs to keep track of the sequence of ptrace-stops in order to not misinterpret syscall-enter-stop as syscall-exit-stop or vice versa. In general, a syscall-enter-stop is always followed by syscall-exit-stop, **PTRACE_EVENT** stop, or the tracee’s death; no other kinds of ptrace-stop can occur in between.

However, note that seccomp stops (see below) can cause syscall-exit-stops, without preceding syscall-entry-stops. If seccomp is in use, care needs to be taken not to misinterpret such stops as syscall-entry-stops.

If after syscall-enter-stop, the tracer uses a restarting command other than **PTRACE_SYSCALL**, syscall-exit-stop is not generated.

PTRACE_GETSIGINFO on syscall-stops returns **SIGTRAP** in *si_signo*, with *si_code* set to **SIGTRAP** or *(SIGTRAP|0x80)*.

PTRACE_EVENT_SECCOMP stops (Linux 3.5 to Linux 4.7)

The behavior of **PTRACE_EVENT_SECCOMP** stops and their interaction with other kinds of ptrace stops has changed between kernel versions. This documents the behavior from their introduction until Linux 4.7 (inclusive). The behavior in later kernel versions is documented in the next section.

A **PTRACE_EVENT_SECCOMP** stop occurs whenever a **SECCOMP_RET_TRACE** rule is triggered. This is independent of which methods was used to restart the system call. Notably, seccomp still runs even if the tracee was restarted using **PTRACE_SYSEMU** and this system call is unconditionally skipped.

Restarts from this stop will behave as if the stop had occurred right before the system call in question. In particular, both **PTRACE_SYSCALL** and **PTRACE_SYSEMU** will normally cause a subsequent syscall-entry-stop. However, if after the **PTRACE_EVENT_SECCOMP** the system call number is negative, both the syscall-entry-stop and the system call itself will be skipped. This means that if the system call number is negative after a **PTRACE_EVENT_SECCOMP** and the tracee is restarted using **PTRACE_SYSCALL**, the next observed stop will be a syscall-exit-stop, rather than the syscall-entry-stop that might have been expected.

PTRACE_EVENT_SECCOMP stops (since Linux 4.8)

Starting with Linux 4.8, the **PTRACE_EVENT_SECCOMP** stop was reordered to occur between syscall-entry-stop and syscall-exit-stop. Note that seccomp no longer runs (and no **PTRACE_EVENT_SECCOMP** will be reported) if the system call is skipped due to **PTRACE_SYSEMU**.

Functionally, a **PTRACE_EVENT_SECCOMP** stop functions comparably to a syscall-entry-stop (i.e., continuations using **PTRACE_SYSCALL** will cause syscall-exit-stops, the system call number may be changed and any other modified registers are visible to the to-be-executed system call as well). Note that there may be, but need not have been a preceding syscall-entry-stop.

After a **PTRACE_EVENT_SECCOMP** stop, seccomp will be rerun, with a **SECCOMP_RET_TRACE** rule now functioning the same as a **SECCOMP_RET_ALLOW**. Specifically, this means that if registers are not modified during the **PTRACE_EVENT_SECCOMP** stop, the system call will then be allowed.

PTRACE_SINGLESTEP stops

[Details of these kinds of stops are yet to be documented.]

Informational and restarting ptrace commands

Most ptrace commands (all except **PTRACE_ATTACH**, **PTRACE_SEIZE**, **PTRACE_TRACEME**, **PTRACE_INTERRUPT**, and **PTRACE_KILL**) require the tracee to be in a ptrace-stop, otherwise they fail with **ESRCH**.

When the tracee is in ptrace-stop, the tracer can read and write data to the tracee using informational commands. These commands leave the tracee in ptrace-stopped state:

```
ptrace(PTRACE_PEEKTEXT/PEEKDATA/PEEKUSER, pid, addr, 0);
ptrace(PTRACE_POKETEXT/POKEDATA/POKEUSER, pid, addr, long_val);
ptrace(PTRACE_GETREGS/GETFPREGS, pid, 0, &struct);
ptrace(PTRACE_SETREGS/SETFPREGS, pid, 0, &struct);
ptrace(PTRACE_GETREGSET, pid, NT_foo, &iov);
ptrace(PTRACE_SETREGSET, pid, NT_foo, &iov);
ptrace(PTRACE_GETSIGINFO, pid, 0, &siginfo);
ptrace(PTRACE_SETSIGINFO, pid, 0, &siginfo);
ptrace(PTRACE_GETEVENTMSG, pid, 0, &long_var);
ptrace(PTRACE_SETOPTIONS, pid, 0, PTRACE_O_flags);
```

Note that some errors are not reported. For example, setting signal information (*siginfo*) may have no effect in some ptrace-stops, yet the call may succeed (return 0 and not set *errno*); querying **PTRACE_GETEVENTMSG** may succeed and return some random value if current ptrace-stop is not documented as returning a meaningful event message.

The call

```
ptrace(PTRACE_SETOPTIONS, pid, 0, PTRACE_O_flags);
```

affects one tracee. The tracee's current flags are replaced. Flags are inherited by new tracees created and "auto-attached" via active **PTRACE_O_TRACEFORK**, **PTRACE_O_TRACEVFORK**, or **PTRACE_O_TRACECLONE** options.

Another group of commands makes the ptrace-stopped tracee run. They have the form:

```
ptrace(cmd, pid, 0, sig);
```

where *cmd* is **PTRACE_CONT**, **PTRACE_LISTEN**, **PTRACE_DETACH**, **PTRACE_SYSCALL**, **PTRACE_SINGLESTEP**, **PTRACE_SYSEMU**, or **PTRACE_SYSEMU_SINGLESTEP**. If the tracee is in signal-delivery-stop, *sig* is the signal to be injected (if it is nonzero). Otherwise, *sig* may be ignored. (When restarting a tracee from a ptrace-stop other than signal-delivery-stop, recommended practice is to always pass 0 in *sig*.)

Attaching and detaching

A thread can be attached to the tracer using the call

```
ptrace(PTRACE_ATTACH, pid, 0, 0);
```

or

```
ptrace(PTRACE_SEIZE, pid, 0, PTRACE_O_flags);
```

PTRACE_ATTACH sends **SIGSTOP** to this thread. If the tracer wants this **SIGSTOP** to have no effect, it needs to suppress it. Note that if other signals are concurrently sent to this thread during attach, the tracer may see the tracee enter signal-delivery-stop with other signal(s) first! The usual practice is to reinject these signals until **SIGSTOP** is seen, then suppress **SIGSTOP** injection. The design bug here is that a ptrace attach and a concurrently delivered **SIGSTOP** may race and the concurrent **SIGSTOP** may be lost.

Since attaching sends **SIGSTOP** and the tracer usually suppresses it, this may cause a stray **EINTR** return from the currently executing system call in the tracee, as described in the "Signal injection and suppression" section.

Since Linux 3.4, **PTRACE_SEIZE** can be used instead of **PTRACE_ATTACH**. **PTRACE_SEIZE** does not stop the attached process. If you need to stop it after attach (or at any other time) without sending it any signals, use **PTRACE_INTERRUPT** command.

The operation

```
ptrace(PTRACE_TRACEME, 0, 0, 0);
```

turns the calling thread into a tracee. The thread continues to run (doesn't enter ptrace-stop). A common practice is to follow the **PTRACE_TRACEME** with

```
raise(SIGSTOP);
```

and allow the parent (which is our tracer now) to observe our signal-delivery-stop.

If the **PTRACE_O_TRACEFORK**, **PTRACE_O_TRACEVFORK**, or **PTRACE_O_TRACECLONE** options are in effect, then children created by, respectively, *vfork*(2) or *clone*(2) with the **CLONE_VFORK** flag, *fork*(2) or *clone*(2) with the exit signal set to **SIGCHLD**, and other kinds of *clone*(2), are automatically attached to the same tracer which traced their parent. **SIGSTOP** is delivered to the children, causing them to enter signal-delivery-stop after they exit the system call which created them.

Detaching of the tracee is performed by:

```
ptrace(PTRACE_DETACH, pid, 0, sig);
```

PTRACE_DETACH is a restarting operation; therefore it requires the tracee to be in ptrace-stop. If the tracee is in signal-delivery-stop, a signal can be injected. Otherwise, the *sig* parameter may be silently ignored.

If the tracee is running when the tracer wants to detach it, the usual solution is to send **SIGSTOP** (using *tgkill*(2), to make sure it goes to the correct thread), wait for the tracee to stop in signal-delivery-stop for **SIGSTOP** and then detach it (suppressing **SIGSTOP** injection). A design bug is that this can race with concurrent **SIGSTOP**s. Another complication is that the tracee may enter other ptrace-stops and needs to be restarted and waited for again, until **SIGSTOP** is seen. Yet another complication is to be sure that the tracee is not already ptrace-stopped, because no signal delivery happens while it is—not even **SIGSTOP**.

If the tracer dies, all tracees are automatically detached and restarted, unless they were in group-stop. Handling of restart from group-stop is currently buggy, but the "as planned" behavior is to leave tracee stopped and waiting for **SIGCONT**. If the tracee is restarted from signal-delivery-stop, the pending signal is injected.

execve(2) under ptrace

When one thread in a multithreaded process calls *execve*(2), the kernel destroys all other threads in the process, and resets the thread ID of the execing thread to the thread group ID (process ID). (Or, to put things another way, when a multithreaded process does an *execve*(2), at completion of the call, it appears as though the *execve*(2) occurred in the thread group leader, regardless of which thread did the *execve*(2).) This resetting of the thread ID looks very confusing to tracers:

- All other threads stop in **PTRACE_EVENT_EXIT** stop, if the **PTRACE_O_TRACEEXIT** option was turned on. Then all other threads except the thread group leader report death as if they exited via *_exit*(2) with exit code 0.
- The execing tracee changes its thread ID while it is in the *execve*(2). (Remember, under ptrace, the "pid" returned from *waitpid*(2), or fed into ptrace calls, is the tracee's thread ID.) That is, the tracee's thread ID is reset to be the same as its process ID, which is the same as the thread group leader's thread ID.
- Then a **PTRACE_EVENT_EXEC** stop happens, if the **PTRACE_O_TRACEEXEC** option was turned on.
- If the thread group leader has reported its **PTRACE_EVENT_EXIT** stop by this time, it appears to the tracer that the dead thread leader "reappears from nowhere". (Note: the thread group leader does not report death via *WIFEXITED(status)* until there is at least one other live thread. This eliminates the possibility that the tracer will see it dying and then reappearing.) If the thread group leader was still alive, for the tracer this may look as if thread group leader returns from a different system call than it entered, or even "returned from a system call even though it was not in any system call". If the thread group leader was not traced (or was traced by a different tracer), then during *execve*(2) it will appear as if it has become a tracee of the tracer of the execing tracee.

All of the above effects are the artifacts of the thread ID change in the tracee.

The **PTRACE_O_TRACEEXEC** option is the recommended tool for dealing with this situation. First, it enables **PTRACE_EVENT_EXEC** stop, which occurs before *execve*(2) returns. In this stop, the tracer can use **PTRACE_GETEVENTMSG** to retrieve the tracee's former thread ID. (This feature was introduced in Linux 3.0.) Second, the **PTRACE_O_TRACEEXEC** option disables legacy **SIGTRAP** generation on *execve*(2).

When the tracer receives **PTRACE_EVENT_EXEC** stop notification, it is guaranteed that except this tracee and the thread group leader, no other threads from the process are alive.

On receiving the **PTRACE_EVENT_EXEC** stop notification, the tracer should clean up all its internal data structures describing the threads of this process, and retain only one data structure—one which describes the single still running tracee, with

```
thread ID == thread group ID == process ID.
```

Example: two threads call *execve*(2) at the same time:

*** we get syscall-enter-stop in thread 1: **
PID1 execve("/bin/foo", "foo" <unfinished ...>
*** we issue PTRACE_SYSCALL for thread 1 **
*** we get syscall-enter-stop in thread 2: **
PID2 execve("/bin/bar", "bar" <unfinished ...>
*** we issue PTRACE_SYSCALL for thread 2 **

```
*** we get PTRACE_EVENT_EXEC for PID0, we issue PTRACE_SYSCALL **
*** we get syscall-exit-stop for PID0: **
PID0 <... execve resumed> )             = 0
```

If the **PTRACE_O_TRACEEXEC** option is *not* in effect for the execing tracee, and if the tracee was **PTRACE_ATTACH**ed rather that **PTRACE_SEIZE**d, the kernel delivers an extra **SIGTRAP** to the tracee after *execve*(2) returns. This is an ordinary signal (similar to one which can be generated by *kill −TRAP*), not a special kind of ptrace-stop. Employing **PTRACE_GETSIGINFO** for this signal returns *si_code* set to 0 (*SI_USER*). This signal may be blocked by signal mask, and thus may be delivered (much) later.

Usually, the tracer (for example, *strace*(1)) would not want to show this extra post-execve **SIGTRAP** signal to the user, and would suppress its delivery to the tracee (if **SIGTRAP** is set to **SIG_DFL**, it is a killing signal). However, determining *which* **SIGTRAP** to suppress is not easy. Setting the **PTRACE_O_TRACEEXEC** option or using **PTRACE_SEIZE** and thus suppressing this extra **SIGTRAP** is the recommended approach.

Real parent

The ptrace API (ab)uses the standard UNIX parent/child signaling over *waitpid*(2). This used to cause the real parent of the process to stop receiving several kinds of *waitpid*(2) notifications when the child process is traced by some other process.

Many of these bugs have been fixed, but as of Linux 2.6.38 several still exist; see BUGS below.

As of Linux 2.6.38, the following is believed to work correctly:

- exit/death by signal is reported first to the tracer, then, when the tracer consumes the *waitpid*(2) result, to the real parent (to the real parent only when the whole multithreaded process exits). If the tracer and the real parent are the same process, the report is sent only once.

RETURN VALUE

On success, the **PTRACE_PEEK*** operations return the requested data (but see NOTES), the **PTRACE_SECCOMP_GET_FILTER** operation returns the number of instructions in the BPF program, the **PTRACE_GET_SYSCALL_INFO** operation returns the number of bytes available to be written by the kernel, and other operations return zero.

On error, all operations return −1, and *errno* is set to indicate the error. Since the value returned by a successful **PTRACE_PEEK*** operation may be −1, the caller must clear *errno* before the call, and then check it afterward to determine whether or not an error occurred.

ERRORS

EBUSY
(i386 only) There was an error with allocating or freeing a debug register.

EFAULT
There was an attempt to read from or write to an invalid area in the tracer's or the tracee's memory, probably because the area wasn't mapped or accessible. Unfortunately, under Linux, different variations of this fault will return **EIO** or **EFAULT** more or less arbitrarily.

EINVAL
An attempt was made to set an invalid option.

EIO *op* is invalid, or an attempt was made to read from or write to an invalid area in the tracer's or the tracee's memory, or there was a word-alignment violation, or an invalid signal was specified during a restart operation.

EPERM
The specified process cannot be traced. This could be because the tracer has insufficient privileges (the required capability is **CAP_SYS_PTRACE**); unprivileged processes cannot trace processes that they cannot send signals to or those running set-user-ID/set-group-ID programs, for obvious reasons. Alternatively, the process may already be being traced, or (before Linux 2.6.26) be *init*(1) (PID 1).

ESRCH
The specified process does not exist, or is not currently being traced by the caller, or is not stopped (for operations that require a stopped tracee).

STANDARDS

None.

HISTORY

SVr4, 4.3BSD.

Before Linux 2.6.26, *init*(1), the process with PID 1, may not be traced.

NOTES

Although arguments to **ptrace**() are interpreted according to the prototype given, glibc currently declares **ptrace**() as a variadic function with only the *op* argument fixed. It is recommended to always supply four arguments, even if the requested operation does not use them, setting unused/ignored arguments to *0L* or *(void *) 0*.

A tracees parent continues to be the tracer even if that tracer calls *execve*(2).

The layout of the contents of memory and the USER area are quite operating-system- and architecture-specific. The offset supplied, and the data returned, might not entirely match with the definition of *struct user*.

The size of a "word" is determined by the operating-system variant (e.g., for 32-bit Linux it is 32 bits).

This page documents the way the **ptrace**() call works currently in Linux. Its behavior differs significantly on other flavors of UNIX. In any case, use of **ptrace**() is highly specific to the operating system and architecture.

Ptrace access mode checking

Various parts of the kernel-user-space API (not just **ptrace**() operations), require so-called "ptrace access mode" checks, whose outcome determines whether an operation is permitted (or, in a few cases, causes a "read" operation to return sanitized data). These checks are performed in cases where one process can inspect sensitive information about, or in some cases modify the state of, another process. The checks are based on factors such as the credentials and capabilities of the two processes, whether or not the "target" process is dumpable, and the results of checks performed by any enabled Linux Security Module (LSM)—for example, SELinux, Yama, or Smack—and by the commoncap LSM (which is always invoked).

Prior to Linux 2.6.27, all access checks were of a single type. Since Linux 2.6.27, two access mode levels are distinguished:

PTRACE_MODE_READ
: For "read" operations or other operations that are less dangerous, such as: *get_robust_list*(2); *kcmp*(2); reading */proc/*pid*/auxv*, */proc/*pid*/environ*, or */proc/*pid*/stat*; or *readlink*(2) of a */proc/*pid*/ns/** file.

PTRACE_MODE_ATTACH
: For "write" operations, or other operations that are more dangerous, such as: ptrace attaching (**PTRACE_ATTACH**) to another process or calling *process_vm_writev*(2). (**PTRACE_MODE_ATTACH** was effectively the default before Linux 2.6.27.)

Since Linux 4.5, the above access mode checks are combined (ORed) with one of the following modifiers:

PTRACE_MODE_FSCREDS
: Use the caller's filesystem UID and GID (see *credentials*(7)) or effective capabilities for LSM checks.

PTRACE_MODE_REALCREDS
: Use the caller's real UID and GID or permitted capabilities for LSM checks. This was effectively the default before Linux 4.5.

Because combining one of the credential modifiers with one of the aforementioned access modes is typical, some macros are defined in the kernel sources for the combinations:

PTRACE_MODE_READ_FSCREDS
: Defined as **PTRACE_MODE_READ | PTRACE_MODE_FSCREDS**.

PTRACE_MODE_READ_REALCREDS
: Defined as **PTRACE_MODE_READ | PTRACE_MODE_REALCREDS**.

PTRACE_MODE_ATTACH_FSCREDS
Defined as **PTRACE_MODE_ATTACH | PTRACE_MODE_FSCREDS**.

PTRACE_MODE_ATTACH_REALCREDS
Defined as **PTRACE_MODE_ATTACH | PTRACE_MODE_REALCREDS**.

One further modifier can be ORed with the access mode:

PTRACE_MODE_NOAUDIT (since Linux 3.3)
Don't audit this access mode check. This modifier is employed for ptrace access mode checks (such as checks when reading */proc/*pid*/stat*) that merely cause the output to be filtered or sanitized, rather than causing an error to be returned to the caller. In these cases, accessing the file is not a security violation and there is no reason to generate a security audit record. This modifier suppresses the generation of such an audit record for the particular access check.

Note that all of the **PTRACE_MODE_*** constants described in this subsection are kernel-internal, and not visible to user space. The constant names are mentioned here in order to label the various kinds of ptrace access mode checks that are performed for various system calls and accesses to various pseudo-files (e.g., under */proc*). These names are used in other manual pages to provide a simple shorthand for labeling the different kernel checks.

The algorithm employed for ptrace access mode checking determines whether the calling process is allowed to perform the corresponding action on the target process. (In the case of opening */proc/*pid files, the "calling process" is the one opening the file, and the process with the corresponding PID is the "target process".) The algorithm is as follows:

(1) If the calling thread and the target thread are in the same thread group, access is always allowed.

(2) If the access mode specifies **PTRACE_MODE_FSCREDS**, then, for the check in the next step, employ the caller's filesystem UID and GID. (As noted in *credentials*(7), the filesystem UID and GID almost always have the same values as the corresponding effective IDs.)

Otherwise, the access mode specifies **PTRACE_MODE_REALCREDS**, so use the caller's real UID and GID for the checks in the next step. (Most APIs that check the caller's UID and GID use the effective IDs. For historical reasons, the **PTRACE_MODE_REALCREDS** check uses the real IDs instead.)

(3) Deny access if *neither* of the following is true:

- The real, effective, and saved-set user IDs of the target match the caller's user ID, *and* the real, effective, and saved-set group IDs of the target match the caller's group ID.
- The caller has the **CAP_SYS_PTRACE** capability in the user namespace of the target.

(4) Deny access if the target process "dumpable" attribute has a value other than 1 (**SUID_DUMP_USER**; see the discussion of **PR_SET_DUMPABLE** in *prctl*(2)), and the caller does not have the **CAP_SYS_PTRACE** capability in the user namespace of the target process.

(5) The kernel LSM *security_ptrace_access_check*() interface is invoked to see if ptrace access is permitted. The results depend on the LSM(s). The implementation of this interface in the commoncap LSM performs the following steps:

(5.1) If the access mode includes **PTRACE_MODE_FSCREDS**, then use the caller's *effective* capability set in the following check; otherwise (the access mode specifies **PTRACE_MODE_REALCREDS**, so) use the caller's *permitted* capability set.

(5.2) Deny access if *neither* of the following is true:

- The caller and the target process are in the same user namespace, and the caller's capabilities are a superset of the target process's *permitted* capabilities.
- The caller has the **CAP_SYS_PTRACE** capability in the target process's user namespace.

Note that the commoncap LSM does not distinguish between **PTRACE_MODE_READ** and **PTRACE_MODE_ATTACH**.

(6) If access has not been denied by any of the preceding steps, then access is allowed.

/proc/sys/kernel/yama/ptrace_scope

On systems with the Yama Linux Security Module (LSM) installed (i.e., the kernel was configured with **CONFIG_SECURITY_YAMA**), the */proc/sys/kernel/yama/ptrace_scope* file (available since Linux 3.4) can be used to restrict the ability to trace a process with **ptrace**() (and thus also the ability to use tools such as *strace*(1) and *gdb*(1)). The goal of such restrictions is to prevent attack escalation whereby a compromised process can ptrace-attach to other sensitive processes (e.g., a GPG agent or an SSH session) owned by the user in order to gain additional credentials that may exist in memory and thus expand the scope of the attack.

More precisely, the Yama LSM limits two types of operations:

- Any operation that performs a ptrace access mode **PTRACE_MODE_ATTACH** check—for example, **ptrace**() **PTRACE_ATTACH**. (See the "Ptrace access mode checking" discussion above.)
- **ptrace**() **PTRACE_TRACEME**.

A process that has the **CAP_SYS_PTRACE** capability can update the */proc/sys/kernel/yama/ptrace_scope* file with one of the following values:

0 ("classic ptrace permissions")
: No additional restrictions on operations that perform **PTRACE_MODE_ATTACH** checks (beyond those imposed by the commoncap and other LSMs).

  The use of **PTRACE_TRACEME** is unchanged.

1 ("restricted ptrace") [default value]
: When performing an operation that requires a **PTRACE_MODE_ATTACH** check, the calling process must either have the **CAP_SYS_PTRACE** capability in the user namespace of the target process or it must have a predefined relationship with the target process. By default, the predefined relationship is that the target process must be a descendant of the caller.

  A target process can employ the *prctl*(2) **PR_SET_PTRACER** operation to declare an additional PID that is allowed to perform **PTRACE_MODE_ATTACH** operations on the target. See the kernel source file *Documentation/admin−guide/LSM/Yama.rst* (or *Documentation/security/Yama.txt* before Linux 4.13) for further details.

  The use of **PTRACE_TRACEME** is unchanged.

2 ("admin-only attach")
: Only processes with the **CAP_SYS_PTRACE** capability in the user namespace of the target process may perform **PTRACE_MODE_ATTACH** operations or trace children that employ **PTRACE_TRACEME**.

3 ("no attach")
: No process may perform **PTRACE_MODE_ATTACH** operations or trace children that employ **PTRACE_TRACEME**.

  Once this value has been written to the file, it cannot be changed.

With respect to values 1 and 2, note that creating a new user namespace effectively removes the protection offered by Yama. This is because a process in the parent user namespace whose effective UID matches the UID of the creator of a child namespace has all capabilities (including **CAP_SYS_PTRACE**) when performing operations within the child user namespace (and further-removed descendants of that namespace). Consequently, when a process tries to use user namespaces to sandbox itself, it inadvertently weakens the protections offered by the Yama LSM.

C library/kernel differences

At the system call level, the **PTRACE_PEEKTEXT**, **PTRACE_PEEKDATA**, and **PTRACE_PEEKUSER** operations have a different API: they store the result at the address specified by the *data* parameter, and the return value is the error flag. The glibc wrapper function provides the API given in DESCRIPTION above, with the result being returned via the function return value.

BUGS

On hosts with Linux 2.6 kernel headers, **PTRACE_SETOPTIONS** is declared with a different value than the one for Linux 2.4. This leads to applications compiled with Linux 2.6 kernel headers failing when run on Linux 2.4. This can be worked around by redefining **PTRACE_SETOPTIONS** to **PTRACE_OLDSETOPTIONS**, if that is defined.

Group-stop notifications are sent to the tracer, but not to real parent. Last confirmed on 2.6.38.6.

If a thread group leader is traced and exits by calling *_exit*(2), a **PTRACE_EVENT_EXIT** stop will happen for it (if requested), but the subsequent **WIFEXITED** notification will not be delivered until all other threads exit. As explained above, if one of other threads calls *execve*(2), the death of the thread group leader will *never* be reported. If the execed thread is not traced by this tracer, the tracer will never know that *execve*(2) happened. One possible workaround is to **PTRACE_DETACH** the thread group leader instead of restarting it in this case. Last confirmed on 2.6.38.6.

A **SIGKILL** signal may still cause a **PTRACE_EVENT_EXIT** stop before actual signal death. This may be changed in the future; **SIGKILL** is meant to always immediately kill tasks even under ptrace. Last confirmed on Linux 3.13.

Some system calls return with **EINTR** if a signal was sent to a tracee, but delivery was suppressed by the tracer. (This is very typical operation: it is usually done by debuggers on every attach, in order to not introduce a bogus **SIGSTOP**). As of Linux 3.2.9, the following system calls are affected (this list is likely incomplete): *epoll_wait*(2), and *read*(2) from an *inotify*(7) file descriptor. The usual symptom of this bug is that when you attach to a quiescent process with the command

```
strace -p <process-ID>
```

then, instead of the usual and expected one-line output such as

```
restart_syscall(<... resuming interrupted call ...>_
```

or

```
select(6, [5], NULL, [5], NULL_
```

('_' denotes the cursor position), you observe more than one line. For example:

```
clock_gettime(CLOCK_MONOTONIC, {15370, 690928118}) = 0
epoll_wait(4,_
```

What is not visible here is that the process was blocked in *epoll_wait*(2) before *strace*(1) has attached to it. Attaching caused *epoll_wait*(2) to return to user space with the error **EINTR**. In this particular case, the program reacted to **EINTR** by checking the current time, and then executing *epoll_wait*(2) again. (Programs which do not expect such "stray" **EINTR** errors may behave in an unintended way upon an *strace*(1) attach.)

Contrary to the normal rules, the glibc wrapper for **ptrace**() can set *errno* to zero.

NAME

query_module − query the kernel for various bits pertaining to modules

SYNOPSIS

#include <linux/module.h>

[[deprecated]] int query_module(const char ****name*, int** *which***,**
void *buf* **[.**bufsize**], size_t** *bufsize***,**
size_t ****ret*);**

DESCRIPTION

Note: This system call is present only before Linux 2.6.

query_module() requests information from the kernel about loadable modules. The returned information is placed in the buffer pointed to by *buf*. The caller must specify the size of *buf* in *bufsize*. The precise nature and format of the returned information depend on the operation specified by *which*. Some operations require *name* to identify a currently loaded module, some allow *name* to be NULL, indicating the kernel proper.

The following values can be specified for *which*:

0 Returns success, if the kernel supports **query_module**(). Used to probe for availability of the system call.

QM_MODULES
Returns the names of all loaded modules. The returned buffer consists of a sequence of null-terminated strings; *ret* is set to the number of modules.

QM_DEPS
Returns the names of all modules used by the indicated module. The returned buffer consists of a sequence of null-terminated strings; *ret* is set to the number of modules.

QM_REFS
Returns the names of all modules using the indicated module. This is the inverse of **QM_DEPS**. The returned buffer consists of a sequence of null-terminated strings; *ret* is set to the number of modules.

QM_SYMBOLS
Returns the symbols and values exported by the kernel or the indicated module. The returned buffer is an array of structures of the following form

```
struct module_symbol {
    unsigned long value;
    unsigned long name;
};
```

followed by null-terminated strings. The value of *name* is the character offset of the string relative to the start of *buf*; *ret* is set to the number of symbols.

QM_INFO
Returns miscellaneous information about the indicated module. The output buffer format is:

```
struct module_info {
    unsigned long address;
    unsigned long size;
    unsigned long flags;
};
```

where *address* is the kernel address at which the module resides, *size* is the size of the module in bytes, and *flags* is a mask of **MOD_RUNNING**, **MOD_AUTOCLEAN**, and so on, that indicates the current status of the module (see the Linux kernel source file *include/linux/module.h*). *ret* is set to the size of the *module_info* structure.

RETURN VALUE

On success, zero is returned. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
At least one of *name*, *buf*, or *ret* was outside the program's accessible address space.

EINVAL
Invalid *which*; or *name* is NULL (indicating "the kernel"), but this is not permitted with the specified value of *which*.

ENOENT
No module by that *name* exists.

ENOSPC
The buffer size provided was too small. *ret* is set to the minimum size needed.

ENOSYS
query_module() is not supported in this version of the kernel (e.g., Linux 2.6 or later).

STANDARDS
Linux.

VERSIONS
Removed in Linux 2.6.

Some of the information that was formerly available via **query_module**() can be obtained from */proc/modules*, */proc/kallsyms*, and the files under the directory */sys/module*.

The **query_module**() system call is not supported by glibc. No declaration is provided in glibc headers, but, through a quirk of history, glibc does export an ABI for this system call. Therefore, in order to employ this system call, it is sufficient to manually declare the interface in your code; alternatively, you can invoke the system call using *syscall*(2).

NAME

quotactl − manipulate disk quotas

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/quota.h>
#include <xfs/xqm.h> /* Definition of **Q_X*** and **XFS_QUOTA_*** constants
(or **<linux/dqblk_xfs.h>**; see NOTES) */

int quotactl(int *op***, const char *_Nullable** *special***, int** *id***,**
caddr_t *addr***);**

DESCRIPTION

The quota system can be used to set per-user, per-group, and per-project limits on the amount of disk space used on a filesystem. For each user and/or group, a soft limit and a hard limit can be set for each filesystem. The hard limit can't be exceeded. The soft limit can be exceeded, but warnings will ensue. Moreover, the user can't exceed the soft limit for more than grace period duration (one week by default) at a time; after this, the soft limit counts as a hard limit.

The **quotactl**() call manipulates disk quotas. The *op* argument indicates an operation to be applied to the user or group ID specified in *id*. To initialize the *op* argument, use the *QCMD(subop, type)* macro. The *type* value is either **USRQUOTA**, for user quotas, **GRPQUOTA**, for group quotas, or (since Linux 4.1) **PRJQUOTA**, for project quotas. The *subop* value is described below.

The *special* argument is a pointer to a null-terminated string containing the pathname of the (mounted) block special device for the filesystem being manipulated.

The *addr* argument is the address of an optional, operation-specific, data structure that is copied in or out of the system. The interpretation of *addr* is given with each operation below.

The *subop* value is one of the following operations:

Q_QUOTAON
Turn on quotas for a filesystem. The *id* argument is the identification number of the quota format to be used. Currently, there are three supported quota formats:

QFMT_VFS_OLD
The original quota format.

QFMT_VFS_V0
The standard VFS v0 quota format, which can handle 32-bit UIDs and GIDs and quota limits up to 2^42 bytes and 2^32 inodes.

QFMT_VFS_V1
A quota format that can handle 32-bit UIDs and GIDs and quota limits of 2^63 − 1 bytes and 2^63 − 1 inodes.

The *addr* argument points to the pathname of a file containing the quotas for the filesystem. The quota file must exist; it is normally created with the *quotacheck*(8) program

Quota information can be also stored in hidden system inodes for ext4, XFS, and other filesystems if the filesystem is configured so. In this case, there are no visible quota files and there is no need to use *quotacheck*(8)Quota information is always kept consistent by the filesystem and the **Q_QUOTAON** operation serves only to enable enforcement of quota limits. The presence of hidden system inodes with quota information is indicated by the **DQF_SYS_FILE** flag in the *dqi_flags* field returned by the **Q_GETINFO** operation.

This operation requires privilege (**CAP_SYS_ADMIN**).

Q_QUOTAOFF
Turn off quotas for a filesystem. The *addr* and *id* arguments are ignored. This operation requires privilege (**CAP_SYS_ADMIN**).

Q_GETQUOTA
Get disk quota limits and current usage for user or group *id*. The *addr* argument is a pointer to a *dqblk* structure defined in <*sys/quota.h*> as follows:

```
/* uint64_t is an unsigned 64-bit integer;
   uint32_t is an unsigned 32-bit integer */

struct dqblk {      /* Definition since Linux 2.4.22 */
    uint64_t dqb_bhardlimit;  /* Absolute limit on disk
                                 quota blocks alloc */
    uint64_t dqb_bsoftlimit;  /* Preferred limit on
                                 disk quota blocks */
    uint64_t dqb_curspace;    /* Current occupied space
                                 (in bytes) */
    uint64_t dqb_ihardlimit;  /* Maximum number of
                                 allocated inodes */
    uint64_t dqb_isoftlimit;  /* Preferred inode limit */
    uint64_t dqb_curinodes;   /* Current number of
                                 allocated inodes */
    uint64_t dqb_btime;       /* Time limit for excessive
                                 disk use */
    uint64_t dqb_itime;       /* Time limit for excessive
                                 files */
    uint32_t dqb_valid;       /* Bit mask of QIF_*
                                 constants */
};

/* Flags in dqb_valid that indicate which fields in
   dqblk structure are valid. */

#define QIF_BLIMITS   1
#define QIF_SPACE     2
#define QIF_ILIMITS   4
#define QIF_INODES    8
#define QIF_BTIME     16
#define QIF_ITIME     32
#define QIF_LIMITS    (QIF_BLIMITS | QIF_ILIMITS)
#define QIF_USAGE     (QIF_SPACE | QIF_INODES)
#define QIF_TIMES     (QIF_BTIME | QIF_ITIME)
#define QIF_ALL       (QIF_LIMITS | QIF_USAGE | QIF_TIMES)
```

The *dqb_valid* field is a bit mask that is set to indicate the entries in the *dqblk* structure that are valid. Currently, the kernel fills in all entries of the *dqblk* structure and marks them as valid in the *dqb_valid* field. Unprivileged users may retrieve only their own quotas; a privileged user (**CAP_SYS_ADMIN**) can retrieve the quotas of any user.

Q_GETNEXTQUOTA (since Linux 4.6)

This operation is the same as **Q_GETQUOTA**, but it returns quota information for the next ID greater than or equal to *id* that has a quota set.

The *addr* argument is a pointer to a *nextdqblk* structure whose fields are as for the *dqblk*, except for the addition of a *dqb_id* field that is used to return the ID for which quota information is being returned:

```
struct nextdqblk {
    uint64_t dqb_bhardlimit;
    uint64_t dqb_bsoftlimit;
    uint64_t dqb_curspace;
    uint64_t dqb_ihardlimit;
    uint64_t dqb_isoftlimit;
    uint64_t dqb_curinodes;
    uint64_t dqb_btime;
    uint64_t dqb_itime;
    uint32_t dqb_valid;
    uint32_t dqb_id;
```

```
};
```

Q_SETQUOTA
Set quota information for user or group *id*, using the information supplied in the *dqblk* structure pointed to by *addr*. The *dqb_valid* field of the *dqblk* structure indicates which entries in the structure have been set by the caller. This operation supersedes the **Q_SETQLIM** and **Q_SETUSE** operations in the previous quota interfaces. This operation requires privilege (**CAP_SYS_ADMIN**).

Q_GETINFO (since Linux 2.4.22)
Get information (like grace times) about quotafile. The *addr* argument should be a pointer to a *dqinfo* structure. This structure is defined in <*sys/quota.h*> as follows:

```
/* uint64_t is an unsigned 64-bit integer;
   uint32_t is an unsigned 32-bit integer */

struct dqinfo {         /* Defined since Linux 2.4.22 */
    uint64_t dqi_bgrace;  /* Time before block soft limit
                             becomes hard limit */
    uint64_t dqi_igrace;  /* Time before inode soft limit
                             becomes hard limit */
    uint32_t dqi_flags;   /* Flags for quotafile
                             (DQF_*) */
    uint32_t dqi_valid;
};

/* Bits for dqi_flags */

/* Quota format QFMT_VFS_OLD */

#define DQF_ROOT_SQUASH (1 << 0) /* Root squash enabled */
             /* Before Linux v4.0, this had been defined
                privately as V1_DQF_RSQUASH */

/* Quota format QFMT_VFS_V0 / QFMT_VFS_V1 */

#define DQF_SYS_FILE    (1 << 16)   /* Quota stored in
                                       a system file */

/* Flags in dqi_valid that indicate which fields in
   dqinfo structure are valid. */

#define IIF_BGRACE  1
#define IIF_IGRACE  2
#define IIF_FLAGS   4
#define IIF_ALL     (IIF_BGRACE | IIF_IGRACE | IIF_FLAGS)
```

The *dqi_valid* field in the *dqinfo* structure indicates the entries in the structure that are valid. Currently, the kernel fills in all entries of the *dqinfo* structure and marks them all as valid in the *dqi_valid* field. The *id* argument is ignored.

Q_SETINFO (since Linux 2.4.22)
Set information about quotafile. The *addr* argument should be a pointer to a *dqinfo* structure. The *dqi_valid* field of the *dqinfo* structure indicates the entries in the structure that have been set by the caller. This operation supersedes the **Q_SETGRACE** and **Q_SETFLAGS** operations in the previous quota interfaces. The *id* argument is ignored. This operation requires privilege (**CAP_SYS_ADMIN**).

Q_GETFMT (since Linux 2.4.22)
Get quota format used on the specified filesystem. The *addr* argument should be a pointer to a 4-byte buffer where the format number will be stored.

Q_SYNC
Update the on-disk copy of quota usages for a filesystem. If *special* is NULL, then all filesystems with active quotas are sync'ed. The *addr* and *id* arguments are ignored.

Q_GETSTATS (supported up to Linux 2.4.21)
Get statistics and other generic information about the quota subsystem. The *addr* argument should be a pointer to a *dqstats* structure in which data should be stored. This structure is defined in <*sys/quota.h*>. The *special* and *id* arguments are ignored.

This operation is obsolete and was removed in Linux 2.4.22. Files in */proc/sys/fs/quota/* carry the information instead.

For XFS filesystems making use of the XFS Quota Manager (XQM), the above operations are bypassed and the following operations are used:

Q_XQUOTAON
Turn on quotas for an XFS filesystem. XFS provides the ability to turn on/off quota limit enforcement with quota accounting. Therefore, XFS expects *addr* to be a pointer to an *unsigned int* that contains a bitwise combination of the following flags (defined in <*xfs/xqm.h*>):

```
XFS_QUOTA_UDQ_ACCT  /* User quota accounting */
XFS_QUOTA_UDQ_ENFD  /* User quota limits enforcement */
XFS_QUOTA_GDQ_ACCT  /* Group quota accounting */
XFS_QUOTA_GDQ_ENFD  /* Group quota limits enforcement */
XFS_QUOTA_PDQ_ACCT  /* Project quota accounting */
XFS_QUOTA_PDQ_ENFD  /* Project quota limits enforcement */
```

This operation requires privilege (**CAP_SYS_ADMIN**). The *id* argument is ignored.

Q_XQUOTAOFF
Turn off quotas for an XFS filesystem. As with **Q_QUOTAON**, XFS filesystems expect a pointer to an *unsigned int* that specifies whether quota accounting and/or limit enforcement need to be turned off (using the same flags as for **Q_XQUOTAON** operation). This operation requires privilege (**CAP_SYS_ADMIN**). The *id* argument is ignored.

Q_XGETQUOTA
Get disk quota limits and current usage for user *id*. The *addr* argument is a pointer to an *fs_disk_quota* structure, which is defined in <*xfs/xqm.h*> as follows:

```
/* All the blk units are in BBs (Basic Blocks) of
   512 bytes. */

#define FS_DQUOT_VERSION  1  /* fs_disk_quota.d_version */

#define XFS_USER_QUOTA    (1<<0)  /* User quota type */
#define XFS_PROJ_QUOTA    (1<<1)  /* Project quota type */
#define XFS_GROUP_QUOTA   (1<<2)  /* Group quota type */

struct fs_disk_quota {
    int8_t   d_version;   /* Version of this structure */
    int8_t   d_flags;     /* XFS_{USER,PROJ,GROUP}_QUOTA */
    uint16_t d_fieldmask; /* Field specifier */
    uint32_t d_id;        /* User, project, or group ID */
    uint64_t d_blk_hardlimit; /* Absolute limit on
                                 disk blocks */
    uint64_t d_blk_softlimit; /* Preferred limit on
                                 disk blocks */
    uint64_t d_ino_hardlimit; /* Maximum # allocated
                                 inodes */
    uint64_t d_ino_softlimit; /* Preferred inode limit */
    uint64_t d_bcount;    /* # disk blocks owned by
                             the user */
    uint64_t d_icount;    /* # inodes owned by the user */
    int32_t  d_itimer;    /* Zero if within inode limits */
```

```
                            /* If not, we refuse service */
    int32_t  d_btimer;      /* Similar to above; for
                               disk blocks */
    uint16_t d_iwarns;      /* # warnings issued with
                               respect to # of inodes */
    uint16_t d_bwarns;      /* # warnings issued with
                               respect to disk blocks */
    int32_t  d_padding2;    /* Padding - for future use */
    uint64_t d_rtb_hardlimit; /* Absolute limit on realtime
                                 (RT) disk blocks */
    uint64_t d_rtb_softlimit; /* Preferred limit on RT
                                 disk blocks */
    uint64_t d_rtbcount;    /* # realtime blocks owned */
    int32_t  d_rtbtimer;    /* Similar to above; for RT
                               disk blocks */
    uint16_t d_rtbwarns;    /* # warnings issued with
                               respect to RT disk blocks */
    int16_t  d_padding3;    /* Padding - for future use */
    char     d_padding4[8];   /* Yet more padding */
};
```

Unprivileged users may retrieve only their own quotas; a privileged user (**CAP_SYS_ADMIN**) may retrieve the quotas of any user.

Q_XGETNEXTQUOTA (since Linux 4.6)
This operation is the same as **Q_XGETQUOTA**, but it returns (in the *fs_disk_quota* structure pointed by *addr*) quota information for the next ID greater than or equal to *id* that has a quota set. Note that since *fs_disk_quota* already has *q_id* field, no separate structure type is needed (in contrast with **Q_GETQUOTA** and **Q_GETNEXTQUOTA** operations)

Q_XSETQLIM
Set disk quota limits for user *id*. The *addr* argument is a pointer to an *fs_disk_quota* structure. This operation requires privilege (**CAP_SYS_ADMIN**).

Q_XGETQSTAT
Returns XFS filesystem-specific quota information in the *fs_quota_stat* structure pointed by *addr*. This is useful for finding out how much space is used to store quota information, and also to get the quota on/off status of a given local XFS filesystem. The *fs_quota_stat* structure itself is defined as follows:

```
#define FS_QSTAT_VERSION 1  /* fs_quota_stat.qs_version */

struct fs_qfilestat {
    uint64_t qfs_ino;       /* Inode number */
    uint64_t qfs_nblks;     /* Number of BBs
                               512-byte-blocks */
    uint32_t qfs_nextents;  /* Number of extents */
};

struct fs_quota_stat {
    int8_t   qs_version; /* Version number for
                            future changes */
    uint16_t qs_flags; /* XFS_QUOTA_{U,P,G}DQ_{ACCT,ENFD} */
    int8_t   qs_pad;   /* Unused */
    struct fs_qfilestat qs_uquota;  /* User quota storage
                                       information */
    struct fs_qfilestat qs_gquota;  /* Group quota storage
                                       information */
    uint32_t qs_incoredqs;   /* Number of dquots in core */
    int32_t  qs_btimelimit;  /* Limit for blocks timer */
    int32_t  qs_itimelimit;  /* Limit for inodes timer */
    int32_t  qs_rtbtimelimit;/* Limit for RT
```

```
                                    blocks timer */
    uint16_t qs_bwarnlimit;  /* Limit for # of warnings */
    uint16_t qs_iwarnlimit;  /* Limit for # of warnings */
};
```

The *id* argument is ignored.

Q_XGETQSTATV

Returns XFS filesystem-specific quota information in the *fs_quota_statv* pointed to by *addr*. This version of the operation uses a structure with proper versioning support, along with appropriate layout (all fields are naturally aligned) and padding to avoiding special compat handling; it also provides the ability to get statistics regarding the project quota file. The *fs_quota_statv* structure itself is defined as follows:

```
#define FS_QSTATV_VERSION1 1 /* fs_quota_statv.qs_version */

struct fs_qfilestatv {
    uint64_t qfs_ino;       /* Inode number */
    uint64_t qfs_nblks;     /* Number of BBs
                               512-byte-blocks */
    uint32_t qfs_nextents;  /* Number of extents */
    uint32_t qfs_pad;       /* Pad for 8-byte alignment */
};

struct fs_quota_statv {
    int8_t   qs_version;    /* Version for future
                               changes */
    uint8_t  qs_pad1;       /* Pad for 16-bit alignment */
    uint16_t qs_flags;      /* XFS_QUOTA_.* flags */
    uint32_t qs_incoredqs;  /* Number of dquots incore */
    struct fs_qfilestatv qs_uquota;  /* User quota
                                        information */
    struct fs_qfilestatv qs_gquota;  /* Group quota
                                        information */
    struct fs_qfilestatv qs_pquota;  /* Project quota
                                        information */
    int32_t  qs_btimelimit;   /* Limit for blocks timer */
    int32_t  qs_itimelimit;   /* Limit for inodes timer */
    int32_t  qs_rtbtimelimit; /* Limit for RT blocks
                                 timer */
    uint16_t qs_bwarnlimit;   /* Limit for # of warnings */
    uint16_t qs_iwarnlimit;   /* Limit for # of warnings */
    uint64_t qs_pad2[8];      /* For future proofing */
};
```

The *qs_version* field of the structure should be filled with the version of the structure supported by the callee (for now, only *FS_QSTAT_VERSION1* is supported). The kernel will fill the structure in accordance with version provided. The *id* argument is ignored.

Q_XQUOTARM (buggy until Linux 3.16)

Free the disk space taken by disk quotas. The *addr* argument should be a pointer to an *unsigned int* value containing flags (the same as in *d_flags* field of *fs_disk_quota* structure) which identify what types of quota should be removed. (Note that the quota type passed in the *op* argument is ignored, but should remain valid in order to pass preliminary quotactl syscall handler checks.)

Quotas must have already been turned off. The *id* argument is ignored.

Q_XQUOTASYNC (since Linux 2.6.15; no-op since Linux 3.4)

This operation was an XFS quota equivalent to **Q_SYNC**, but it is no-op since Linux 3.4, as *sync*(1) writes quota information to disk now (in addition to the other filesystem metadata that it writes out). The *special*, *id* and *addr* arguments are ignored.

RETURN VALUE

On success, **quotactl**() returns 0; on error −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
: *op* is **Q_QUOTAON**, and the quota file pointed to by *addr* exists, but is not a regular file or is not on the filesystem pointed to by *special*.

EBUSY
: *op* is **Q_QUOTAON**, but another **Q_QUOTAON** had already been performed.

EFAULT
: *addr* or *special* is invalid.

EINVAL
: *op* or *type* is invalid.

EINVAL
: *op* is **Q_QUOTAON**, but the specified quota file is corrupted.

EINVAL (since Linux 5.5)
: *op* is **Q_XQUOTARM**, but *addr* does not point to valid quota types.

ENOENT
: The file specified by *special* or *addr* does not exist.

ENOSYS
: The kernel has not been compiled with the **CONFIG_QUOTA** option.

ENOTBLK
: *special* is not a block device.

EPERM
: The caller lacked the required privilege (**CAP_SYS_ADMIN**) for the specified operation.

ERANGE
: *op* is **Q_SETQUOTA**, but the specified limits are out of the range allowed by the quota format.

ESRCH
: No disk quota is found for the indicated user. Quotas have not been turned on for this filesystem.

ESRCH
: *op* is **Q_QUOTAON**, but the specified quota format was not found.

ESRCH
: *op* is **Q_GETNEXTQUOTA** or **Q_XGETNEXTQUOTA**, but there is no ID greater than or equal to *id* that has an active quota.

NOTES

Instead of <*xfs/xqm.h*> one can use <*linux/dqblk_xfs.h*>, taking into account that there are several naming discrepancies:

- Quota enabling flags (of format **XFS_QUOTA_[UGP]DQ_{ACCT,ENFD}**) are defined without a leading "X", as **FS_QUOTA_[UGP]DQ_{ACCT,ENFD}**.
- The same is true for **XFS_{USER,GROUP,PROJ}_QUOTA** quota type flags, which are defined as **FS_{USER,GROUP,PROJ}_QUOTA**.
- The *dqblk_xfs.h* header file defines its own **XQM_USRQUOTA**, **XQM_GRPQUOTA**, and **XQM_PRJQUOTA** constants for the available quota types, but their values are the same as for constants without the **XQM_** prefix.

quota(1), *getrlimit*(2), *quotacheck*(8), *quotaon*(8)

NAME

read − read from a file descriptor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

ssize_t read(int *fd***, void** *buf***[.***count***], size_t** *count***);**

DESCRIPTION

read() attempts to read up to *count* bytes from file descriptor *fd* into the buffer starting at *buf*.

On files that support seeking, the read operation commences at the file offset, and the file offset is incremented by the number of bytes read. If the file offset is at or past the end of file, no bytes are read, and **read**() returns zero.

If *count* is zero, **read**() *may* detect the errors described below. In the absence of any errors, or if **read**() does not check for errors, a **read**() with a *count* of 0 returns zero and has no other effects.

According to POSIX.1, if *count* is greater than **SSIZE_MAX**, the result is implementation-defined; see NOTES for the upper limit on Linux.

RETURN VALUE

On success, the number of bytes read is returned (zero indicates end of file), and the file position is advanced by this number. It is not an error if this number is smaller than the number of bytes requested; this may happen for example because fewer bytes are actually available right now (maybe because we were close to end-of-file, or because we are reading from a pipe, or from a terminal), or because **read**() was interrupted by a signal. See also NOTES.

On error, −1 is returned, and *errno* is set to indicate the error. In this case, it is left unspecified whether the file position (if any) changes.

ERRORS

EAGAIN
: The file descriptor *fd* refers to a file other than a socket and has been marked nonblocking (**O_NONBLOCK**), and the read would block. See *open*(2) for further details on the **O_NONBLOCK** flag.

EAGAIN or **EWOULDBLOCK**
: The file descriptor *fd* refers to a socket and has been marked nonblocking (**O_NONBLOCK**), and the read would block. POSIX.1-2001 allows either error to be returned for this case, and does not require these constants to have the same value, so a portable application should check for both possibilities.

EBADF
: *fd* is not a valid file descriptor or is not open for reading.

EFAULT
: *buf* is outside your accessible address space.

EINTR
: The call was interrupted by a signal before any data was read; see *signal*(7).

EINVAL
: *fd* is attached to an object which is unsuitable for reading; or the file was opened with the **O_DIRECT** flag, and either the address specified in *buf*, the value specified in *count*, or the file offset is not suitably aligned.

EINVAL
: *fd* was created via a call to *timerfd_create*(2) and the wrong size buffer was given to **read**(); see *timerfd_create*(2) for further information.

EIO I/O error. This will happen for example when the process is in a background process group, tries to read from its controlling terminal, and either it is ignoring or blocking **SIGTTIN** or its process group is orphaned. It may also occur when there is a low-level I/O error while reading from a disk or tape. A further possible cause of **EIO** on networked filesystems is when an advisory lock had been taken out on the file descriptor and this lock has been lost. See the *Lost*

locks section of *fcntl*(2) for further details.

EISDIR
fd refers to a directory.

Other errors may occur, depending on the object connected to *fd*.

STANDARDS
POSIX.1-2008.

HISTORY
SVr4, 4.3BSD, POSIX.1-2001.

NOTES
On Linux, **read**() (and similar system calls) will transfer at most 0x7ffff000 (2,147,479,552) bytes, returning the number of bytes actually transferred. (This is true on both 32-bit and 64-bit systems.)

On NFS filesystems, reading small amounts of data will update the timestamp only the first time, subsequent calls may not do so. This is caused by client side attribute caching, because most if not all NFS clients leave *st_atime* (last file access time) updates to the server, and client side reads satisfied from the client's cache will not cause *st_atime* updates on the server as there are no server-side reads. UNIX semantics can be obtained by disabling client-side attribute caching, but in most situations this will substantially increase server load and decrease performance.

BUGS
According to POSIX.1-2008/SUSv4 Section XSI 2.9.7 ("Thread Interactions with Regular File Operations"):

> All of the following functions shall be atomic with respect to each other in the effects specified in POSIX.1-2008 when they operate on regular files or symbolic links: ...

Among the APIs subsequently listed are **read**() and *readv*(2). And among the effects that should be atomic across threads (and processes) are updates of the file offset. However, before Linux 3.14, this was not the case: if two processes that share an open file description (see *open*(2)) perform a **read**() (or *readv*(2)) at the same time, then the I/O operations were not atomic with respect to updating the file offset, with the result that the reads in the two processes might (incorrectly) overlap in the blocks of data that they obtained. This problem was fixed in Linux 3.14.

NAME

readahead − initiate file readahead into page cache

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#define _FILE_OFFSET_BITS 64
#include <fcntl.h>

ssize_t readahead(int fd, off_t offset, size_t count);
```

DESCRIPTION

readahead() initiates readahead on a file so that subsequent reads from that file will be satisfied from the cache, and not block on disk I/O (assuming the readahead was initiated early enough and that other activity on the system did not in the meantime flush pages from the cache).

The *fd* argument is a file descriptor identifying the file which is to be read. The *offset* argument specifies the starting point from which data is to be read and *count* specifies the number of bytes to be read. I/O is performed in whole pages, so that *offset* is effectively rounded down to a page boundary and bytes are read up to the next page boundary greater than or equal to *(offset+count)*. **readahead**() does not read beyond the end of the file. The file offset of the open file description referred to by the file descriptor *fd* is left unchanged.

RETURN VALUE

On success, **readahead**() returns 0; on failure, −1 is returned, with *errno* set to indicate the error.

ERRORS

EBADF
: *fd* is not a valid file descriptor or is not open for reading.

EINVAL
: *fd* does not refer to a file type to which **readahead**() can be applied.

VERSIONS

On some 32-bit architectures, the calling signature for this system call differs, for the reasons described in *syscall*(2).

STANDARDS

Linux.

HISTORY

Linux 2.4.13, glibc 2.3.

NOTES

_FILE_OFFSET_BITS should be defined to be 64 in code that uses a pointer to **readahead**, if the code is intended to be portable to traditional 32-bit x86 and ARM platforms where **off_t**'s width defaults to 32 bits.

BUGS

readahead() attempts to schedule the reads in the background and return immediately. However, it may block while it reads the filesystem metadata needed to locate the requested blocks. This occurs frequently with ext[234] on large files using indirect blocks instead of extents, giving the appearance that the call blocks until the requested data has been read.

SEE ALSO

lseek(2), *madvise*(2), *mmap*(2), *posix_fadvise*(2), *read*(2)

NAME

readdir − read directory entry

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_readdir, unsigned int *fd***,**
struct old_linux_dirent ***dirp*, unsigned int** *count***);**

Note: There is no definition of **struct old_linux_dirent**; see NOTES.

DESCRIPTION

This is not the function you are interested in. Look at *readdir*(3) for the POSIX conforming C library interface. This page documents the bare kernel system call interface, which is superseded by *getdents*(2).

readdir() reads one *old_linux_dirent* structure from the directory referred to by the file descriptor *fd* into the buffer pointed to by *dirp*. The argument *count* is ignored; at most one *old_linux_dirent* structure is read.

The *old_linux_dirent* structure is declared (privately in Linux kernel file **fs/readdir.c**) as follows:

```
struct old_linux_dirent {
    unsigned long d_ino;     /* inode number */
    unsigned long d_offset;  /* offset to this old_linux_dirent */
    unsigned short d_namlen; /* length of this d_name */
    char  d_name[1];         /* filename (null-terminated) */
}
```

d_ino is an inode number. *d_offset* is the distance from the start of the directory to this *old_linux_dirent*. *d_reclen* is the size of *d_name*, not counting the terminating null byte ('\0'). *d_name* is a null-terminated filename.

RETURN VALUE

On success, 1 is returned. On end of directory, 0 is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
Invalid file descriptor *fd*.

EFAULT
Argument points outside the calling process's address space.

EINVAL
Result buffer is too small.

ENOENT
No such directory.

ENOTDIR
File descriptor does not refer to a directory.

VERSIONS

You will need to define the *old_linux_dirent* structure yourself. However, probably you should use *readdir*(3) instead.

This system call does not exist on x86-64.

STANDARDS

Linux.

NAME

readlink, readlinkat − read value of a symbolic link

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

ssize_t readlink(const char *restrict pathname, char *restrict buf,
                 size_t bufsiz);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <unistd.h>

ssize_t readlinkat(int dirfd, const char *restrict pathname,
                   char *restrict buf, size_t bufsiz);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

readlink():
  _XOPEN_SOURCE >= 500 || _POSIX_C_SOURCE >= 200112L
    || /* glibc <= 2.19: */ _BSD_SOURCE

readlinkat():
  Since glibc 2.10:
    _POSIX_C_SOURCE >= 200809L
  Before glibc 2.10:
    _ATFILE_SOURCE

DESCRIPTION

readlink() places the contents of the symbolic link *pathname* in the buffer *buf*, which has size *bufsiz*. **readlink**() does not append a terminating null byte to *buf*. It will (silently) truncate the contents (to a length of *bufsiz* characters), in case the buffer is too small to hold all of the contents.

readlinkat()

The **readlinkat**() system call operates in exactly the same way as **readlink**(), except for the differences described here.

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **readlink**() for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like *readlink*())

If *pathname* is absolute, then *dirfd* is ignored.

Since Linux 2.6.39, *pathname* can be an empty string, in which case the call operates on the symbolic link referred to by *dirfd* (which should have been obtained using *open*(2) with the **O_PATH** and **O_NOFOLLOW** flags).

See *openat*(2) for an explanation of the need for **readlinkat**().

RETURN VALUE

On success, these calls return the number of bytes placed in *buf*. (If the returned value equals *bufsiz*, then truncation may have occurred.) On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
: Search permission is denied for a component of the path prefix. (See also *path_resolution*(7).)

EBADF
: (**readlinkat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT
: *buf* extends outside the process's allocated address space.

EINVAL
bufsiz is not positive.

EINVAL
The named file (i.e., the final filename component of *pathname*) is not a symbolic link.

EIO An I/O error occurred while reading from the filesystem.

ELOOP
Too many symbolic links were encountered in translating the pathname.

ENAMETOOLONG
A pathname, or a component of a pathname, was too long.

ENOENT
The named file does not exist.

ENOMEM
Insufficient kernel memory was available.

ENOTDIR
A component of the path prefix is not a directory.

ENOTDIR
(**readlinkat**()) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

STANDARDS

POSIX.1-2008.

HISTORY

readlink()
4.4BSD (first appeared in 4.2BSD), POSIX.1-2001, POSIX.1-2008.

readlinkat()
POSIX.1-2008. Linux 2.6.16, glibc 2.4.

Up to and including glibc 2.4, the return type of **readlink**() was declared as *int*. Nowadays, the return type is declared as *ssize_t*, as (newly) required in POSIX.1-2001.

glibc
On older kernels where **readlinkat**() is unavailable, the glibc wrapper function falls back to the use of **readlink**(). When *pathname* is a relative pathname, glibc constructs a pathname based on the symbolic link in */proc/self/fd* that corresponds to the *dirfd* argument.

NOTES

Using a statically sized buffer might not provide enough room for the symbolic link contents. The required size for the buffer can be obtained from the *stat.st_size* value returned by a call to *lstat*(2) on the link. However, the number of bytes written by **readlink**() and **readlinkat**() should be checked to make sure that the size of the symbolic link did not increase between the calls. Dynamically allocating the buffer for **readlink**() and **readlinkat**() also addresses a common portability problem when using **PATH_MAX** for the buffer size, as this constant is not guaranteed to be defined per POSIX if the system does not have such limit.

EXAMPLES

The following program allocates the buffer needed by **readlink**() dynamically from the information provided by *lstat*(2), falling back to a buffer of size **PATH_MAX** in cases where *lstat*(2) reports a size of zero.

```
#include <limits.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/stat.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
```

```
        char         *buf;
        ssize_t      nbytes, bufsiz;
        struct stat  sb;

        if (argc != 2) {
            fprintf(stderr, "Usage: %s <pathname>\n", argv[0]);
            exit(EXIT_FAILURE);
        }

        if (lstat(argv[1], &sb) == -1) {
            perror("lstat");
            exit(EXIT_FAILURE);
        }

        /* Add one to the link size, so that we can determine whether
           the buffer returned by readlink() was truncated. */

        bufsiz = sb.st_size + 1;

        /* Some magic symlinks under (for example) /proc and /sys
           report 'st_size' as zero. In that case, take PATH_MAX as
           a "good enough" estimate. */

        if (sb.st_size == 0)
            bufsiz = PATH_MAX;

        buf = malloc(bufsiz);
        if (buf == NULL) {
            perror("malloc");
            exit(EXIT_FAILURE);
        }

        nbytes = readlink(argv[1], buf, bufsiz);
        if (nbytes == -1) {
            perror("readlink");
            exit(EXIT_FAILURE);
        }

        /* Print only 'nbytes' of 'buf', as it doesn't contain a terminating
           null byte ('\0'). */
        printf("'%s' points to '%.*s'\n", argv[1], (int) nbytes, buf);

        /* If the return value was equal to the buffer size, then
           the link target was larger than expected (perhaps because the
           target was changed between the call to lstat() and the call to
           readlink()). Warn the user that the returned target may have
           been truncated. */

        if (nbytes == bufsiz)
            printf("(Returned buffer may have been truncated)\n");

        free(buf);
        exit(EXIT_SUCCESS);
    }
```

NAME

readv, writev, preadv, pwritev, preadv2, pwritev2 − read or write data into multiple buffers

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/uio.h>

ssize_t readv(int fd, const struct iovec *iov, int iovcnt);
ssize_t writev(int fd, const struct iovec *iov, int iovcnt);

ssize_t preadv(int fd, const struct iovec *iov, int iovcnt,
               off_t offset);
ssize_t pwritev(int fd, const struct iovec *iov, int iovcnt,
               off_t offset);

ssize_t preadv2(int fd, const struct iovec *iov, int iovcnt,
               off_t offset, int flags);
ssize_t pwritev2(int fd, const struct iovec *iov, int iovcnt,
               off_t offset, int flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

preadv(), **pwritev**():
Since glibc 2.19:
_DEFAULT_SOURCE
glibc 2.19 and earlier:
_BSD_SOURCE

DESCRIPTION

The **readv**() system call reads *iovcnt* buffers from the file associated with the file descriptor *fd* into the buffers described by *iov* ("scatter input").

The **writev**() system call writes *iovcnt* buffers of data described by *iov* to the file associated with the file descriptor *fd* ("gather output").

The pointer *iov* points to an array of *iovec* structures, described in *iovec*(3type).

The **readv**() system call works just like *read*(2) except that multiple buffers are filled.

The **writev**() system call works just like *write*(2) except that multiple buffers are written out.

Buffers are processed in array order. This means that **readv**() completely fills *iov[0]* before proceeding to *iov[1]*, and so on. (If there is insufficient data, then not all buffers pointed to by *iov* may be filled.) Similarly, **writev**() writes out the entire contents of *iov[0]* before proceeding to *iov[1]*, and so on.

The data transfers performed by **readv**() and **writev**() are atomic: the data written by **writev**() is written as a single block that is not intermingled with output from writes in other processes; analogously, **readv**() is guaranteed to read a contiguous block of data from the file, regardless of read operations performed in other threads or processes that have file descriptors referring to the same open file description (see *open*(2)).

preadv() and pwritev()

The **preadv**() system call combines the functionality of **readv**() and *pread*(2). It performs the same task as **readv**(), but adds a fourth argument, *offset*, which specifies the file offset at which the input operation is to be performed.

The **pwritev**() system call combines the functionality of **writev**() and *pwrite*(2). It performs the same task as **writev**(), but adds a fourth argument, *offset*, which specifies the file offset at which the output operation is to be performed.

The file offset is not changed by these system calls. The file referred to by *fd* must be capable of seeking.

preadv2() and pwritev2()

These system calls are similar to **preadv**() and **pwritev**() calls, but add a fifth argument, *flags*, which modifies the behavior on a per-call basis.

Unlike **preadv**() and **pwritev**(), if the *offset* argument is −1, then the current file offset is used and

updated.

The *flags* argument contains a bitwise OR of zero or more of the following flags:

RWF_DSYNC (since Linux 4.7)
Provide a per-write equivalent of the **O_DSYNC** *open*(2) flag. This flag is meaningful only for **pwritev2**(), and its effect applies only to the data range written by the system call.

RWF_HIPRI (since Linux 4.6)
High priority read/write. Allows block-based filesystems to use polling of the device, which provides lower latency, but may use additional resources. (Currently, this feature is usable only on a file descriptor opened using the **O_DIRECT** flag.)

RWF_SYNC (since Linux 4.7)
Provide a per-write equivalent of the **O_SYNC** *open*(2) flag. This flag is meaningful only for **pwritev2**(), and its effect applies only to the data range written by the system call.

RWF_NOWAIT (since Linux 4.14)
Do not wait for data which is not immediately available. If this flag is specified, the **preadv2**() system call will return instantly if it would have to read data from the backing storage or wait for a lock. If some data was successfully read, it will return the number of bytes read. If no bytes were read, it will return −1 and set *errno* to **EAGAIN** (but see **BUGS**). Currently, this flag is meaningful only for **preadv2**().

RWF_APPEND (since Linux 4.16)
Provide a per-write equivalent of the **O_APPEND** *open*(2) flag. This flag is meaningful only for **pwritev2**(), and its effect applies only to the data range written by the system call. The *offset* argument does not affect the write operation; the data is always appended to the end of the file. However, if the *offset* argument is −1, the current file offset is updated.

RETURN VALUE

On success, **readv**(), **preadv**(), and **preadv2**() return the number of bytes read; **writev**(), **pwritev**(), and **pwritev2**() return the number of bytes written.

Note that it is not an error for a successful call to transfer fewer bytes than requested (see *read*(2) and *write*(2)).

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

The errors are as given for *read*(2) and *write*(2). Furthermore, **preadv**(), **preadv2**(), **pwritev**(), and **pwritev2**() can also fail for the same reasons as *lseek*(2). Additionally, the following errors are defined:

EINVAL
The sum of the *iov_len* values overflows an *ssize_t* value.

EINVAL
The vector count, *iovcnt*, is less than zero or greater than the permitted maximum.

EOPNOTSUPP
An unknown flag is specified in *flags*.

VERSIONS

C library/kernel differences

The raw **preadv**() and **pwritev**() system calls have call signatures that differ slightly from that of the corresponding GNU C library wrapper functions shown in the SYNOPSIS. The final argument, *offset*, is unpacked by the wrapper functions into two arguments in the system calls:

unsigned long *pos_l*, **unsigned long** *pos*

These arguments contain, respectively, the low order and high order 32 bits of *offset*.

STANDARDS

readv()
writev()
POSIX.1-2008.

preadv()
pwritev()
BSD.

preadv2()
pwritev2()
Linux.

HISTORY

readv()
writev()
POSIX.1-2001, 4.4BSD (first appeared in 4.2BSD).

preadv(), **pwritev**(): Linux 2.6.30, glibc 2.10.

preadv2(), **pwritev2**(): Linux 4.6, glibc 2.26.

Historical C library/kernel differences

To deal with the fact that **IOV_MAX** was so low on early versions of Linux, the glibc wrapper functions for **readv**() and **writev**() did some extra work if they detected that the underlying kernel system call failed because this limit was exceeded. In the case of **readv**(), the wrapper function allocated a temporary buffer large enough for all of the items specified by *iov*, passed that buffer in a call to *read*(2), copied data from the buffer to the locations specified by the *iov_base* fields of the elements of *iov*, and then freed the buffer. The wrapper function for **writev**() performed the analogous task using a temporary buffer and a call to *write*(2).

The need for this extra effort in the glibc wrapper functions went away with Linux 2.2 and later. However, glibc continued to provide this behavior until glibc 2.10. Starting with glibc 2.9, the wrapper functions provide this behavior only if the library detects that the system is running a Linux kernel older than Linux 2.6.18 (an arbitrarily selected kernel version). And since glibc 2.20 (which requires a minimum of Linux 2.6.32), the glibc wrapper functions always just directly invoke the system calls.

NOTES

POSIX.1 allows an implementation to place a limit on the number of items that can be passed in *iov*. An implementation can advertise its limit by defining **IOV_MAX** in *<limits.h>* or at run time via the return value from *sysconf(_SC_IOV_MAX)*. On modern Linux systems, the limit is 1024. Back in Linux 2.0 days, this limit was 16.

BUGS

Linux 5.9 and Linux 5.10 have a bug where **preadv2**() with the **RWF_NOWAIT** flag may return 0 even when not at end of file.

EXAMPLES

The following code sample demonstrates the use of **writev**():

```
char          *str0 = "hello ";
char          *str1 = "world\n";
ssize_t       nwritten;
struct iovec  iov[2];

iov[0].iov_base = str0;
iov[0].iov_len = strlen(str0);
iov[1].iov_base = str1;
iov[1].iov_len = strlen(str1);

nwritten = writev(STDOUT_FILENO, iov, 2);
```

NAME

reboot − reboot or enable/disable Ctrl-Alt-Del

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
/* Since Linux 2.1.30 there are symbolic names LINUX_REBOOT_*
   for the constants and a fourth argument to the call: */

#include <linux/reboot.h>  /* Definition of LINUX_REBOOT_* constants */
#include <sys/syscall.h>   /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_reboot, int magic, int magic2, int op, void *arg);

/* Under glibc and most alternative libc's (including uclibc, dietlibc,
   musl and a few others), some of the constants involved have gotten
   symbolic names RB_*, and the library call is a 1-argument
   wrapper around the system call: */

#include <sys/reboot.h>    /* Definition of RB_* constants */
#include <unistd.h>

int reboot(int op);
```

DESCRIPTION

The **reboot**() call reboots the system, or enables/disables the reboot keystroke (abbreviated CAD, since the default is Ctrl-Alt-Delete; it can be changed using *loadkeys*(1)).

This system call fails (with the error **EINVAL**) unless *magic* equals **LINUX_REBOOT_MAGIC1** (that is, 0xfee1dead) and *magic2* equals **LINUX_REBOOT_MAGIC2** (that is, 0x28121969). However, since Linux 2.1.17 also **LINUX_REBOOT_MAGIC2A** (that is, 0x05121996) and since Linux 2.1.97 also **LINUX_REBOOT_MAGIC2B** (that is, 0x16041998) and since Linux 2.5.71 also **LINUX_REBOOT_MAGIC2C** (that is, 0x20112000) are permitted as values for *magic2*. (The hexadecimal values of these constants are meaningful.)

The *op* argument can have the following values:

LINUX_REBOOT_CMD_CAD_OFF
(**RB_DISABLE_CAD**, 0). CAD is disabled. This means that the CAD keystroke will cause a **SIGINT** signal to be sent to init (process 1), whereupon this process may decide upon a proper action (maybe: kill all processes, sync, reboot).

LINUX_REBOOT_CMD_CAD_ON
(**RB_ENABLE_CAD**, 0x89abcdef). CAD is enabled. This means that the CAD keystroke will immediately cause the action associated with **LINUX_REBOOT_CMD_RESTART**.

LINUX_REBOOT_CMD_HALT
(**RB_HALT_SYSTEM**, 0xcdef0123; since Linux 1.1.76). The message "System halted." is printed, and the system is halted. Control is given to the ROM monitor, if there is one. If not preceded by a *sync*(2), data will be lost.

LINUX_REBOOT_CMD_KEXEC
(**RB_KEXEC**, 0x45584543, since Linux 2.6.13). Execute a kernel that has been loaded earlier with *kexec_load*(2). This option is available only if the kernel was configured with **CONFIG_KEXEC**.

LINUX_REBOOT_CMD_POWER_OFF
(**RB_POWER_OFF**, 0x4321fedc; since Linux 2.1.30). The message "Power down." is printed, the system is stopped, and all power is removed from the system, if possible. If not preceded by a *sync*(2), data will be lost.

LINUX_REBOOT_CMD_RESTART
(**RB_AUTOBOOT**, 0x1234567). The message "Restarting system." is printed, and a default restart is performed immediately. If not preceded by a *sync*(2), data will be lost.

LINUX_REBOOT_CMD_RESTART2
(0xa1b2c3d4; since Linux 2.1.30). The message "Restarting system with command '%s'" is printed, and a restart (using the command string given in *arg*) is performed immediately. If not preceded by a *sync*(2), data will be lost.

LINUX_REBOOT_CMD_SW_SUSPEND
(**RB_SW_SUSPEND**, 0xd000fce1; since Linux 2.5.18). The system is suspended (hibernated) to disk. This option is available only if the kernel was configured with **CONFIG_HIBERNATION**.

Only the superuser may call **reboot**().

The precise effect of the above actions depends on the architecture. For the i386 architecture, the additional argument does not do anything at present (2.1.122), but the type of reboot can be determined by kernel command-line arguments ("reboot=...") to be either warm or cold, and either hard or through the BIOS.

Behavior inside PID namespaces

Since Linux 3.4, if **reboot**() is called from a PID namespace other than the initial PID namespace with one of the *op* values listed below, it performs a "reboot" of that namespace: the "init" process of the PID namespace is immediately terminated, with the effects described in *pid_namespaces*(7).

The values that can be supplied in *op* when calling **reboot**() in this case are as follows:

LINUX_REBOOT_CMD_RESTART
LINUX_REBOOT_CMD_RESTART2
The "init" process is terminated, and *wait*(2) in the parent process reports that the child was killed with a **SIGHUP** signal.

LINUX_REBOOT_CMD_POWER_OFF
LINUX_REBOOT_CMD_HALT
The "init" process is terminated, and *wait*(2) in the parent process reports that the child was killed with a **SIGINT** signal.

For the other *op* values, **reboot**() returns −1 and *errno* is set to **EINVAL**.

RETURN VALUE

For the values of *op* that stop or restart the system, a successful call to **reboot**() does not return. For the other *op* values, zero is returned on success. In all cases, −1 is returned on failure, and *errno* is set to indicate the error.

ERRORS

EFAULT
Problem with getting user-space data under **LINUX_REBOOT_CMD_RESTART2**.

EINVAL
Bad magic numbers or *op*.

EPERM
The calling process has insufficient privilege to call **reboot**(); the caller must have the **CAP_SYS_BOOT** inside its user namespace.

STANDARDS

Linux.

NAME

recv, recvfrom, recvmsg − receive a message from a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/socket.h>

ssize_t recv(int sockfd, void buf[.len], size_t len,
             int flags);
ssize_t recvfrom(int sockfd, void buf[restrict .len], size_t len,
             int flags,
             struct sockaddr *_Nullable restrict src_addr,
             socklen_t *_Nullable restrict addrlen);
ssize_t recvmsg(int sockfd, struct msghdr *msg, int flags);
```

DESCRIPTION

The **recv**(), **recvfrom**(), and **recvmsg**() calls are used to receive messages from a socket. They may be used to receive data on both connectionless and connection-oriented sockets. This page first describes common features of all three system calls, and then describes the differences between the calls.

The only difference between **recv**() and *read*(2) is the presence of *flags*. With a zero *flags* argument, **recv**() is generally equivalent to *read*(2) (but see NOTES). Also, the following call

```
recv(sockfd, buf, len, flags);
```

is equivalent to

```
recvfrom(sockfd, buf, len, flags, NULL, NULL);
```

All three calls return the length of the message on successful completion. If a message is too long to fit in the supplied buffer, excess bytes may be discarded depending on the type of socket the message is received from.

If no messages are available at the socket, the receive calls wait for a message to arrive, unless the socket is nonblocking (see *fcntl*(2)), in which case the value −1 is returned and *errno* is set to **EAGAIN** or **EWOULDBLOCK**. The receive calls normally return any data available, up to the requested amount, rather than waiting for receipt of the full amount requested.

An application can use *select*(2), *poll*(2), or *epoll*(7) to determine when more data arrives on a socket.

The flags argument

The *flags* argument is formed by ORing one or more of the following values:

MSG_CMSG_CLOEXEC (**recvmsg**() only; since Linux 2.6.23)
Set the close-on-exec flag for the file descriptor received via a UNIX domain file descriptor using the **SCM_RIGHTS** operation (described in *unix*(7)). This flag is useful for the same reasons as the **O_CLOEXEC** flag of *open*(2).

MSG_DONTWAIT (since Linux 2.2)
Enables nonblocking operation; if the operation would block, the call fails with the error **EAGAIN** or **EWOULDBLOCK**. This provides similar behavior to setting the **O_NONBLOCK** flag (via the *fcntl*(2) **F_SETFL** operation), but differs in that **MSG_DONTWAIT** is a per-call option, whereas **O_NONBLOCK** is a setting on the open file description (see *open*(2)), which will affect all threads in the calling process as well as other processes that hold file descriptors referring to the same open file description.

MSG_ERRQUEUE (since Linux 2.2)
This flag specifies that queued errors should be received from the socket error queue. The error is passed in an ancillary message with a type dependent on the protocol (for IPv4 **IP_RECVERR**). The user should supply a buffer of sufficient size. See *cmsg*(3) and *ip*(7) for more information. The payload of the original packet that caused the error is passed as normal data via *msg_iovec*. The original destination address of the datagram that caused the error is supplied via *msg_name*.

The error is supplied in a *sock_extended_err* structure:

```
#define SO_EE_ORIGIN_NONE    0
#define SO_EE_ORIGIN_LOCAL   1
#define SO_EE_ORIGIN_ICMP    2
#define SO_EE_ORIGIN_ICMP6   3

struct sock_extended_err
{
    uint32_t ee_errno;   /* Error number */
    uint8_t  ee_origin;  /* Where the error originated */
    uint8_t  ee_type;    /* Type */
    uint8_t  ee_code;    /* Code */
    uint8_t  ee_pad;     /* Padding */
    uint32_t ee_info;    /* Additional information */
    uint32_t ee_data;    /* Other data */
    /* More data may follow */
};

struct sockaddr *SO_EE_OFFENDER(struct sock_extended_err *);
```

ee_errno contains the *errno* number of the queued error. *ee_origin* is the origin code of where the error originated. The other fields are protocol-specific. The macro **SO_EE_OFFENDER** returns a pointer to the address of the network object where the error originated from given a pointer to the ancillary message. If this address is not known, the *sa_family* member of the *sockaddr* contains **AF_UNSPEC** and the other fields of the *sockaddr* are undefined. The payload of the packet that caused the error is passed as normal data.

For local errors, no address is passed (this can be checked with the *cmsg_len* member of the *cmsghdr*). For error receives, the **MSG_ERRQUEUE** flag is set in the *msghdr*. After an error has been passed, the pending socket error is regenerated based on the next queued error and will be passed on the next socket operation.

MSG_OOB
This flag requests receipt of out-of-band data that would not be received in the normal data stream. Some protocols place expedited data at the head of the normal data queue, and thus this flag cannot be used with such protocols.

MSG_PEEK
This flag causes the receive operation to return data from the beginning of the receive queue without removing that data from the queue. Thus, a subsequent receive call will return the same data.

MSG_TRUNC (since Linux 2.2)
For raw (**AF_PACKET**), Internet datagram (since Linux 2.4.27/2.6.8), netlink (since Linux 2.6.22), and UNIX datagram as well as sequenced-packet (since Linux 3.4) sockets: return the real length of the packet or datagram, even when it was longer than the passed buffer.

For use with Internet stream sockets, see *tcp*(7).

MSG_WAITALL (since Linux 2.2)
This flag requests that the operation block until the full request is satisfied. However, the call may still return less data than requested if a signal is caught, an error or disconnect occurs, or the next data to be received is of a different type than that returned. This flag has no effect for datagram sockets.

recvfrom()
recvfrom() places the received message into the buffer *buf*. The caller must specify the size of the buffer in *len*.

If *src_addr* is not NULL, and the underlying protocol provides the source address of the message, that source address is placed in the buffer pointed to by *src_addr*. In this case, *addrlen* is a value-result argument. Before the call, it should be initialized to the size of the buffer associated with *src_addr*. Upon return, *addrlen* is updated to contain the actual size of the source address. The returned address is truncated if the buffer provided is too small; in this case, *addrlen* will return a value greater than was supplied to the call.

If the caller is not interested in the source address, *src_addr* and *addrlen* should be specified as NULL.

recv()

The **recv**() call is normally used only on a *connected* socket (see *connect*(2)). It is equivalent to the call:

```
recvfrom(fd, buf, len, flags, NULL, 0);
```

recvmsg()

The **recvmsg**() call uses a *msghdr* structure to minimize the number of directly supplied arguments. This structure is defined as follows in <*sys/socket.h*>:

```
struct msghdr {
    void         *msg_name;       /* Optional address */
    socklen_t     msg_namelen;    /* Size of address */
    struct iovec *msg_iov;        /* Scatter/gather array */
    size_t        msg_iovlen;     /* # elements in msg_iov */
    void         *msg_control;    /* Ancillary data, see below */
    size_t        msg_controllen; /* Ancillary data buffer len */
    int           msg_flags;      /* Flags on received message */
};
```

The *msg_name* field points to a caller-allocated buffer that is used to return the source address if the socket is unconnected. The caller should set *msg_namelen* to the size of this buffer before this call; upon return from a successful call, *msg_namelen* will contain the length of the returned address. If the application does not need to know the source address, *msg_name* can be specified as NULL.

The fields *msg_iov* and *msg_iovlen* describe scatter-gather locations, as discussed in *readv*(2).

The field *msg_control*, which has length *msg_controllen*, points to a buffer for other protocol control-related messages or miscellaneous ancillary data. When **recvmsg**() is called, *msg_controllen* should contain the length of the available buffer in *msg_control*; upon return from a successful call it will contain the length of the control message sequence.

The messages are of the form:

```
struct cmsghdr {
    size_t cmsg_len;    /* Data byte count, including header
                           (type is socklen_t in POSIX) */
    int    cmsg_level;  /* Originating protocol */
    int    cmsg_type;   /* Protocol-specific type */
/* followed by
    unsigned char cmsg_data[]; */
};
```

Ancillary data should be accessed only by the macros defined in *cmsg*(3).

As an example, Linux uses this ancillary data mechanism to pass extended errors, IP options, or file descriptors over UNIX domain sockets. For further information on the use of ancillary data in various socket domains, see *unix*(7) and *ip*(7).

The *msg_flags* field in the *msghdr* is set on return of **recvmsg**(). It can contain several flags:

MSG_EOR
: indicates end-of-record; the data returned completed a record (generally used with sockets of type **SOCK_SEQPACKET**).

MSG_TRUNC
: indicates that the trailing portion of a datagram was discarded because the datagram was larger than the buffer supplied.

MSG_CTRUNC
: indicates that some control data was discarded due to lack of space in the buffer for ancillary data.

MSG_OOB
: is returned to indicate that expedited or out-of-band data was received.

MSG_ERRQUEUE
indicates that no data was received but an extended error from the socket error queue.

MSG_CMSG_CLOEXEC (since Linux 2.6.23)
indicates that **MSG_CMSG_CLOEXEC** was specified in the *flags* argument of **recvmsg**().

RETURN VALUE

These calls return the number of bytes received, or −1 if an error occurred. In the event of an error, *errno* is set to indicate the error.

When a stream socket peer has performed an orderly shutdown, the return value will be 0 (the traditional "end-of-file" return).

Datagram sockets in various domains (e.g., the UNIX and Internet domains) permit zero-length datagrams. When such a datagram is received, the return value is 0.

The value 0 may also be returned if the requested number of bytes to receive from a stream socket was 0.

ERRORS

These are some standard errors generated by the socket layer. Additional errors may be generated and returned from the underlying protocol modules; see their manual pages.

EAGAIN or **EWOULDBLOCK**
The socket is marked nonblocking and the receive operation would block, or a receive timeout had been set and the timeout expired before data was received. POSIX.1 allows either error to be returned for this case, and does not require these constants to have the same value, so a portable application should check for both possibilities.

EBADF
The argument *sockfd* is an invalid file descriptor.

ECONNREFUSED
A remote host refused to allow the network connection (typically because it is not running the requested service).

EFAULT
The receive buffer pointer(s) point outside the process's address space.

EINTR
The receive was interrupted by delivery of a signal before any data was available; see *signal*(7).

EINVAL
Invalid argument passed.

ENOMEM
Could not allocate memory for **recvmsg**().

ENOTCONN
The socket is associated with a connection-oriented protocol and has not been connected (see *connect*(2) and *accept*(2)).

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

VERSIONS

According to POSIX.1, the *msg_controllen* field of the *msghdr* structure should be typed as *socklen_t*, and the *msg_iovlen* field should be typed as *int*, but glibc currently types both as *size_t*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.4BSD (first appeared in 4.2BSD).

POSIX.1 describes only the **MSG_OOB**, **MSG_PEEK**, and **MSG_WAITALL** flags.

NOTES

If a zero-length datagram is pending, *read*(2) and **recv**() with a *flags* argument of zero provide different behavior. In this circumstance, *read*(2) has no effect (the datagram remains pending), while **recv**()

consumes the pending datagram.

See *recvmmsg*(2) for information about a Linux-specific system call that can be used to receive multiple datagrams in a single call.

EXAMPLES

An example of the use of **recvfrom**() is shown in *getaddrinfo*(3).

NAME

recvmmsg − receive multiple messages on a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sys/socket.h>

int recvmmsg(int sockfd, struct mmsghdr *msgvec, unsigned int vlen,
             int flags, struct timespec *timeout);
```

DESCRIPTION

The **recvmmsg**() system call is an extension of *recvmsg*(2) that allows the caller to receive multiple messages from a socket using a single system call. (This has performance benefits for some applications.) A further extension over *recvmsg*(2) is support for a timeout on the receive operation.

The *sockfd* argument is the file descriptor of the socket to receive data from.

The *msgvec* argument is a pointer to an array of *mmsghdr* structures. The size of this array is specified in *vlen*.

The *mmsghdr* structure is defined in <*sys/socket.h*> as:

```
struct mmsghdr {
    struct msghdr msg_hdr;  /* Message header */
    unsigned int  msg_len;  /* Number of received bytes for header */
};
```

The *msg_hdr* field is a *msghdr* structure, as described in *recvmsg*(2). The *msg_len* field is the number of bytes returned for the message in the entry. This field has the same value as the return value of a single *recvmsg*(2) on the header.

The *flags* argument contains flags ORed together. The flags are the same as documented for *recvmsg*(2), with the following addition:

MSG_WAITFORONE (since Linux 2.6.34)
Turns on **MSG_DONTWAIT** after the first message has been received.

The *timeout* argument points to a *struct timespec* (see *clock_gettime*(2)) defining a timeout (seconds plus nanoseconds) for the receive operation (*but see BUGS!*). (This interval will be rounded up to the system clock granularity, and kernel scheduling delays mean that the blocking interval may overrun by a small amount.) If *timeout* is NULL, then the operation blocks indefinitely.

A blocking **recvmmsg**() call blocks until *vlen* messages have been received or until the timeout expires. A nonblocking call reads as many messages as are available (up to the limit specified by *vlen*) and returns immediately.

On return from **recvmmsg**(), successive elements of *msgvec* are updated to contain information about each received message: *msg_len* contains the size of the received message; the subfields of *msg_hdr* are updated as described in *recvmsg*(2). The return value of the call indicates the number of elements of *msgvec* that have been updated.

RETURN VALUE

On success, **recvmmsg**() returns the number of messages received in *msgvec*; on error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Errors are as for *recvmsg*(2). In addition, the following error can occur:

EINVAL
timeout is invalid.

See also BUGS.

STANDARDS

Linux.

HISTORY

Linux 2.6.33, glibc 2.12.

BUGS

The *timeout* argument does not work as intended. The timeout is checked only after the receipt of each datagram, so that if up to *vlen−1* datagrams are received before the timeout expires, but then no further datagrams are received, the call will block forever.

If an error occurs after at least one message has been received, the call succeeds, and returns the number of messages received. The error code is expected to be returned on a subsequent call to **recvmmsg**(). In the current implementation, however, the error code can be overwritten in the meantime by an unrelated network event on a socket, for example an incoming ICMP packet.

EXAMPLES

The following program uses **recvmmsg**() to receive multiple messages on a socket and stores them in multiple buffers. The call returns if all buffers are filled or if the timeout specified has expired.

The following snippet periodically generates UDP datagrams containing a random number:

```
$ while true; do echo $RANDOM > /dev/udp/127.0.0.1/1234;
      sleep 0.25; done
```

These datagrams are read by the example application, which can give the following output:

```
$ ./a.out
5 messages received
1 11782
2 11345
3 304
4 13514
5 28421
```

Program source

```
#define _GNU_SOURCE
#include <arpa/inet.h>
#include <netinet/in.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/socket.h>
#include <time.h>

main(void)
{
#define VLEN 10
#define BUFSIZE 200
#define TIMEOUT 1
    int                 sockfd, retval;
    char                bufs[VLEN][BUFSIZE+1];
    struct iovec        iovecs[VLEN];
    struct mmsghdr      msgs[VLEN];
    struct timespec     timeout;
    struct sockaddr_in  addr;

    sockfd = socket(AF_INET, SOCK_DGRAM, 0);
    if (sockfd == -1) {
        perror("socket()");
        exit(EXIT_FAILURE);
    }

    addr.sin_family = AF_INET;
```

```
        addr.sin_addr.s_addr = htonl(INADDR_LOOPBACK);
        addr.sin_port = htons(1234);
        if (bind(sockfd, (struct sockaddr *) &addr, sizeof(addr)) == -1) {
            perror("bind()");
            exit(EXIT_FAILURE);
        }

        memset(msgs, 0, sizeof(msgs));
        for (size_t i = 0; i < VLEN; i++) {
            iovecs[i].iov_base         = bufs[i];
            iovecs[i].iov_len          = BUFSIZE;
            msgs[i].msg_hdr.msg_iov    = &iovecs[i];
            msgs[i].msg_hdr.msg_iovlen = 1;
        }

        timeout.tv_sec = TIMEOUT;
        timeout.tv_nsec = 0;

        retval = recvmmsg(sockfd, msgs, VLEN, 0, &timeout);
        if (retval == -1) {
            perror("recvmmsg()");
            exit(EXIT_FAILURE);
        }

        printf("%d messages received\n", retval);
        for (size_t i = 0; i < retval; i++) {
            bufs[i][msgs[i].msg_len] = 0;
            printf("%zu %s", i+1, bufs[i]);
        }
        exit(EXIT_SUCCESS);
    }
```

NAME

remap_file_pages − create a nonlinear file mapping

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sys/mman.h>

[[deprecated]] int remap_file_pages(void addr[.size], size_t size,
                                    int prot, size_t pgoff, int flags);
```

DESCRIPTION

Note: this system call was marked as deprecated starting with Linux 3.16. In Linux 4.0, the implementation was replaced by a slower in-kernel emulation. Those few applications that use this system call should consider migrating to alternatives. This change was made because the kernel code for this system call was complex, and it is believed to be little used or perhaps even completely unused. While it had some use cases in database applications on 32-bit systems, those use cases don't exist on 64-bit systems.

The **remap_file_pages**() system call is used to create a nonlinear mapping, that is, a mapping in which the pages of the file are mapped into a nonsequential order in memory. The advantage of using **remap_file_pages**() over using repeated calls to *mmap*(2) is that the former approach does not require the kernel to create additional VMA (Virtual Memory Area) data structures.

To create a nonlinear mapping we perform the following steps:

1. Use *mmap*(2) to create a mapping (which is initially linear). This mapping must be created with the **MAP_SHARED** flag.
2. Use one or more calls to **remap_file_pages**() to rearrange the correspondence between the pages of the mapping and the pages of the file. It is possible to map the same page of a file into multiple locations within the mapped region.

The *pgoff* and *size* arguments specify the region of the file that is to be relocated within the mapping: *pgoff* is a file offset in units of the system page size; *size* is the length of the region in bytes.

The *addr* argument serves two purposes. First, it identifies the mapping whose pages we want to rearrange. Thus, *addr* must be an address that falls within a region previously mapped by a call to *mmap*(2). Second, *addr* specifies the address at which the file pages identified by *pgoff* and *size* will be placed.

The values specified in *addr* and *size* should be multiples of the system page size. If they are not, then the kernel rounds *both* values *down* to the nearest multiple of the page size.

The *prot* argument must be specified as 0.

The *flags* argument has the same meaning as for *mmap*(2), but all flags other than **MAP_NONBLOCK** are ignored.

RETURN VALUE

On success, **remap_file_pages**() returns 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
: *addr* does not refer to a valid mapping created with the **MAP_SHARED** flag.

EINVAL
: *addr*, *size*, *prot*, or *pgoff* is invalid.

STANDARDS

Linux.

HISTORY

Linux 2.5.46, glibc 2.3.3.

NOTES

Since Linux 2.6.23, **remap_file_pages**() creates non-linear mappings only on in-memory filesystems such as *tmpfs*(5), hugetlbfs or ramfs. On filesystems with a backing store, **remap_file_pages**() is not much more efficient than using *mmap*(2) to adjust which parts of the file are mapped to which addresses.

getpagesize(2), *mmap*(2), *mmap2*(2), *mprotect*(2), *mremap*(2), *msync*(2)

NAME

removexattr, lremovexattr, fremovexattr − remove an extended attribute

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/xattr.h>

int removexattr(const char *path, const char *name);
int lremovexattr(const char *path, const char *name);
int fremovexattr(int fd, const char *name);
```

DESCRIPTION

Extended attributes are *name*:*value* pairs associated with inodes (files, directories, symbolic links, etc.). They are extensions to the normal attributes which are associated with all inodes in the system (i.e., the *stat*(2) data). A complete overview of extended attributes concepts can be found in *xattr*(7).

removexattr() removes the extended attribute identified by *name* and associated with the given *path* in the filesystem.

lremovexattr() is identical to **removexattr**(), except in the case of a symbolic link, where the extended attribute is removed from the link itself, not the file that it refers to.

fremovexattr() is identical to **removexattr**(), only the extended attribute is removed from the open file referred to by *fd* (as returned by *open*(2)) in place of *path*.

An extended attribute name is a null-terminated string. The *name* includes a namespace prefix; there may be several, disjoint namespaces associated with an individual inode.

RETURN VALUE

On success, zero is returned. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

ENODATA
: The named attribute does not exist.

ENOTSUP
: Extended attributes are not supported by the filesystem, or are disabled.

In addition, the errors documented in *stat*(2) can also occur.

STANDARDS

Linux.

HISTORY

Linux 2.4, glibc 2.3.

SEE ALSO

NAME

rename, renameat, renameat2 − change the name or location of a file

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <stdio.h>

int rename(const char *oldpath, const char *newpath);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <stdio.h>

int renameat(int olddirfd, const char *oldpath,
             int newdirfd, const char *newpath);
int renameat2(int olddirfd, const char *oldpath,
              int newdirfd, const char *newpath, unsigned int flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

renameat():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_ATFILE_SOURCE

renameat2():
_GNU_SOURCE

DESCRIPTION

rename() renames a file, moving it between directories if required. Any other hard links to the file (as created using *link*(2)) are unaffected. Open file descriptors for *oldpath* are also unaffected.

Various restrictions determine whether or not the rename operation succeeds: see ERRORS below.

If *newpath* already exists, it will be atomically replaced, so that there is no point at which another process attempting to access *newpath* will find it missing. However, there will probably be a window in which both *oldpath* and *newpath* refer to the file being renamed.

If *oldpath* and *newpath* are existing hard links referring to the same file, then **rename**() does nothing, and returns a success status.

If *newpath* exists but the operation fails for some reason, **rename**() guarantees to leave an instance of *newpath* in place.

oldpath can specify a directory. In this case, *newpath* must either not exist, or it must specify an empty directory.

If *oldpath* refers to a symbolic link, the link is renamed; if *newpath* refers to a symbolic link, the link will be overwritten.

renameat()

The **renameat**() system call operates in exactly the same way as **rename**(), except for the differences described here.

If the pathname given in *oldpath* is relative, then it is interpreted relative to the directory referred to by the file descriptor *olddirfd* (rather than relative to the current working directory of the calling process, as is done by **rename**() for a relative pathname).

If *oldpath* is relative and *olddirfd* is the special value **AT_FDCWD**, then *oldpath* is interpreted relative to the current working directory of the calling process (like *rename*())

If *oldpath* is absolute, then *olddirfd* is ignored.

The interpretation of *newpath* is as for *oldpath*, except that a relative pathname is interpreted relative to the directory referred to by the file descriptor *newdirfd*.

See *openat*(2) for an explanation of the need for **renameat**().

renameat2()

renameat2() has an additional *flags* argument. A **renameat2**() call with a zero *flags* argument is equivalent to **renameat**().

The *flags* argument is a bit mask consisting of zero or more of the following flags:

RENAME_EXCHANGE

Atomically exchange *oldpath* and *newpath*. Both pathnames must exist but may be of different types (e.g., one could be a non-empty directory and the other a symbolic link).

RENAME_NOREPLACE

Don't overwrite *newpath* of the rename. Return an error if *newpath* already exists.

RENAME_NOREPLACE can't be employed together with **RENAME_EXCHANGE**.

RENAME_NOREPLACE requires support from the underlying filesystem. Support for various filesystems was added as follows:

- ext4 (Linux 3.15);
- btrfs, tmpfs, and cifs (Linux 3.17);
- xfs (Linux 4.0);
- Support for many other filesystems was added in Linux 4.9, including ext2, minix, reiserfs, jfs, vfat, and bpf.

RENAME_WHITEOUT (since Linux 3.18)

This operation makes sense only for overlay/union filesystem implementations.

Specifying **RENAME_WHITEOUT** creates a "whiteout" object at the source of the rename at the same time as performing the rename. The whole operation is atomic, so that if the rename succeeds then the whiteout will also have been created.

A "whiteout" is an object that has special meaning in union/overlay filesystem constructs. In these constructs, multiple layers exist and only the top one is ever modified. A whiteout on an upper layer will effectively hide a matching file in the lower layer, making it appear as if the file didn't exist.

When a file that exists on the lower layer is renamed, the file is first copied up (if not already on the upper layer) and then renamed on the upper, read-write layer. At the same time, the source file needs to be "whiteouted" (so that the version of the source file in the lower layer is rendered invisible). The whole operation needs to be done atomically.

When not part of a union/overlay, the whiteout appears as a character device with a {0,0} device number. (Note that other union/overlay implementations may employ different methods for storing whiteout entries; specifically, BSD union mount employs a separate inode type, **DT_WHT**, which, while supported by some filesystems available in Linux, such as CODA and XFS, is ignored by the kernel's whiteout support code, as of Linux 4.19, at least.)

RENAME_WHITEOUT requires the same privileges as creating a device node (i.e., the **CAP_MKNOD** capability).

RENAME_WHITEOUT can't be employed together with **RENAME_EXCHANGE**.

RENAME_WHITEOUT requires support from the underlying filesystem. Among the filesystems that support it are tmpfs (since Linux 3.18), ext4 (since Linux 3.18), XFS (since Linux 4.1), f2fs (since Linux 4.2), btrfs (since Linux 4.7), and ubifs (since Linux 4.9).

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES

Write permission is denied for the directory containing *oldpath* or *newpath*, or, search permission is denied for one of the directories in the path prefix of *oldpath* or *newpath*, or *oldpath* is a directory and does not allow write permission (needed to update the .. entry). (See also *path_resolution*(7).)

EBUSY
The rename fails because *oldpath* or *newpath* is a directory that is in use by some process (perhaps as current working directory, or as root directory, or because it was open for reading) or is in use by the system (for example as a mount point), while the system considers this an error. (Note that there is no requirement to return **EBUSY** in such cases—there is nothing wrong with doing the rename anyway—but it is allowed to return **EBUSY** if the system cannot otherwise handle such situations.)

EDQUOT
The user's quota of disk blocks on the filesystem has been exhausted.

EFAULT
oldpath or *newpath* points outside your accessible address space.

EINVAL
The new pathname contained a path prefix of the old, or, more generally, an attempt was made to make a directory a subdirectory of itself.

EISDIR
newpath is an existing directory, but *oldpath* is not a directory.

ELOOP
Too many symbolic links were encountered in resolving *oldpath* or *newpath*.

EMLINK
oldpath already has the maximum number of links to it, or it was a directory and the directory containing *newpath* has the maximum number of links.

ENAMETOOLONG
oldpath or *newpath* was too long.

ENOENT
The link named by *oldpath* does not exist; or, a directory component in *newpath* does not exist; or, *oldpath* or *newpath* is an empty string.

ENOMEM
Insufficient kernel memory was available.

ENOSPC
The device containing the file has no room for the new directory entry.

ENOTDIR
A component used as a directory in *oldpath* or *newpath* is not, in fact, a directory. Or, *oldpath* is a directory, and *newpath* exists but is not a directory.

ENOTEMPTY or **EEXIST**
newpath is a nonempty directory, that is, contains entries other than "." and "..".

EPERM or **EACCES**
The directory containing *oldpath* has the sticky bit (**S_ISVTX**) set and the process's effective user ID is neither the user ID of the file to be deleted nor that of the directory containing it, and the process is not privileged (Linux: does not have the **CAP_FOWNER** capability); or *newpath* is an existing file and the directory containing it has the sticky bit set and the process's effective user ID is neither the user ID of the file to be replaced nor that of the directory containing it, and the process is not privileged (Linux: does not have the **CAP_FOWNER** capability); or the filesystem containing *oldpath* does not support renaming of the type requested.

EROFS
The file is on a read-only filesystem.

EXDEV
oldpath and *newpath* are not on the same mounted filesystem. (Linux permits a filesystem to be mounted at multiple points, but **rename**() does not work across different mount points, even if the same filesystem is mounted on both.)

The following additional errors can occur for **renameat**() and **renameat2**():

EBADF
oldpath (*newpath*) is relative but *olddirfd* (*newdirfd*) is not a valid file descriptor.

ENOTDIR
oldpath is relative and *olddirfd* is a file descriptor referring to a file other than a directory; or similar for *newpath* and *newdirfd*

The following additional errors can occur for **renameat2**():

EEXIST
flags contains **RENAME_NOREPLACE** and *newpath* already exists.

EINVAL
An invalid flag was specified in *flags*.

EINVAL
Both **RENAME_NOREPLACE** and **RENAME_EXCHANGE** were specified in *flags*.

EINVAL
Both **RENAME_WHITEOUT** and **RENAME_EXCHANGE** were specified in *flags*.

EINVAL
The filesystem does not support one of the flags in *flags*.

ENOENT
flags contains **RENAME_EXCHANGE** and *newpath* does not exist.

EPERM
RENAME_WHITEOUT was specified in *flags*, but the caller does not have the **CAP_MKNOD** capability.

STANDARDS

rename()
C11, POSIX.1-2008.

renameat()
POSIX.1-2008.

renameat2()
Linux.

HISTORY

rename()
4.3BSD, C89, POSIX.1-2001.

renameat()
Linux 2.6.16, glibc 2.4.

renameat2()
Linux 3.15, glibc 2.28.

glibc notes

On older kernels where **renameat**() is unavailable, the glibc wrapper function falls back to the use of **rename**(). When *oldpath* and *newpath* are relative pathnames, glibc constructs pathnames based on the symbolic links in */proc/self/fd* that correspond to the *olddirfd* and *newdirfd* arguments.

BUGS

On NFS filesystems, you can not assume that if the operation failed, the file was not renamed. If the server does the rename operation and then crashes, the retransmitted RPC which will be processed when the server is up again causes a failure. The application is expected to deal with this. See *link*(2) for a similar problem.

NAME

request_key − request a key from the kernel's key management facility

LIBRARY

Linux Key Management Utilities (*libkeyutils*, *−lkeyutils*)

SYNOPSIS

#include <keyutils.h>

key_serial_t request_key(const char ****type*, const char ****description***,**
const char *_Nullable *callout_info***,**
key_serial_t *dest_keyring***);**

DESCRIPTION

request_key() attempts to find a key of the given *type* with a description (name) that matches the specified *description*. If such a key could not be found, then the key is optionally created. If the key is found or created, **request_key**() attaches it to the keyring whose ID is specified in *dest_keyring* and returns the key's serial number.

request_key() first recursively searches for a matching key in all of the keyrings attached to the calling process. The keyrings are searched in the order: thread-specific keyring, process-specific keyring, and then session keyring.

If **request_key**() is called from a program invoked by **request_key**() on behalf of some other process to generate a key, then the keyrings of that other process will be searched next, using that other process's user ID, group ID, supplementary group IDs, and security context to determine access.

The search of the keyring tree is breadth-first: the keys in each keyring searched are checked for a match before any child keyrings are recursed into. Only keys for which the caller has *search* permission be found, and only keyrings for which the caller has *search* permission may be searched.

If the key is not found and *callout* is NULL, then the call fails with the error **ENOKEY**.

If the key is not found and *callout* is not NULL, then the kernel attempts to invoke a user-space program to instantiate the key. The details are given below.

The *dest_keyring* serial number may be that of a valid keyring for which the caller has *write* permission, or it may be one of the following special keyring IDs:

KEY_SPEC_THREAD_KEYRING
This specifies the caller's thread-specific keyring (see *thread-keyring*(7)).

KEY_SPEC_PROCESS_KEYRING
This specifies the caller's process-specific keyring (see *process-keyring*(7)).

KEY_SPEC_SESSION_KEYRING
This specifies the caller's session-specific keyring (see *session-keyring*(7)).

KEY_SPEC_USER_KEYRING
This specifies the caller's UID-specific keyring (see *user-keyring*(7)).

KEY_SPEC_USER_SESSION_KEYRING
This specifies the caller's UID-session keyring (see *user-session-keyring*(7)).

When the *dest_keyring* is specified as 0 and no key construction has been performed, then no additional linking is done.

Otherwise, if *dest_keyring* is 0 and a new key is constructed, the new key will be linked to the "default" keyring. More precisely, when the kernel tries to determine to which keyring the newly constructed key should be linked, it tries the following keyrings, beginning with the keyring set via the *keyctl*(2) **KEYCTL_SET_REQKEY_KEYRING** operation and continuing in the order shown below until it finds the first keyring that exists:

- The requestor keyring (**KEY_REQKEY_DEFL_REQUESTOR_KEYRING**, since Linux 2.6.29).
- The thread-specific keyring (**KEY_REQKEY_DEFL_THREAD_KEYRING**; see *thread-keyring*(7)).

- The process-specific keyring (**KEY_REQKEY_DEFL_PROCESS_KEYRING**; see *process-keyring*(7)).
- The session-specific keyring (**KEY_REQKEY_DEFL_SESSION_KEYRING**; see *session-keyring*(7)).
- The session keyring for the process's user ID (**KEY_REQKEY_DEFL_USER_SESSION_KEYRING**; see *user-session-keyring*(7)). This keyring is expected to always exist.
- The UID-specific keyring (**KEY_REQKEY_DEFL_USER_KEYRING**; see *user-keyring*(7)). This keyring is also expected to always exist.

If the *keyctl*(2) **KEYCTL_SET_REQKEY_KEYRING** operation specifies **KEY_REQKEY_DEFL_DEFAULT** (or no **KEYCTL_SET_REQKEY_KEYRING** operation is performed), then the kernel looks for a keyring starting from the beginning of the list.

Requesting user-space instantiation of a key

If the kernel cannot find a key matching *type* and *description*, and *callout* is not NULL, then the kernel attempts to invoke a user-space program to instantiate a key with the given *type* and *description*. In this case, the following steps are performed:

(1) The kernel creates an uninstantiated key, U, with the requested *type* and *description*.

(2) The kernel creates an authorization key, V, that refers to the key U and records the facts that the caller of **request_key**() is:

(2.1) the context in which the key U should be instantiated and secured, and

(2.2) the context from which associated key requests may be satisfied.

The authorization key is constructed as follows:

- The key type is *".request_key_auth"*.
- The key's UID and GID are the same as the corresponding filesystem IDs of the requesting process.
- The key grants *view*, *read*, and *search* permissions to the key possessor as well as *view* permission for the key user.
- The description (name) of the key is the hexadecimal string representing the ID of the key that is to be instantiated in the requesting program.
- The payload of the key is taken from the data specified in *callout_info*.
- Internally, the kernel also records the PID of the process that called **request_key**().

(3) The kernel creates a process that executes a user-space service such as *request-key*(8) with a new session keyring that contains a link to the authorization key, V.

This program is supplied with the following command-line arguments:

[0] The string *"/sbin/request−key"*.

[1] The string *"create"* (indicating that a key is to be created).

[2] The ID of the key that is to be instantiated.

[3] The filesystem UID of the caller of **request_key**().

[4] The filesystem GID of the caller of **request_key**().

[5] The ID of the thread keyring of the caller of **request_key**(). This may be zero if that keyring hasn't been created.

[6] The ID of the process keyring of the caller of **request_key**(). This may be zero if that keyring hasn't been created.

[7] The ID of the session keyring of the caller of **request_key**().

Note: each of the command-line arguments that is a key ID is encoded in *decimal* (unlike the key IDs shown in */proc/keys*, which are shown as hexadecimal values).

(4) The program spawned in the previous step:

- Assumes the authority to instantiate the key U using the *keyctl*(2) **KEYCTL_ASSUME_AUTHORITY** operation (typically via the *keyctl_assume_authority*(3) function).
- Obtains the callout data from the payload of the authorization key V (using the *keyctl*(2) **KEYCTL_READ** operation (or, more commonly, the *keyctl_read*(3) function) with a key ID value of **KEY_SPEC_REQKEY_AUTH_KEY**).
- Instantiates the key (or execs another program that performs that task), specifying the payload and destination keyring. (The destination keyring that the requestor specified when calling **request_key**() can be accessed using the special key ID **KEY_SPEC_REQUESTOR_KEYRING**.) Instantiation is performed using the *keyctl*(2) **KEYCTL_INSTANTIATE** operation (or, more commonly, the *keyctl_instantiate*(3) function). At this point, the **request_key**() call completes, and the requesting program can continue execution.

If these steps are unsuccessful, then an **ENOKEY** error will be returned to the caller of **request_key**() and a temporary, negatively instantiated key will be installed in the keyring specified by *dest_keyring*. This will expire after a few seconds, but will cause subsequent calls to **request_key**() to fail until it does. The purpose of this negatively instantiated key is to prevent (possibly different) processes making repeated requests (that require expensive *request-key*(8) upcalls) for a key that can't (at the moment) be positively instantiated.

Once the key has been instantiated, the authorization key (**KEY_SPEC_REQKEY_AUTH_KEY**) is revoked, and the destination keyring (**KEY_SPEC_REQUESTOR_KEYRING**) is no longer accessible from the *request-key*(8) program.

If a key is created, then—regardless of whether it is a valid key or a negatively instantiated key—it will displace any other key with the same type and description from the keyring specified in *dest_keyring*.

RETURN VALUE

On success, **request_key**() returns the serial number of the key it found or caused to be created. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EACCES
The keyring wasn't available for modification by the user.

EDQUOT
The key quota for this user would be exceeded by creating this key or linking it to the keyring.

EFAULT
One of *type*, *description*, or *callout_info* points outside the process's accessible address space.

EINTR
The request was interrupted by a signal; see *signal*(7).

EINVAL
The size of the string (including the terminating null byte) specified in *type* or *description* exceeded the limit (32 bytes and 4096 bytes respectively).

EINVAL
The size of the string (including the terminating null byte) specified in *callout_info* exceeded the system page size.

EKEYEXPIRED
An expired key was found, but no replacement could be obtained.

EKEYREJECTED
The attempt to generate a new key was rejected.

EKEYREVOKED
A revoked key was found, but no replacement could be obtained.

ENOKEY
No matching key was found.

ENOMEM
Insufficient memory to create a key.

EPERM
The *type* argument started with a period ('.').

STANDARDS
Linux.

HISTORY
Linux 2.6.10.

The ability to instantiate keys upon request was added in Linux 2.6.13.

EXAMPLES
The program below demonstrates the use of **request_key**(). The *type*, *description*, and *callout_info* arguments for the system call are taken from the values supplied in the command-line arguments. The call specifies the session keyring as the target keyring.

In order to demonstrate this program, we first create a suitable entry in the file */etc/request−key.conf*.

```
$ sudo sh
# echo 'create user mtk:* *   /bin/keyctl instantiate %k %c %S' \
        > /etc/request-key.conf
# exit
```

This entry specifies that when a new "user" key with the prefix "mtk:" must be instantiated, that task should be performed via the *keyctl*(1) command's **instantiate** operation. The arguments supplied to the **instantiate** operation are: the ID of the uninstantiated key (*%k*); the callout data supplied to the **request_key**() call (*%c*); and the session keyring (*%S*) of the requestor (i.e., the caller of *request_key*())See *request-key.conf* (5) for details of these *%* specifiers.

Then we run the program and check the contents of */proc/keys* to verify that the requested key has been instantiated:

```
$ ./t_request_key user mtk:key1 "Payload data"
$ grep '2dddaf50' /proc/keys
2dddaf50 I--Q---  1 perm 3f010000  1000  1000 user  mtk:key1: 12
```

For another example of the use of this program, see *keyctl*(2).

Program source

```
/* t_request_key.c */

#include <keyutils.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>

int
main(int argc, char *argv[])
{
    key_serial_t key;

    if (argc != 4) {
        fprintf(stderr, "Usage: %s type description callout-data\n",
                argv[0]);
        exit(EXIT_FAILURE);
    }

    key = request_key(argv[1], argv[2], argv[3],
                      KEY_SPEC_SESSION_KEYRING);
    if (key == -1) {
        perror("request_key");
        exit(EXIT_FAILURE);
```

```
        }

        printf("Key ID is %jx\n", (uintmax_t) key);

        exit(EXIT_SUCCESS);
    }
```

The kernel source files *Documentation/security/keys/core.rst* and *Documentation/keys/request−key.rst* (or, before Linux 4.13, in the files *Documentation/security/keys.txt* and *Documentation/security/keys−request−key.txt*).

NAME

restart_syscall − restart a system call after interruption by a stop signal

SYNOPSIS

long restart_syscall(void);

Note: There is no glibc wrapper for this system call; see NOTES.

DESCRIPTION

The **restart_syscall**() system call is used to restart certain system calls after a process that was stopped by a signal (e.g., **SIGSTOP** or **SIGTSTP**) is later resumed after receiving a **SIGCONT** signal. This system call is designed only for internal use by the kernel.

restart_syscall() is used for restarting only those system calls that, when restarted, should adjust their time-related parameters—namely *poll*(2) (since Linux 2.6.24), *nanosleep*(2) (since Linux 2.6), *clock_nanosleep*(2) (since Linux 2.6), and *futex*(2), when employed with the **FUTEX_WAIT** (since Linux 2.6.22) and **FUTEX_WAIT_BITSET** (since Linux 2.6.31) operations. **restart_syscall**() restarts the interrupted system call with a time argument that is suitably adjusted to account for the time that has already elapsed (including the time where the process was stopped by a signal). Without the **restart_syscall**() mechanism, restarting these system calls would not correctly deduct the already elapsed time when the process continued execution.

RETURN VALUE

The return value of **restart_syscall**() is the return value of whatever system call is being restarted.

ERRORS

errno is set as per the errors for whatever system call is being restarted by **restart_syscall**().

STANDARDS

Linux.

HISTORY

Linux 2.6.

NOTES

There is no glibc wrapper for this system call, because it is intended for use only by the kernel and should never be called by applications.

The kernel uses **restart_syscall**() to ensure that when a system call is restarted after a process has been stopped by a signal and then resumed by **SIGCONT**, then the time that the process spent in the stopped state is counted against the timeout interval specified in the original system call. In the case of system calls that take a timeout argument and automatically restart after a stop signal plus **SIGCONT**, but which do not have the **restart_syscall**() mechanism built in, then, after the process resumes execution, the time that the process spent in the stop state is *not* counted against the timeout value. Notable examples of system calls that suffer this problem are *ppoll*(2), *select*(2), and *pselect*(2).

From user space, the operation of **restart_syscall**() is largely invisible: to the process that made the system call that is restarted, it appears as though that system call executed and returned in the usual fashion.

sigaction(2), *sigreturn*(2), *signal*(7)

NAME

rmdir − delete a directory

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int rmdir(const char * *pathname*);

DESCRIPTION

rmdir() deletes a directory, which must be empty.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
: Write access to the directory containing *pathname* was not allowed, or one of the directories in the path prefix of *pathname* did not allow search permission. (See also *path_resolution*(7).)

EBUSY
: *pathname* is currently in use by the system or some process that prevents its removal. On Linux, this means *pathname* is currently used as a mount point or is the root directory of the calling process.

EFAULT
: *pathname* points outside your accessible address space.

EINVAL
: *pathname* has . as last component.

ELOOP
: Too many symbolic links were encountered in resolving *pathname*.

ENAMETOOLONG
: *pathname* was too long.

ENOENT
: A directory component in *pathname* does not exist or is a dangling symbolic link.

ENOMEM
: Insufficient kernel memory was available.

ENOTDIR
: *pathname*, or a component used as a directory in *pathname*, is not, in fact, a directory.

ENOTEMPTY
: *pathname* contains entries other than . and .. ; or, *pathname* has .. as its final component. POSIX.1 also allows **EEXIST** for this condition.

EPERM
: The directory containing *pathname* has the sticky bit (**S_ISVTX**) set and the process's effective user ID is neither the user ID of the file to be deleted nor that of the directory containing it, and the process is not privileged (Linux: does not have the **CAP_FOWNER** capability).

EPERM
: The filesystem containing *pathname* does not support the removal of directories.

EROFS
: *pathname* refers to a directory on a read-only filesystem.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4, 4.3BSD.

BUGS

Infelicities in the protocol underlying NFS can cause the unexpected disappearance of directories which are still being used.

NAME

rt_sigqueueinfo, rt_tgsigqueueinfo − queue a signal and data

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/signal.h>     /* Definition of SI_* constants */
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_rt_sigqueueinfo, pid_t tgid,
        int sig, siginfo_t *info);
int syscall(SYS_rt_tgsigqueueinfo, pid_t tgid, pid_t tid,
        int sig, siginfo_t *info);
```

Note: There are no glibc wrappers for these system calls; see NOTES.

DESCRIPTION

The **rt_sigqueueinfo**() and **rt_tgsigqueueinfo**() system calls are the low-level interfaces used to send a signal plus data to a process or thread. The receiver of the signal can obtain the accompanying data by establishing a signal handler with the *sigaction*(2) **SA_SIGINFO** flag.

These system calls are not intended for direct application use; they are provided to allow the implementation of *sigqueue*(3) and *pthread_sigqueue*(3).

The **rt_sigqueueinfo**() system call sends the signal *sig* to the thread group with the ID *tgid*. (The term "thread group" is synonymous with "process", and *tid* corresponds to the traditional UNIX process ID.) The signal will be delivered to an arbitrary member of the thread group (i.e., one of the threads that is not currently blocking the signal).

The *info* argument specifies the data to accompany the signal. This argument is a pointer to a structure of type *siginfo_t*, described in *sigaction*(2) (and defined by including <*sigaction.h*>). The caller should set the following fields in this structure:

si_code
: This should be one of the **SI_*** codes in the Linux kernel source file *include/asm−generic/siginfo.h*. If the signal is being sent to any process other than the caller itself, the following restrictions apply:

  - The code can't be a value greater than or equal to zero. In particular, it can't be **SI_USER**, which is used by the kernel to indicate a signal sent by *kill*(2), and nor can it be **SI_KERNEL**, which is used to indicate a signal generated by the kernel.
  - The code can't (since Linux 2.6.39) be **SI_TKILL**, which is used by the kernel to indicate a signal sent using *tgkill*(2).

si_pid This should be set to a process ID, typically the process ID of the sender.

si_uid This should be set to a user ID, typically the real user ID of the sender.

si_value
: This field contains the user data to accompany the signal. For more information, see the description of the last (*union sigval*) argument of *sigqueue*(3).

Internally, the kernel sets the *si_signo* field to the value specified in *sig*, so that the receiver of the signal can also obtain the signal number via that field.

The **rt_tgsigqueueinfo**() system call is like **rt_sigqueueinfo**(), but sends the signal and data to the single thread specified by the combination of *tgid*, a thread group ID, and *tid*, a thread in that thread group.

RETURN VALUE

On success, these system calls return 0. On error, they return −1 and *errno* is set to indicate the error.

ERRORS

EAGAIN
: The limit of signals which may be queued has been reached. (See *signal*(7) for further information.)

EINVAL
sig, *tgid*, or *tid* was invalid.

EPERM
The caller does not have permission to send the signal to the target. For the required permissions, see *kill*(2).

EPERM
tgid specifies a process other than the caller and *info->si_code* is invalid.

ESRCH
rt_sigqueueinfo(): No thread group matching *tgid* was found.

rt_tgsigqueinfo(): No thread matching *tgid* and *tid* was found.

STANDARDS
Linux.

HISTORY
rt_sigqueueinfo()
Linux 2.2.

rt_tgsigqueueinfo()
Linux 2.6.31.

NOTES
Since these system calls are not intended for application use, there are no glibc wrapper functions; use *syscall*(2) in the unlikely case that you want to call them directly.

As with *kill*(2), the null signal (0) can be used to check if the specified process or thread exists.

NAME

s390_guarded_storage − operations with z/Architecture guarded storage facility

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <asm/guarded_storage.h> /* Definition of **GS_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_s390_guarded_storage, int *command***,**
struct gs_cb ***gs_cb*);**

Note: glibc provides no wrapper for **s390_guarded_storage**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **s390_guarded_storage**() system call enables the use of the Guarded Storage Facility (a z/Architecture-specific feature) for user-space processes.

The guarded storage facility is a hardware feature that allows marking up to 64 memory regions (as of z14) as guarded; reading a pointer with a newly introduced "Load Guarded" (LGG) or "Load Logical and Shift Guarded" (LLGFSG) instructions will cause a range check on the loaded value and invoke a (previously set up) user-space handler if one of the guarded regions is affected.

The *command* argument indicates which function to perform. The following commands are supported:

GS_ENABLE
Enable the guarded storage facility for the calling task. The initial content of the guarded storage control block will be all zeros. After enablement, user-space code can use the "Load Guarded Storage Controls" (LGSC) instruction (or the **load_gs_cb**() function wrapper provided in the *asm/guarded_storage.h* header) to load an arbitrary control block. While a task is enabled, the kernel will save and restore the calling content of the guarded storage registers on context switch.

GS_DISABLE
Disables the use of the guarded storage facility for the calling task. The kernel will cease to save and restore the content of the guarded storage registers, the task-specific content of these registers is lost.

GS_SET_BC_CB
Set a broadcast guarded storage control block to the one provided in the *gs_cb* argument. This is called per thread and associates a specific guarded storage control block with the calling task. This control block will be used in the broadcast command **GS_BROADCAST**.

GS_CLEAR_BC_CB
Clears the broadcast guarded storage control block. The guarded storage control block will no longer have the association established by the **GS_SET_BC_CB** command.

GS_BROADCAST
Sends a broadcast to all thread siblings of the calling task. Every sibling that has established a broadcast guarded storage control block will load this control block and will be enabled for guarded storage. The broadcast guarded storage control block is consumed; a second broadcast without a refresh of the stored control block with **GS_SET_BC_CB** will not have any effect.

The *gs_cb* argument specifies the address of a guarded storage control block structure and is currently used only by the **GS_SET_BC_CB** command; all other aforementioned commands ignore this argument.

RETURN VALUE

On success, the return value of **s390_guarded_storage**() is 0.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
command was **GS_SET_BC_CB** and the copying of the guarded storage control block structure pointed by the *gs_cb* argument has failed.

EINVAL
The value provided in the *command* argument was not valid.

ENOMEM
command was one of **GS_ENABLE** or **GS_SET_BC_CB**, and the allocation of a new guarded storage control block has failed.

EOPNOTSUPP
The guarded storage facility is not supported by the hardware.

STANDARDS
Linux on s390.

HISTORY
Linux 4.12. System z14.

NOTES
The description of the guarded storage facility along with related instructions and Guarded Storage Control Block and Guarded Storage Event Parameter List structure layouts is available in "z/Architecture Principles of Operations" beginning from the twelfth edition.

The *gs_cb* structure has a field *gsepla* (Guarded Storage Event Parameter List Address), which is a user-space pointer to a Guarded Storage Event Parameter List structure (that contains the address of the aforementioned event handler in the *gseha* field), and its layout is available as a **gs_epl** structure type definition in the *asm/guarded_storage.h* header.

SEE ALSO
syscall(2)

NAME

s390_pci_mmio_write, s390_pci_mmio_read − transfer data to/from PCI MMIO memory page

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_s390_pci_mmio_write, unsigned long mmio_addr,
            const void user_buffer[.length], size_t length);
int syscall(SYS_s390_pci_mmio_read, unsigned long mmio_addr,
            void user_buffer[.length], size_t length);
```

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

The **s390_pci_mmio_write**() system call writes *length* bytes of data from the user-space buffer *user_buffer* to the PCI MMIO memory location specified by *mmio_addr*. The **s390_pci_mmio_read**() system call reads *length* bytes of data from the PCI MMIO memory location specified by *mmio_addr* to the user-space buffer *user_buffer*.

These system calls must be used instead of the simple assignment or data-transfer operations that are used to access the PCI MMIO memory areas mapped to user space on the Linux System z platform. The address specified by *mmio_addr* must belong to a PCI MMIO memory page mapping in the caller's address space, and the data being written or read must not cross a page boundary. The *length* value cannot be greater than the system page size.

RETURN VALUE

On success, **s390_pci_mmio_write**() and **s390_pci_mmio_read**() return 0. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
: The address in *mmio_addr* is invalid.

EFAULT
: *user_buffer* does not point to a valid location in the caller's address space.

EINVAL
: Invalid *length* argument.

ENODEV
: PCI support is not enabled.

ENOMEM
: Insufficient memory.

STANDARDS

Linux on s390.

HISTORY

Linux 3.19. System z EC12.

syscall(2)

NAME

s390_runtime_instr − enable/disable s390 CPU run-time instrumentation

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <asm/runtime_instr.h> /* Definition of **S390_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_s390_runtime_instr, int *command***, int** *signum***);**

Note: glibc provides no wrapper for **s390_runtime_instr**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **s390_runtime_instr**() system call starts or stops CPU run-time instrumentation for the calling thread.

The *command* argument controls whether run-time instrumentation is started (**S390_RUNTIME_INSTR_START**, 1) or stopped (**S390_RUNTIME_INSTR_STOP**, 2) for the calling thread.

The *signum* argument specifies the number of a real-time signal. This argument was used to specify a signal number that should be delivered to the thread if the run-time instrumentation buffer was full or if the run-time-instrumentation-halted interrupt had occurred. This feature was never used, and in Linux 4.4 support for this feature was removed; thus, in current kernels, this argument is ignored.

RETURN VALUE

On success, **s390_runtime_instr**() returns 0 and enables the thread for run-time instrumentation by assigning the thread a default run-time instrumentation control block. The caller can then read and modify the control block and start the run-time instrumentation. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EINVAL
The value specified in *command* is not a valid command.

EINVAL
The value specified in *signum* is not a real-time signal number. From Linux 4.4 onwards, the *signum* argument has no effect, so that an invalid signal number will not result in an error.

ENOMEM
Allocating memory for the run-time instrumentation control block failed.

EOPNOTSUPP
The run-time instrumentation facility is not available.

STANDARDS

Linux on s390.

HISTORY

Linux 3.7. System z EC12.

NOTES

The *asm/runtime_instr.h* header file is available since Linux 4.16.

Starting with Linux 4.4, support for signalling was removed, as was the check whether *signum* is a valid real-time signal. For backwards compatibility with older kernels, it is recommended to pass a valid real-time signal number in *signum* and install a handler for that signal.

SEE ALSO

syscall(2), *signal*(7)

NAME

s390_sthyi − emulate STHYI instruction

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <asm/sthyi.h>      /* Definition of STHYI_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_s390_sthyi, unsigned long  function_code,
        void *resp_buffer, uint64_t *return_code,
        unsigned long  flags);
```

Note: glibc provides no wrapper for **s390_sthyi**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **s390_sthyi**() system call emulates the STHYI (Store Hypervisor Information) instruction. It provides hardware resource information for the machine and its virtualization levels. This includes CPU type and capacity, as well as the machine model and other metrics.

The *function_code* argument indicates which function to perform. The following code(s) are supported:

STHYI_FC_CP_IFL_CAP
: Return CP (Central Processor) and IFL (Integrated Facility for Linux) capacity information.

The *resp_buffer* argument specifies the address of a response buffer. When the *function_code* is **STHYI_FC_CP_IFL_CAP**, the buffer must be one page (4K) in size. If the system call returns 0, the response buffer will be filled with CPU capacity information. Otherwise, the response buffer's content is unchanged.

The *return_code* argument stores the return code of the STHYI instruction, using one of the following values:

Success.

4 Unsupported function code.

For further details about *return_code*, *function_code*, and *resp_buffer*, see the reference given in NOTES.

The *flags* argument is provided to allow for future extensions and currently must be set to 0.

RETURN VALUE

On success (that is: emulation succeeded), the return value of **s390_sthyi**() matches the condition code of the STHYI instructions, which is a value in the range [0..3]. A return value of 0 indicates that CPU capacity information is stored in **resp_buffer*. A return value of 3 indicates "unsupported function code" and the content of **resp_buffer* is unchanged. The return values 1 and 2 are reserved.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
: The value specified in *resp_buffer* or *return_code* is not a valid address.

EINVAL
: The value specified in *flags* is nonzero.

ENOMEM
: Allocating memory for handling the CPU capacity information failed.

EOPNOTSUPP
: The value specified in *function_code* is not valid.

STANDARDS

Linux on s390.

HISTORY

Linux 4.15.

NOTES

For details of the STHYI instruction, see the documentation page.

When the system call interface is used, the response buffer doesn't have to fulfill alignment requirements described in the STHYI instruction definition.

The kernel caches the response (for up to one second, as of Linux 4.16). Subsequent system call invocations may return the cached response.

SEE ALSO

syscall(2)

NAME

sched_get_priority_max, sched_get_priority_min − get static priority range

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sched.h>

int sched_get_priority_max(int policy);
int sched_get_priority_min(int policy);
```

DESCRIPTION

sched_get_priority_max() returns the maximum priority value that can be used with the scheduling algorithm identified by *policy*. **sched_get_priority_min**() returns the minimum priority value that can be used with the scheduling algorithm identified by *policy*. Supported *policy* values are **SCHED_FIFO**, **SCHED_RR**, **SCHED_OTHER**, **SCHED_BATCH**, **SCHED_IDLE**, and **SCHED_DEADLINE**. Further details about these policies can be found in *sched*(7).

Processes with numerically higher priority values are scheduled before processes with numerically lower priority values. Thus, the value returned by **sched_get_priority_max**() will be greater than the value returned by **sched_get_priority_min**().

Linux allows the static priority range 1 to 99 for the **SCHED_FIFO** and **SCHED_RR** policies, and the priority 0 for the remaining policies. Scheduling priority ranges for the various policies are not alterable.

The range of scheduling priorities may vary on other POSIX systems, thus it is a good idea for portable applications to use a virtual priority range and map it to the interval given by **sched_get_priority_max**() and **sched_get_priority_min**() POSIX.1 requires a spread of at least 32 between the maximum and the minimum values for **SCHED_FIFO** and **SCHED_RR**.

POSIX systems on which **sched_get_priority_max**() and **sched_get_priority_min**() are available define **_POSIX_PRIORITY_SCHEDULING** in <*unistd.h*>.

RETURN VALUE

On success, **sched_get_priority_max**() and **sched_get_priority_min**() return the maximum/minimum priority value for the named scheduling policy. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
: The argument *policy* does not identify a defined scheduling policy.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

sched_getaffinity(2), *sched_getparam*(2), *sched_getscheduler*(2), *sched_setaffinity*(2), *sched_setparam*(2), *sched_setscheduler*(2), *sched*(7)

NAME

sched_rr_get_interval − get the SCHED_RR interval for the named process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sched.h>

int sched_rr_get_interval(pid_t *pid***, struct timespec ****tp***);**

DESCRIPTION

sched_rr_get_interval() writes into the *timespec*(3) structure pointed to by *tp* the round-robin time quantum for the process identified by *pid*. The specified process should be running under the **SCHED_RR** scheduling policy.

If *pid* is zero, the time quantum for the calling process is written into **tp*.

RETURN VALUE

On success, **sched_rr_get_interval**() returns 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
Problem with copying information to user space.

EINVAL
Invalid pid.

ENOSYS
The system call is not yet implemented (only on rather old kernels).

ESRCH
Could not find a process with the ID *pid*.

VERSIONS

Linux

Linux 3.9 added a new mechanism for adjusting (and viewing) the **SCHED_RR** quantum: the */proc/sys/kernel/sched_rr_timeslice_ms* file exposes the quantum as a millisecond value, whose default is 100. Writing 0 to this file resets the quantum to the default value.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

Linux

POSIX does not specify any mechanism for controlling the size of the round-robin time quantum. Older Linux kernels provide a (nonportable) method of doing this. The quantum can be controlled by adjusting the process's nice value (see *setpriority*(2)). Assigning a negative (i.e., high) nice value results in a longer quantum; assigning a positive (i.e., low) nice value results in a shorter quantum. The default quantum is 0.1 seconds; the degree to which changing the nice value affects the quantum has varied somewhat across kernel versions. This method of adjusting the quantum was removed starting with Linux 2.6.24.

NOTES

POSIX systems on which **sched_rr_get_interval**() is available define **_POSIX_PRIORITY_SCHEDULING** in <*unistd.h*>.

SEE ALSO

timespec(3), *sched*(7)

NAME

sched_setaffinity, sched_getaffinity − set and get a thread's CPU affinity mask

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sched.h>

int sched_setaffinity(pid_t pid, size_t cpusetsize,
                      const cpu_set_t *mask);
int sched_getaffinity(pid_t pid, size_t cpusetsize,
                      cpu_set_t *mask);
```

DESCRIPTION

A thread's CPU affinity mask determines the set of CPUs on which it is eligible to run. On a multiprocessor system, setting the CPU affinity mask can be used to obtain performance benefits. For example, by dedicating one CPU to a particular thread (i.e., setting the affinity mask of that thread to specify a single CPU, and setting the affinity mask of all other threads to exclude that CPU), it is possible to ensure maximum execution speed for that thread. Restricting a thread to run on a single CPU also avoids the performance cost caused by the cache invalidation that occurs when a thread ceases to execute on one CPU and then recommences execution on a different CPU.

A CPU affinity mask is represented by the *cpu_set_t* structure, a "CPU set", pointed to by *mask*. A set of macros for manipulating CPU sets is described in *CPU_SET*(3).

sched_setaffinity() sets the CPU affinity mask of the thread whose ID is *pid* to the value specified by *mask*. If *pid* is zero, then the calling thread is used. The argument *cpusetsize* is the length (in bytes) of the data pointed to by *mask*. Normally this argument would be specified as *sizeof(cpu_set_t)*.

If the thread specified by *pid* is not currently running on one of the CPUs specified in *mask*, then that thread is migrated to one of the CPUs specified in *mask*.

sched_getaffinity() writes the affinity mask of the thread whose ID is *pid* into the *cpu_set_t* structure pointed to by *mask*. The *cpusetsize* argument specifies the size (in bytes) of *mask*. If *pid* is zero, then the mask of the calling thread is returned.

RETURN VALUE

On success, **sched_setaffinity**() and **sched_getaffinity**() return 0 (but see "C library/kernel differences" below, which notes that the underlying **sched_getaffinity**() differs in its return value). On failure, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
: A supplied memory address was invalid.

EINVAL
: The affinity bit mask *mask* contains no processors that are currently physically on the system and permitted to the thread according to any restrictions that may be imposed by *cpuset* cgroups or the "cpuset" mechanism described in *cpuset*(7).

EINVAL
: (**sched_getaffinity**() and, before Linux 2.6.9, *sched_setaffinity*()) *cpusetsize* is smaller than the size of the affinity mask used by the kernel.

EPERM
: (**sched_setaffinity**()) The calling thread does not have appropriate privileges. The caller needs an effective user ID equal to the real user ID or effective user ID of the thread identified by *pid*, or it must possess the **CAP_SYS_NICE** capability in the user namespace of the thread *pid*.

ESRCH
: The thread whose ID is *pid* could not be found.

STANDARDS

Linux.

HISTORY

Linux 2.5.8, glibc 2.3.

Initially, the glibc interfaces included a *cpusetsize* argument, typed as *unsigned int*. In glibc 2.3.3, the *cpusetsize* argument was removed, but was then restored in glibc 2.3.4, with type *size_t*.

NOTES

After a call to **sched_setaffinity**(), the set of CPUs on which the thread will actually run is the intersection of the set specified in the *mask* argument and the set of CPUs actually present on the system. The system may further restrict the set of CPUs on which the thread runs if the "cpuset" mechanism described in *cpuset*(7) is being used. These restrictions on the actual set of CPUs on which the thread will run are silently imposed by the kernel.

There are various ways of determining the number of CPUs available on the system, including: inspecting the contents of */proc/cpuinfo*; using *sysconf*(3) to obtain the values of the **_SC_NPROCESSORS_CONF** and **_SC_NPROCESSORS_ONLN** parameters; and inspecting the list of CPU directories under */sys/devices/system/cpu/*.

sched(7) has a description of the Linux scheduling scheme.

The affinity mask is a per-thread attribute that can be adjusted independently for each of the threads in a thread group. The value returned from a call to *gettid*(2) can be passed in the argument *pid*. Specifying *pid* as 0 will set the attribute for the calling thread, and passing the value returned from a call to *getpid*(2) will set the attribute for the main thread of the thread group. (If you are using the POSIX threads API, then use *pthread_setaffinity_np*(3) instead of *sched_setaffinity*().)

The *isolcpus* boot option can be used to isolate one or more CPUs at boot time, so that no processes are scheduled onto those CPUs. Following the use of this boot option, the only way to schedule processes onto the isolated CPUs is via **sched_setaffinity**() or the *cpuset*(7) mechanism. For further information, see the kernel source file *Documentation/admin−guide/kernel−parameters.txt*. As noted in that file, *isolcpus* is the preferred mechanism of isolating CPUs (versus the alternative of manually setting the CPU affinity of all processes on the system).

A child created via *fork*(2) inherits its parent's CPU affinity mask. The affinity mask is preserved across an *execve*(2).

C library/kernel differences

This manual page describes the glibc interface for the CPU affinity calls. The actual system call interface is slightly different, with the *mask* being typed as *unsigned long* *, reflecting the fact that the underlying implementation of CPU sets is a simple bit mask.

On success, the raw **sched_getaffinity**() system call returns the number of bytes placed copied into the *mask* buffer; this will be the minimum of *cpusetsize* and the size (in bytes) of the *cpumask_t* data type that is used internally by the kernel to represent the CPU set bit mask.

Handling systems with large CPU affinity masks

The underlying system calls (which represent CPU masks as bit masks of type *unsigned long* *) impose no restriction on the size of the CPU mask. However, the *cpu_set_t* data type used by glibc has a fixed size of 128 bytes, meaning that the maximum CPU number that can be represented is 1023. If the kernel CPU affinity mask is larger than 1024, then calls of the form:

```
sched_getaffinity(pid, sizeof(cpu_set_t), &mask);
```

fail with the error **EINVAL**, the error produced by the underlying system call for the case where the *mask* size specified in *cpusetsize* is smaller than the size of the affinity mask used by the kernel. (Depending on the system CPU topology, the kernel affinity mask can be substantially larger than the number of active CPUs in the system.)

When working on systems with large kernel CPU affinity masks, one must dynamically allocate the *mask* argument (see *CPU_ALLOC*(3)). Currently, the only way to do this is by probing for the size of the required mask using **sched_getaffinity**() calls with increasing mask sizes (until the call does not fail with the error **EINVAL**).

Be aware that *CPU_ALLOC*(3) may allocate a slightly larger CPU set than requested (because CPU sets are implemented as bit masks allocated in units of *sizeof(long)*). Consequently, **sched_getaffinity**() can set bits beyond the requested allocation size, because the kernel sees a few additional bits. Therefore, the caller should iterate over the bits in the returned set, counting those which are set, and

stop upon reaching the value returned by *CPU_COUNT*(3) (rather than iterating over the number of bits requested to be allocated).

EXAMPLES

The program below creates a child process. The parent and child then each assign themselves to a specified CPU and execute identical loops that consume some CPU time. Before terminating, the parent waits for the child to complete. The program takes three command-line arguments: the CPU number for the parent, the CPU number for the child, and the number of loop iterations that both processes should perform.

As the sample runs below demonstrate, the amount of real and CPU time consumed when running the program will depend on intra-core caching effects and whether the processes are using the same CPU.

We first employ *lscpu*(1) to determine that this (x86) system has two cores, each with two CPUs:

```
$ lscpu | egrep -i 'core.*:|socket'
Thread(s) per core:    2
Core(s) per socket:    2
Socket(s):             1
```

We then time the operation of the example program for three cases: both processes running on the same CPU; both processes running on different CPUs on the same core; and both processes running on different CPUs on different cores.

```
$ time -p ./a.out 0 0 100000000
real 14.75
user 3.02
sys 11.73
$ time -p ./a.out 0 1 100000000
real 11.52
user 3.98
sys 19.06
$ time -p ./a.out 0 3 100000000
real 7.89
user 3.29
sys 12.07
```

Program source

```
#define _GNU_SOURCE
#include <err.h>
#include <sched.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/wait.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int           parentCPU, childCPU;
    cpu_set_t     set;
    unsigned int  nloops;

    if (argc != 4) {
        fprintf(stderr, "Usage: %s parent-cpu child-cpu num-loops\n",
                argv[0]);
        exit(EXIT_FAILURE);
    }

    parentCPU = atoi(argv[1]);
    childCPU = atoi(argv[2]);
    nloops = atoi(argv[3]);
```

```
        CPU_ZERO(&set);

        switch (fork()) {
        case -1:            /* Error */
            err(EXIT_FAILURE, "fork");

        case 0:             /* Child */
            CPU_SET(childCPU, &set);

            if (sched_setaffinity(getpid(), sizeof(set), &set) == -1)
                err(EXIT_FAILURE, "sched_setaffinity");

            for (unsigned int j = 0; j < nloops; j++)
                getppid();

            exit(EXIT_SUCCESS);

        default:            /* Parent */
            CPU_SET(parentCPU, &set);

            if (sched_setaffinity(getpid(), sizeof(set), &set) == -1)
                err(EXIT_FAILURE, "sched_setaffinity");

            for (unsigned int j = 0; j < nloops; j++)
                getppid();

            wait(NULL);     /* Wait for child to terminate */
            exit(EXIT_SUCCESS);
        }
    }
```

NAME

sched_setattr, sched_getattr − set and get scheduling policy and attributes

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sched.h>          /* Definition of SCHED_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_sched_setattr, pid_t pid, struct sched_attr *attr,
        unsigned int flags);
int syscall(SYS_sched_getattr, pid_t pid, struct sched_attr *attr,
        unsigned int size, unsigned int flags);
```

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

sched_setattr()

The **sched_setattr**() system call sets the scheduling policy and associated attributes for the thread whose ID is specified in *pid*. If *pid* equals zero, the scheduling policy and attributes of the calling thread will be set.

Currently, Linux supports the following "normal" (i.e., non-real-time) scheduling policies as values that may be specified in *policy*:

SCHED_OTHER
: the standard round-robin time-sharing policy;

SCHED_BATCH
: for "batch" style execution of processes; and

SCHED_IDLE for running *very* low priority background jobs.

Various "real-time" policies are also supported, for special time-critical applications that need precise control over the way in which runnable threads are selected for execution. For the rules governing when a process may use these policies, see *sched*(7). The real-time policies that may be specified in *policy* are:

SCHED_FIFO a first-in, first-out policy; and

SCHED_RR a round-robin policy.

Linux also provides the following policy:

SCHED_DEADLINE
: a deadline scheduling policy; see *sched*(7) for details.

The *attr* argument is a pointer to a structure that defines the new scheduling policy and attributes for the specified thread. This structure has the following form:

```
struct sched_attr {
    u32 size;              /* Size of this structure */
    u32 sched_policy;      /* Policy (SCHED_*) */
    u64 sched_flags;       /* Flags */
    s32 sched_nice;        /* Nice value (SCHED_OTHER,
                              SCHED_BATCH) */
    u32 sched_priority;    /* Static priority (SCHED_FIFO,
                              SCHED_RR) */
    /* Remaining fields are for SCHED_DEADLINE */
    u64 sched_runtime;
    u64 sched_deadline;
    u64 sched_period;
};
```

The fields of the *sched_attr* structure are as follows:

size This field should be set to the size of the structure in bytes, as in *sizeof(struct sched_attr)*. If the provided structure is smaller than the kernel structure, any additional fields are assumed to be '0'. If the provided structure is larger than the kernel structure, the kernel verifies that all additional fields are 0; if they are not, **sched_setattr**() fails with the error **E2BIG** and updates *size* to contain the size of the kernel structure.

The above behavior when the size of the user-space *sched_attr* structure does not match the size of the kernel structure allows for future extensibility of the interface. Malformed applications that pass oversize structures won't break in the future if the size of the kernel *sched_attr* structure is increased. In the future, it could also allow applications that know about a larger user-space *sched_attr* structure to determine whether they are running on an older kernel that does not support the larger structure.

sched_policy
This field specifies the scheduling policy, as one of the **SCHED_*** values listed above.

sched_flags
This field contains zero or more of the following flags that are ORed together to control scheduling behavior:

SCHED_FLAG_RESET_ON_FORK
Children created by *fork*(2) do not inherit privileged scheduling policies. See *sched*(7) for details.

SCHED_FLAG_RECLAIM (since Linux 4.13)
This flag allows a **SCHED_DEADLINE** thread to reclaim bandwidth unused by other real-time threads.

SCHED_FLAG_DL_OVERRUN (since Linux 4.16)
This flag allows an application to get informed about run-time overruns in **SCHED_DEADLINE** threads. Such overruns may be caused by (for example) coarse execution time accounting or incorrect parameter assignment. Notification takes the form of a **SIGXCPU** signal which is generated on each overrun.

This **SIGXCPU** signal is *process-directed* (see *signal*(7)) rather than thread-directed. This is probably a bug. On the one hand, **sched_setattr**() is being used to set a per-thread attribute. On the other hand, if the process-directed signal is delivered to a thread inside the process other than the one that had a run-time overrun, the application has no way of knowing which thread overran.

sched_nice
This field specifies the nice value to be set when specifying *sched_policy* as **SCHED_OTHER** or **SCHED_BATCH**. The nice value is a number in the range −20 (high priority) to +19 (low priority); see *sched*(7).

sched_priority
This field specifies the static priority to be set when specifying *sched_policy* as **SCHED_FIFO** or **SCHED_RR**. The allowed range of priorities for these policies can be determined using *sched_get_priority_min*(2) and *sched_get_priority_max*(2). For other policies, this field must be specified as 0.

sched_runtime
This field specifies the "Runtime" parameter for deadline scheduling. The value is expressed in nanoseconds. This field, and the next two fields, are used only for **SCHED_DEADLINE** scheduling; for further details, see *sched*(7).

sched_deadline
This field specifies the "Deadline" parameter for deadline scheduling. The value is expressed in nanoseconds.

sched_period
This field specifies the "Period" parameter for deadline scheduling. The value is expressed in nanoseconds.

The *flags* argument is provided to allow for future extensions to the interface; in the current implementation it must be specified as 0.

sched_getattr()

The **sched_getattr**() system call fetches the scheduling policy and the associated attributes for the thread whose ID is specified in *pid*. If *pid* equals zero, the scheduling policy and attributes of the calling thread will be retrieved.

The *size* argument should be set to the size of the *sched_attr* structure as known to user space. The value must be at least as large as the size of the initially published *sched_attr* structure, or the call fails with the error **EINVAL**.

The retrieved scheduling attributes are placed in the fields of the *sched_attr* structure pointed to by *attr*. The kernel sets *attr.size* to the size of its *sched_attr* structure.

If the caller-provided *attr* buffer is larger than the kernel's *sched_attr* structure, the additional bytes in the user-space structure are not touched. If the caller-provided structure is smaller than the kernel *sched_attr* structure, the kernel will silently not return any values which would be stored outside the provided space. As with **sched_setattr**(), these semantics allow for future extensibility of the interface.

The *flags* argument is provided to allow for future extensions to the interface; in the current implementation it must be specified as 0.

RETURN VALUE

On success, **sched_setattr**() and **sched_getattr**() return 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

sched_getattr() and **sched_setattr**() can both fail for the following reasons:

EINVAL
attr is NULL; or *pid* is negative; or *flags* is not zero.

ESRCH
The thread whose ID is *pid* could not be found.

In addition, **sched_getattr**() can fail for the following reasons:

E2BIG The buffer specified by *size* and *attr* is too small.

EINVAL
size is invalid; that is, it is smaller than the initial version of the *sched_attr* structure (48 bytes) or larger than the system page size.

In addition, **sched_setattr**() can fail for the following reasons:

E2BIG The buffer specified by *size* and *attr* is larger than the kernel structure, and one or more of the excess bytes is nonzero.

EBUSY
SCHED_DEADLINE admission control failure, see *sched*(7).

EINVAL
attr.sched_policy is not one of the recognized policies; *attr.sched_flags* contains a flag other than **SCHED_FLAG_RESET_ON_FORK**; or *attr.sched_priority* is invalid; or *attr.sched_policy* is **SCHED_DEADLINE** and the deadline scheduling parameters in *attr* are invalid.

EPERM
The caller does not have appropriate privileges.

EPERM
The CPU affinity mask of the thread specified by *pid* does not include all CPUs in the system (see *sched_setaffinity*(2)).

STANDARDS

Linux.

HISTORY

Linux 3.14.

NOTES

glibc does not provide wrappers for these system calls; call them using *syscall*(2).

sched_setattr() provides a superset of the functionality of *sched_setscheduler*(2), *sched_setparam*(2), *nice*(2), and (other than the ability to set the priority of all processes belonging to a specified user or all processes in a specified group) *setpriority*(2). Analogously, **sched_getattr**() provides a superset of the functionality of *sched_getscheduler*(2), *sched_getparam*(2), and (partially) *getpriority*(2).

BUGS

In Linux versions up to 3.15, **sched_setattr**() failed with the error **EFAULT** instead of **E2BIG** for the case described in ERRORS.

Up to Linux 5.3, **sched_getattr**() failed with the error **EFBIG** if the in-kernel *sched_attr* structure was larger than the *size* passed by user space.

NAME

sched_setparam, sched_getparam − set and get scheduling parameters

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sched.h>

int sched_setparam(pid_t pid, const struct sched_param *param);
int sched_getparam(pid_t pid, struct sched_param *param);

struct sched_param {
    ...
    int sched_priority;
    ...
};
```

DESCRIPTION

sched_setparam() sets the scheduling parameters associated with the scheduling policy for the thread whose thread ID is specified in *pid*. If *pid* is zero, then the parameters of the calling thread are set. The interpretation of the argument *param* depends on the scheduling policy of the thread identified by *pid*. See *sched*(7) for a description of the scheduling policies supported under Linux.

sched_getparam() retrieves the scheduling parameters for the thread identified by *pid*. If *pid* is zero, then the parameters of the calling thread are retrieved.

sched_setparam() checks the validity of *param* for the scheduling policy of the thread. The value *param−>sched_priority* must lie within the range given by *sched_get_priority_min*(2) and *sched_get_priority_max*(2).

For a discussion of the privileges and resource limits related to scheduling priority and policy, see *sched*(7).

POSIX systems on which **sched_setparam**() and **sched_getparam**() are available define **_POSIX_PRIORITY_SCHEDULING** in *<unistd.h>*.

RETURN VALUE

On success, **sched_setparam**() and **sched_getparam**() return 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL
: Invalid arguments: *param* is NULL or *pid* is negative

EINVAL
: (**sched_setparam**()) The argument *param* does not make sense for the current scheduling policy.

EPERM
: (**sched_setparam**()) The caller does not have appropriate privileges (Linux: does not have the **CAP_SYS_NICE** capability).

ESRCH
: The thread whose ID is *pid* could not be found.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

SEE ALSO

getpriority(2), *gettid*(2), *nice*(2), *sched_get_priority_max*(2), *sched_get_priority_min*(2), *sched_getaffinity*(2), *sched_getscheduler*(2), *sched_setaffinity*(2), *sched_setattr*(2), *sched_setscheduler*(2), *setpriority*(2), *capabilities*(7), *sched*(7)

NAME

sched_setscheduler, sched_getscheduler − set and get scheduling policy/parameters

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sched.h>

int sched_setscheduler(pid_t pid, int policy,
                       const struct sched_param *param);
int sched_getscheduler(pid_t pid);
```

DESCRIPTION

The **sched_setscheduler**() system call sets both the scheduling policy and parameters for the thread whose ID is specified in *pid*. If *pid* equals zero, the scheduling policy and parameters of the calling thread will be set.

The scheduling parameters are specified in the *param* argument, which is a pointer to a structure of the following form:

```
struct sched_param {
    ...
    int sched_priority;
    ...
};
```

In the current implementation, the structure contains only one field, *sched_priority*. The interpretation of *param* depends on the selected policy.

Currently, Linux supports the following "normal" (i.e., non-real-time) scheduling policies as values that may be specified in *policy*:

SCHED_OTHER
the standard round-robin time-sharing policy;

SCHED_BATCH
for "batch" style execution of processes; and

SCHED_IDLE for running *very* low priority background jobs.

For each of the above policies, *param−>sched_priority* must be 0.

Various "real-time" policies are also supported, for special time-critical applications that need precise control over the way in which runnable threads are selected for execution. For the rules governing when a process may use these policies, see *sched*(7). The real-time policies that may be specified in *policy* are:

SCHED_FIFO a first-in, first-out policy; and

SCHED_RR a round-robin policy.

For each of the above policies, *param−>sched_priority* specifies a scheduling priority for the thread. This is a number in the range returned by calling *sched_get_priority_min*(2) and *sched_get_priority_max*(2) with the specified *policy*. On Linux, these system calls return, respectively, 1 and 99.

Since Linux 2.6.32, the **SCHED_RESET_ON_FORK** flag can be ORed in *policy* when calling **sched_setscheduler**(). As a result of including this flag, children created by *fork*(2) do not inherit privileged scheduling policies. See *sched*(7) for details.

sched_getscheduler() returns the current scheduling policy of the thread identified by *pid*. If *pid* equals zero, the policy of the calling thread will be retrieved.

RETURN VALUE

On success, **sched_setscheduler**() returns zero. On success, **sched_getscheduler**() returns the policy for the thread (a nonnegative integer). On error, both calls return −1, and *errno* is set to indicate the error.

ERRORS

EINVAL
Invalid arguments: *pid* is negative or *param* is NULL.

EINVAL
(**sched_setscheduler**()) *policy* is not one of the recognized policies.

EINVAL
(**sched_setscheduler**()) *param* does not make sense for the specified *policy*.

EPERM
The calling thread does not have appropriate privileges.

ESRCH
The thread whose ID is *pid* could not be found.

VERSIONS

POSIX.1 does not detail the permissions that an unprivileged thread requires in order to call **sched_setscheduler**(), and details vary across systems. For example, the Solaris 7 manual page says that the real or effective user ID of the caller must match the real user ID or the save set-user-ID of the target.

The scheduling policy and parameters are in fact per-thread attributes on Linux. The value returned from a call to *gettid*(2) can be passed in the argument *pid*. Specifying *pid* as 0 will operate on the attributes of the calling thread, and passing the value returned from a call to *getpid*(2) will operate on the attributes of the main thread of the thread group. (If you are using the POSIX threads API, then use *pthread_setschedparam*(3), *pthread_getschedparam*(3), and *pthread_setschedprio*(3), instead of the **sched_***(2) system calls.)

STANDARDS

POSIX.1-2008 (but see BUGS below).

SCHED_BATCH and **SCHED_IDLE** are Linux-specific.

HISTORY

POSIX.1-2001.

NOTES

Further details of the semantics of all of the above "normal" and "real-time" scheduling policies can be found in the *sched*(7) manual page. That page also describes an additional policy, **SCHED_DEADLINE**, which is settable only via *sched_setattr*(2).

POSIX systems on which **sched_setscheduler**() and **sched_getscheduler**() are available define **_POSIX_PRIORITY_SCHEDULING** in <*unistd.h*>.

BUGS

POSIX.1 says that on success, **sched_setscheduler**() should return the previous scheduling policy. Linux **sched_setscheduler**() does not conform to this requirement, since it always returns 0 on success.

SEE ALSO

chrt(1), *nice*(2), *sched_get_priority_max*(2), *sched_get_priority_min*(2), *sched_getaffinity*(2), *sched_getattr*(2), *sched_getparam*(2), *sched_rr_get_interval*(2), *sched_setaffinity*(2), *sched_setattr*(2), *sched_setparam*(2), *sched_yield*(2), *setpriority*(2), *capabilities*(7), *cpuset*(7), *sched*(7)

NAME

sched_yield − yield the processor

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sched.h>

int sched_yield(void);

DESCRIPTION

sched_yield() causes the calling thread to relinquish the CPU. The thread is moved to the end of the queue for its static priority and a new thread gets to run.

RETURN VALUE

On success, **sched_yield**() returns 0. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

In the Linux implementation, **sched_yield**() always succeeds.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001 (but optional). POSIX.1-2008.

Before POSIX.1-2008, systems on which **sched_yield**() is available defined **_POSIX_PRIORITY_SCHEDULING** in *<unistd.h>*.

CAVEATS

sched_yield() is intended for use with real-time scheduling policies (i.e., **SCHED_FIFO** or **SCHED_RR**). Use of **sched_yield**() with nondeterministic scheduling policies such as **SCHED_OTHER** is unspecified and very likely means your application design is broken.

If the calling thread is the only thread in the highest priority list at that time, it will continue to run after a call to **sched_yield**().

Avoid calling **sched_yield**() unnecessarily or inappropriately (e.g., when resources needed by other schedulable threads are still held by the caller), since doing so will result in unnecessary context switches, which will degrade system performance.

sched(7)

NAME

seccomp − operate on Secure Computing state of the process

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/seccomp.h>  /* Definition of SECCOMP_* constants */
#include <linux/filter.h>   /* Definition of struct sock_fprog */
#include <linux/audit.h>    /* Definition of AUDIT_* constants */
#include <linux/signal.h>   /* Definition of SIG* constants */
#include <sys/ptrace.h>     /* Definition of PTRACE_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_seccomp, unsigned int operation, unsigned int flags,
        void *args);
```

Note: glibc provides no wrapper for **seccomp**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **seccomp**() system call operates on the Secure Computing (seccomp) state of the calling process.

Currently, Linux supports the following *operation* values:

SECCOMP_SET_MODE_STRICT

The only system calls that the calling thread is permitted to make are *read*(2), *write*(2), *_exit*(2) (but not *exit_group*(2)), and *sigreturn*(2). Other system calls result in the termination of the calling thread, or termination of the entire process with the **SIGKILL** signal when there is only one thread. Strict secure computing mode is useful for number-crunching applications that may need to execute untrusted byte code, perhaps obtained by reading from a pipe or socket.

Note that although the calling thread can no longer call *sigprocmask*(2), it can use *sigreturn*(2) to block all signals apart from **SIGKILL** and **SIGSTOP**. This means that *alarm*(2) (for example) is not sufficient for restricting the process's execution time. Instead, to reliably terminate the process, **SIGKILL** must be used. This can be done by using *timer_create*(2) with **SIGEV_SIGNAL** and *sigev_signo* set to **SIGKILL**, or by using *setrlimit*(2) to set the hard limit for **RLIMIT_CPU**.

This operation is available only if the kernel is configured with **CONFIG_SECCOMP** enabled.

The value of *flags* must be 0, and *args* must be NULL.

This operation is functionally identical to the call:

```
prctl(PR_SET_SECCOMP, SECCOMP_MODE_STRICT);
```

SECCOMP_SET_MODE_FILTER

The system calls allowed are defined by a pointer to a Berkeley Packet Filter (BPF) passed via *args*. This argument is a pointer to a *struct sock_fprog*; it can be designed to filter arbitrary system calls and system call arguments. If the filter is invalid, **seccomp**() fails, returning **EINVAL** in *errno*.

If *fork*(2) or *clone*(2) is allowed by the filter, any child processes will be constrained to the same system call filters as the parent. If *execve*(2) is allowed, the existing filters will be preserved across a call to *execve*(2).

In order to use the **SECCOMP_SET_MODE_FILTER** operation, either the calling thread must have the **CAP_SYS_ADMIN** capability in its user namespace, or the thread must already have the *no_new_privs* bit set. If that bit was not already set by an ancestor of this thread, the thread must make the following call:

```
prctl(PR_SET_NO_NEW_PRIVS, 1);
```

Otherwise, the **SECCOMP_SET_MODE_FILTER** operation fails and returns **EACCES** in *errno*. This requirement ensures that an unprivileged process cannot apply a malicious filter and then invoke a set-user-ID or other privileged program using *execve*(2), thus potentially

compromising that program. (Such a malicious filter might, for example, cause an attempt to use *setuid*(2) to set the caller's user IDs to nonzero values to instead return 0 without actually making the system call. Thus, the program might be tricked into retaining superuser privileges in circumstances where it is possible to influence it to do dangerous things because it did not actually drop privileges.)

If *prctl*(2) or **seccomp**() is allowed by the attached filter, further filters may be added. This will increase evaluation time, but allows for further reduction of the attack surface during execution of a thread.

The **SECCOMP_SET_MODE_FILTER** operation is available only if the kernel is configured with **CONFIG_SECCOMP_FILTER** enabled.

When *flags* is 0, this operation is functionally identical to the call:

```
prctl(PR_SET_SECCOMP, SECCOMP_MODE_FILTER, args);
```

The recognized *flags* are:

SECCOMP_FILTER_FLAG_LOG (since Linux 4.14)
All filter return actions except **SECCOMP_RET_ALLOW** should be logged. An administrator may override this filter flag by preventing specific actions from being logged via the */proc/sys/kernel/seccomp/actions_logged* file.

SECCOMP_FILTER_FLAG_NEW_LISTENER (since Linux 5.0)
After successfully installing the filter program, return a new user-space notification file descriptor. (The close-on-exec flag is set for the file descriptor.) When the filter returns **SECCOMP_RET_USER_NOTIF** a notification will be sent to this file descriptor.

At most one seccomp filter using the **SECCOMP_FILTER_FLAG_NEW_LISTENER** flag can be installed for a thread.

See *seccomp_unotify*(2) for further details.

SECCOMP_FILTER_FLAG_SPEC_ALLOW (since Linux 4.17)
Disable Speculative Store Bypass mitigation.

SECCOMP_FILTER_FLAG_TSYNC
When adding a new filter, synchronize all other threads of the calling process to the same seccomp filter tree. A "filter tree" is the ordered list of filters attached to a thread. (Attaching identical filters in separate **seccomp**() calls results in different filters from this perspective.)

If any thread cannot synchronize to the same filter tree, the call will not attach the new seccomp filter, and will fail, returning the first thread ID found that cannot synchronize. Synchronization will fail if another thread in the same process is in **SECCOMP_MODE_STRICT** or if it has attached new seccomp filters to itself, diverging from the calling thread's filter tree.

SECCOMP_GET_ACTION_AVAIL (since Linux 4.14)
Test to see if an action is supported by the kernel. This operation is helpful to confirm that the kernel knows of a more recently added filter return action since the kernel treats all unknown actions as **SECCOMP_RET_KILL_PROCESS**.

The value of *flags* must be 0, and *args* must be a pointer to an unsigned 32-bit filter return action.

SECCOMP_GET_NOTIF_SIZES (since Linux 5.0)
Get the sizes of the seccomp user-space notification structures. Since these structures may evolve and grow over time, this command can be used to determine how much memory to allocate for sending and receiving notifications.

The value of *flags* must be 0, and *args* must be a pointer to a *struct seccomp_notif_sizes*, which has the following form:

```
struct seccomp_notif_sizes
    __u16 seccomp_notif;      /* Size of notification structure */
    __u16 seccomp_notif_resp; /* Size of response structure */
```

```
        __u16 seccomp_data;       /* Size of 'struct seccomp_data' */
    };
```

See *seccomp_unotify*(2) for further details.

Filters

When adding filters via **SECCOMP_SET_MODE_FILTER**, *args* points to a filter program:

```
struct sock_fprog {
    unsigned short      len;    /* Number of BPF instructions */
    struct sock_filter *filter; /* Pointer to array of
                                   BPF instructions */
};
```

Each program must contain one or more BPF instructions:

```
struct sock_filter {            /* Filter block */
    __u16 code;                 /* Actual filter code */
    __u8  jt;                   /* Jump true */
    __u8  jf;                   /* Jump false */
    __u32 k;                    /* Generic multiuse field */
};
```

When executing the instructions, the BPF program operates on the system call information made available (i.e., use the **BPF_ABS** addressing mode) as a (read-only) buffer of the following form:

```
struct seccomp_data {
    int   nr;                   /* System call number */
    __u32 arch;                 /* AUDIT_ARCH_* value
                                   (see <linux/audit.h>) */
    __u64 instruction_pointer;  /* CPU instruction pointer */
    __u64 args[6];              /* Up to 6 system call arguments */
};
```

Because numbering of system calls varies between architectures and some architectures (e.g., x86-64) allow user-space code to use the calling conventions of multiple architectures (and the convention being used may vary over the life of a process that uses *execve*(2) to execute binaries that employ the different conventions), it is usually necessary to verify the value of the *arch* field.

It is strongly recommended to use an allow-list approach whenever possible because such an approach is more robust and simple. A deny-list will have to be updated whenever a potentially dangerous system call is added (or a dangerous flag or option if those are deny-listed), and it is often possible to alter the representation of a value without altering its meaning, leading to a deny-list bypass. See also *Caveats* below.

The *arch* field is not unique for all calling conventions. The x86-64 ABI and the x32 ABI both use **AUDIT_ARCH_X86_64** as *arch*, and they run on the same processors. Instead, the mask **__X32_SYSCALL_BIT** is used on the system call number to tell the two ABIs apart.

This means that a policy must either deny all syscalls with **__X32_SYSCALL_BIT** or it must recognize syscalls with and without **__X32_SYSCALL_BIT** set. A list of system calls to be denied based on *nr* that does not also contain *nr* values with **__X32_SYSCALL_BIT** set can be bypassed by a malicious program that sets **__X32_SYSCALL_BIT**.

Additionally, kernels prior to Linux 5.4 incorrectly permitted *nr* in the ranges 512-547 as well as the corresponding non-x32 syscalls ORed with **__X32_SYSCALL_BIT**. For example, *nr* == 521 and *nr* == (101 | **__X32_SYSCALL_BIT**) would result in invocations of *ptrace*(2) with potentially confused x32-vs-x86_64 semantics in the kernel. Policies intended to work on kernels before Linux 5.4 must ensure that they deny or otherwise correctly handle these system calls. On Linux 5.4 and newer, such system calls will fail with the error **ENOSYS**, without doing anything.

The *instruction_pointer* field provides the address of the machine-language instruction that performed the system call. This might be useful in conjunction with the use of */proc/*pid*/maps* to perform checks based on which region (mapping) of the program made the system call. (Probably, it is wise to lock down the *mmap*(2) and *mprotect*(2) system calls to prevent the program from subverting such checks.)

When checking values from *args*, keep in mind that arguments are often silently truncated before being

processed, but after the seccomp check. For example, this happens if the i386 ABI is used on an x86-64 kernel: although the kernel will normally not look beyond the 32 lowest bits of the arguments, the values of the full 64-bit registers will be present in the seccomp data. A less surprising example is that if the x86-64 ABI is used to perform a system call that takes an argument of type *int*, the more-significant half of the argument register is ignored by the system call, but visible in the seccomp data.

A seccomp filter returns a 32-bit value consisting of two parts: the most significant 16 bits (corresponding to the mask defined by the constant **SECCOMP_RET_ACTION_FULL**) contain one of the "action" values listed below; the least significant 16-bits (defined by the constant **SECCOMP_RET_DATA**) are "data" to be associated with this return value.

If multiple filters exist, they are *all* executed, in reverse order of their addition to the filter tree—that is, the most recently installed filter is executed first. (Note that all filters will be called even if one of the earlier filters returns **SECCOMP_RET_KILL**. This is done to simplify the kernel code and to provide a tiny speed-up in the execution of sets of filters by avoiding a check for this uncommon case.) The return value for the evaluation of a given system call is the first-seen action value of highest precedence (along with its accompanying data) returned by execution of all of the filters.

In decreasing order of precedence, the action values that may be returned by a seccomp filter are:

SECCOMP_RET_KILL_PROCESS (since Linux 4.14)
: This value results in immediate termination of the process, with a core dump. The system call is not executed. By contrast with **SECCOMP_RET_KILL_THREAD** below, all threads in the thread group are terminated. (For a discussion of thread groups, see the description of the **CLONE_THREAD** flag in *clone*(2).)

  The process terminates *as though* killed by a **SIGSYS** signal. Even if a signal handler has been registered for **SIGSYS**, the handler will be ignored in this case and the process always terminates. To a parent process that is waiting on this process (using *waitpid*(2) or similar), the returned *wstatus* will indicate that its child was terminated as though by a **SIGSYS** signal.

SECCOMP_RET_KILL_THREAD (or **SECCOMP_RET_KILL**)
: This value results in immediate termination of the thread that made the system call. The system call is not executed. Other threads in the same thread group will continue to execute.

  The thread terminates *as though* killed by a **SIGSYS** signal. See **SECCOMP_RET_KILL_PROCESS** above.

  Before Linux 4.11, any process terminated in this way would not trigger a coredump (even though **SIGSYS** is documented in *signal*(7) as having a default action of termination with a core dump). Since Linux 4.11, a single-threaded process will dump core if terminated in this way.

  With the addition of **SECCOMP_RET_KILL_PROCESS** in Linux 4.14, **SECCOMP_RET_KILL_THREAD** was added as a synonym for **SECCOMP_RET_KILL**, in order to more clearly distinguish the two actions.

  Note: the use of **SECCOMP_RET_KILL_THREAD** to kill a single thread in a multi-threaded process is likely to leave the process in a permanently inconsistent and possibly corrupt state.

SECCOMP_RET_TRAP
: This value results in the kernel sending a thread-directed **SIGSYS** signal to the triggering thread. (The system call is not executed.) Various fields will be set in the *siginfo_t* structure (see *sigaction*(2)) associated with signal:

  - *si_signo* will contain **SIGSYS**.
  - *si_call_addr* will show the address of the system call instruction.
  - *si_syscall* and *si_arch* will indicate which system call was attempted.
  - *si_code* will contain **SYS_SECCOMP**.
  - *si_errno* will contain the **SECCOMP_RET_DATA** portion of the filter return value.

  The program counter will be as though the system call happened (i.e., the program counter will not point to the system call instruction). The return value register will contain an architecture−dependent value; if resuming execution, set it to something appropriate for the system

call. (The architecture dependency is because replacing it with **ENOSYS** could overwrite some useful information.)

SECCOMP_RET_ERRNO
This value results in the **SECCOMP_RET_DATA** portion of the filter's return value being passed to user space as the *errno* value without executing the system call.

SECCOMP_RET_USER_NOTIF (since Linux 5.0)
Forward the system call to an attached user-space supervisor process to allow that process to decide what to do with the system call. If there is no attached supervisor (either because the filter was not installed with the **SECCOMP_FILTER_FLAG_NEW_LISTENER** flag or because the file descriptor was closed), the filter returns **ENOSYS** (similar to what happens when a filter returns **SECCOMP_RET_TRACE** and there is no tracer). See *seccomp_unotify*(2) for further details.

Note that the supervisor process will not be notified if another filter returns an action value with a precedence greater than **SECCOMP_RET_USER_NOTIF**.

SECCOMP_RET_TRACE
When returned, this value will cause the kernel to attempt to notify a *ptrace*(2)-based tracer prior to executing the system call. If there is no tracer present, the system call is not executed and returns a failure status with *errno* set to **ENOSYS**.

A tracer will be notified if it requests **PTRACE_O_TRACESECCOMP** using *ptrace(PTRACE_SETOPTIONS)*. The tracer will be notified of a **PTRACE_EVENT_SECCOMP** and the **SECCOMP_RET_DATA** portion of the filter's return value will be available to the tracer via **PTRACE_GETEVENTMSG**.

The tracer can skip the system call by changing the system call number to −1. Alternatively, the tracer can change the system call requested by changing the system call to a valid system call number. If the tracer asks to skip the system call, then the system call will appear to return the value that the tracer puts in the return value register.

Before Linux 4.8, the seccomp check will not be run again after the tracer is notified. (This means that, on older kernels, seccomp-based sandboxes **must not** allow use of *ptrace*(2)—even of other sandboxed processes—without extreme care; ptracers can use this mechanism to escape from the seccomp sandbox.)

Note that a tracer process will not be notified if another filter returns an action value with a precedence greater than **SECCOMP_RET_TRACE**.

SECCOMP_RET_LOG (since Linux 4.14)
This value results in the system call being executed after the filter return action is logged. An administrator may override the logging of this action via the */proc/sys/kernel/seccomp/actions_logged* file.

SECCOMP_RET_ALLOW
This value results in the system call being executed.

If an action value other than one of the above is specified, then the filter action is treated as either **SECCOMP_RET_KILL_PROCESS** (since Linux 4.14) or **SECCOMP_RET_KILL_THREAD** (in Linux 4.13 and earlier).

/proc interfaces
The files in the directory */proc/sys/kernel/seccomp* provide additional seccomp information and configuration:

actions_avail (since Linux 4.14)
A read-only ordered list of seccomp filter return actions in string form. The ordering, from left-to-right, is in decreasing order of precedence. The list represents the set of seccomp filter return actions supported by the kernel.

actions_logged (since Linux 4.14)
A read-write ordered list of seccomp filter return actions that are allowed to be logged. Writes to the file do not need to be in ordered form but reads from the file will be ordered in the same way as the *actions_avail* file.

It is important to note that the value of *actions_logged* does not prevent certain filter return actions from being logged when the audit subsystem is configured to audit a task. If the action is not found in the *actions_logged* file, the final decision on whether to audit the action for that task is ultimately left up to the audit subsystem to decide for all filter return actions other than **SECCOMP_RET_ALLOW**.

The "allow" string is not accepted in the *actions_logged* file as it is not possible to log **SECCOMP_RET_ALLOW** actions. Attempting to write "allow" to the file will fail with the error **EINVAL**.

Audit logging of seccomp actions

Since Linux 4.14, the kernel provides the facility to log the actions returned by seccomp filters in the audit log. The kernel makes the decision to log an action based on the action type, whether or not the action is present in the *actions_logged* file, and whether kernel auditing is enabled (e.g., via the kernel boot option *audit=1*). The rules are as follows:

- If the action is **SECCOMP_RET_ALLOW**, the action is not logged.
- Otherwise, if the action is either **SECCOMP_RET_KILL_PROCESS** or **SECCOMP_RET_KILL_THREAD**, and that action appears in the *actions_logged* file, the action is logged.
- Otherwise, if the filter has requested logging (the **SECCOMP_FILTER_FLAG_LOG** flag) and the action appears in the *actions_logged* file, the action is logged.
- Otherwise, if kernel auditing is enabled and the process is being audited (**autrace**(8)), the action is logged.
- Otherwise, the action is not logged.

RETURN VALUE

On success, **seccomp**() returns 0. On error, if **SECCOMP_FILTER_FLAG_TSYNC** was used, the return value is the ID of the thread that caused the synchronization failure. (This ID is a kernel thread ID of the type returned by *clone*(2) and *gettid*(2).) On other errors, −1 is returned, and *errno* is set to indicate the error.

ERRORS

seccomp() can fail for the following reasons:

EACCES
The caller did not have the **CAP_SYS_ADMIN** capability in its user namespace, or had not set *no_new_privs* before using **SECCOMP_SET_MODE_FILTER**.

EBUSY
While installing a new filter, the **SECCOMP_FILTER_FLAG_NEW_LISTENER** flag was specified, but a previous filter had already been installed with that flag.

EFAULT
args was not a valid address.

EINVAL
operation is unknown or is not supported by this kernel version or configuration.

EINVAL
The specified *flags* are invalid for the given *operation*.

EINVAL
operation included **BPF_ABS**, but the specified offset was not aligned to a 32-bit boundary or exceeded *sizeof(struct seccomp_data)*.

EINVAL
A secure computing mode has already been set, and *operation* differs from the existing setting.

EINVAL
operation specified **SECCOMP_SET_MODE_FILTER**, but the filter program pointed to by *args* was not valid or the length of the filter program was zero or exceeded **BPF_MAXINSNS** (4096) instructions.

ENOMEM
Out of memory.

ENOMEM
The total length of all filter programs attached to the calling thread would exceed **MAX_INSNS_PER_PATH** (32768) instructions. Note that for the purposes of calculating this limit, each already existing filter program incurs an overhead penalty of 4 instructions.

EOPNOTSUPP
operation specified **SECCOMP_GET_ACTION_AVAIL**, but the kernel does not support the filter return action specified by *args*.

ESRCH
Another thread caused a failure during thread sync, but its ID could not be determined.

STANDARDS
Linux.

HISTORY
Linux 3.17.

NOTES
Rather than hand-coding seccomp filters as shown in the example below, you may prefer to employ the *libseccomp* library, which provides a front-end for generating seccomp filters.

The *Seccomp* field of the */proc/*pid*/status* file provides a method of viewing the seccomp mode of a process; see *proc*(5).

seccomp() provides a superset of the functionality provided by the *prctl*(2) **PR_SET_SECCOMP** operation (which does not support *flags*).

Since Linux 4.4, the *ptrace*(2) **PTRACE_SECCOMP_GET_FILTER** operation can be used to dump a process's seccomp filters.

Architecture support for seccomp BPF
Architecture support for seccomp BPF filtering is available on the following architectures:

- x86-64, i386, x32 (since Linux 3.5)
- ARM (since Linux 3.8)
- s390 (since Linux 3.8)
- MIPS (since Linux 3.16)
- ARM-64 (since Linux 3.19)
- PowerPC (since Linux 4.3)
- Tile (since Linux 4.3)
- PA-RISC (since Linux 4.6)

Caveats
There are various subtleties to consider when applying seccomp filters to a program, including the following:

- Some traditional system calls have user-space implementations in the *vdso*(7) on many architectures. Notable examples include *clock_gettime*(2), *gettimeofday*(2), and *time*(2). On such architectures, seccomp filtering for these system calls will have no effect. (However, there are cases where the *vdso*(7) implementations may fall back to invoking the true system call, in which case seccomp filters would see the system call.)
- Seccomp filtering is based on system call numbers. However, applications typically do not directly invoke system calls, but instead call wrapper functions in the C library which in turn invoke the system calls. Consequently, one must be aware of the following:
  - The glibc wrappers for some traditional system calls may actually employ system calls with different names in the kernel. For example, the *exit*(2) wrapper function actually employs the *exit_group*(2) system call, and the *fork*(2) wrapper function actually calls *clone*(2).
  - The behavior of wrapper functions may vary across architectures, according to the range of system calls provided on those architectures. In other words, the same wrapper function may invoke different system calls on different architectures.

- Finally, the behavior of wrapper functions can change across glibc versions. For example, in older versions, the glibc wrapper function for *open*(2) invoked the system call of the same name, but starting in glibc 2.26, the implementation switched to calling *openat*(2) on all architectures.

The consequence of the above points is that it may be necessary to filter for a system call other than might be expected. Various manual pages in Section 2 provide helpful details about the differences between wrapper functions and the underlying system calls in subsections entitled *C library/kernel differences*.

Furthermore, note that the application of seccomp filters even risks causing bugs in an application, when the filters cause unexpected failures for legitimate operations that the application might need to perform. Such bugs may not easily be discovered when testing the seccomp filters if the bugs occur in rarely used application code paths.

Seccomp-specific BPF details

Note the following BPF details specific to seccomp filters:

- The **BPF_H** and **BPF_B** size modifiers are not supported: all operations must load and store (4-byte) words (**BPF_W**).
- To access the contents of the *seccomp_data* buffer, use the **BPF_ABS** addressing mode modifier.
- The **BPF_LEN** addressing mode modifier yields an immediate mode operand whose value is the size of the *seccomp_data* buffer.

EXAMPLES

The program below accepts four or more arguments. The first three arguments are a system call number, a numeric architecture identifier, and an error number. The program uses these values to construct a BPF filter that is used at run time to perform the following checks:

- If the program is not running on the specified architecture, the BPF filter causes system calls to fail with the error **ENOSYS**.
- If the program attempts to execute the system call with the specified number, the BPF filter causes the system call to fail, with *errno* being set to the specified error number.

The remaining command-line arguments specify the pathname and additional arguments of a program that the example program should attempt to execute using *execv*(3) (a library function that employs the *execve*(2) system call). Some example runs of the program are shown below.

First, we display the architecture that we are running on (x86-64) and then construct a shell function that looks up system call numbers on this architecture:

```
$ uname -m
x86_64
$ syscall_nr() {
    cat /usr/src/linux/arch/x86/syscalls/syscall_64.tbl | \
    awk '$2 != "x32" && $3 == "'$1'" { print $1 }'
}
```

When the BPF filter rejects a system call (case [2] above), it causes the system call to fail with the error number specified on the command line. In the experiments shown here, we'll use error number 99:

```
$ errno 99
EADDRNOTAVAIL 99 Cannot assign requested address
```

In the following example, we attempt to run the command *whoami*(1), but the BPF filter rejects the *execve*(2) system call, so that the command is not even executed:

```
$ syscall_nr execve
59
$ ./a.out
Usage: ./a.out <syscall_nr> <arch> <errno> <prog> [<args>]
Hint for <arch>: AUDIT_ARCH_I386: 0x40000003
                 AUDIT_ARCH_X86_64: 0xC000003E
$ ./a.out 59 0xC000003E 99 /bin/whoami
execv: Cannot assign requested address
```

In the next example, the BPF filter rejects the *write*(2) system call, so that, although it is successfully started, the *whoami*(1) command is not able to write output:

```
$ syscall_nr write
1
$ ./a.out 1 0xC000003E 99 /bin/whoami
```

In the final example, the BPF filter rejects a system call that is not used by the *whoami*(1) command, so it is able to successfully execute and produce output:

```
$ syscall_nr preadv
295
$ ./a.out 295 0xC000003E 99 /bin/whoami
cecilia
```

NAME

seccomp_unotify − Seccomp user-space notification mechanism

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <linux/seccomp.h>
#include <linux/filter.h>
#include <linux/audit.h>

int seccomp(unsigned int operation, unsigned int  flags, void *args);

#include <sys/ioctl.h>

int ioctl(int  fd, SECCOMP_IOCTL_NOTIF_RECV,
        struct seccomp_notif *req);
int ioctl(int  fd, SECCOMP_IOCTL_NOTIF_SEND,
        struct seccomp_notif_resp *resp);
int ioctl(int  fd, SECCOMP_IOCTL_NOTIF_ID_VALID, __u64 *id);
int ioctl(int  fd, SECCOMP_IOCTL_NOTIF_ADDFD,
        struct seccomp_notif_addfd *addfd);
```

DESCRIPTION

This page describes the user-space notification mechanism provided by the Secure Computing (seccomp) facility. As well as the use of the **SECCOMP_FILTER_FLAG_NEW_LISTENER** flag, the **SECCOMP_RET_USER_NOTIF** action value, and the **SECCOMP_GET_NOTIF_SIZES** operation described in *seccomp*(2), this mechanism involves the use of a number of related *ioctl*(2) operations (described below).

Overview

In conventional usage of a seccomp filter, the decision about how to treat a system call is made by the filter itself. By contrast, the user-space notification mechanism allows the seccomp filter to delegate the handling of the system call to another user-space process. Note that this mechanism is explicitly **not** intended as a method implementing security policy; see NOTES.

In the discussion that follows, the thread(s) on which the seccomp filter is installed is (are) referred to as the *target*, and the process that is notified by the user-space notification mechanism is referred to as the *supervisor*.

A suitably privileged supervisor can use the user-space notification mechanism to perform actions on behalf of the target. The advantage of the user-space notification mechanism is that the supervisor will usually be able to retrieve information about the target and the performed system call that the seccomp filter itself cannot. (A seccomp filter is limited in the information it can obtain and the actions that it can perform because it is running on a virtual machine inside the kernel.)

An overview of the steps performed by the target and the supervisor is as follows:

(1) The target establishes a seccomp filter in the usual manner, but with two differences:

- The *seccomp*(2) *flags* argument includes the flag **SECCOMP_FILTER_FLAG_NEW_LISTENER**. Consequently, the return value of the (successful) *seccomp*(2) call is a new "listening" file descriptor that can be used to receive notifications. Only one "listening" seccomp filter can be installed for a thread.
- In cases where it is appropriate, the seccomp filter returns the action value **SECCOMP_RET_USER_NOTIF**. This return value will trigger a notification event.

(2) In order that the supervisor can obtain notifications using the listening file descriptor, (a duplicate of) that file descriptor must be passed from the target to the supervisor. One way in which this could be done is by passing the file descriptor over a UNIX domain socket connection between the target and the supervisor (using the **SCM_RIGHTS** ancillary message type described in *unix*(7)). Another way to do this is through the use of *pidfd_getfd*(2).

(3) The supervisor will receive notification events on the listening file descriptor. These events are returned as structures of type *seccomp_notif*. Because this structure and its size may evolve over kernel versions, the supervisor must first determine the size of this structure using the *seccomp*(2) **SECCOMP_GET_NOTIF_SIZES** operation, which returns a structure of type

seccomp_notif_sizes. The supervisor allocates a buffer of size *seccomp_notif_sizes.seccomp_notif* bytes to receive notification events. In addition,the supervisor allocates another buffer of size *seccomp_notif_sizes.seccomp_notif_resp* bytes for the response (a *struct seccomp_notif_resp* structure) that it will provide to the kernel (and thus the target).

(4) The target then performs its workload, which includes system calls that will be controlled by the seccomp filter. Whenever one of these system calls causes the filter to return the **SECCOMP_RET_USER_NOTIF** action value, the kernel does *not* (yet) execute the system call; instead, execution of the target is temporarily blocked inside the kernel (in a sleep state that is interruptible by signals) and a notification event is generated on the listening file descriptor.

(5) The supervisor can now repeatedly monitor the listening file descriptor for **SECCOMP_RET_USER_NOTIF**-triggered events. To do this, the supervisor uses the **SECCOMP_IOCTL_NOTIF_RECV** *ioctl*(2) operation to read information about a notification event; this operation blocks until an event is available. The operation returns a *seccomp_notif* structure containing information about the system call that is being attempted by the target. (As described in NOTES, the file descriptor can also be monitored with *select*(2), *poll*(2), or *epoll*(7).)

(6) The *seccomp_notif* structure returned by the **SECCOMP_IOCTL_NOTIF_RECV** operation includes the same information (a *seccomp_data* structure) that was passed to the seccomp filter. This information allows the supervisor to discover the system call number and the arguments for the target's system call. In addition, the notification event contains the ID of the thread that triggered the notification and a unique cookie value that is used in subsequent **SECCOMP_IOCTL_NOTIF_ID_VALID** and **SECCOMP_IOCTL_NOTIF_SEND** operations.

The information in the notification can be used to discover the values of pointer arguments for the target's system call. (This is something that can't be done from within a seccomp filter.) One way in which the supervisor can do this is to open the corresponding */proc/*tid*/mem* file (see *proc*(5)) and read bytes from the location that corresponds to one of the pointer arguments whose value is supplied in the notification event. (The supervisor must be careful to avoid a race condition that can occur when doing this; see the description of the **SECCOMP_IOCTL_NOTIF_ID_VALID** *ioctl*(2) operation below.) In addition, the supervisor can access other system information that is visible in user space but which is not accessible from a seccomp filter.

(7) Having obtained information as per the previous step, the supervisor may then choose to perform an action in response to the target's system call (which, as noted above, is not executed when the seccomp filter returns the **SECCOMP_RET_USER_NOTIF** action value).

One example use case here relates to containers. The target may be located inside a container where it does not have sufficient capabilities to mount a filesystem in the container's mount namespace. However, the supervisor may be a more privileged process that does have sufficient capabilities to perform the mount operation.

(8) The supervisor then sends a response to the notification. The information in this response is used by the kernel to construct a return value for the target's system call and provide a value that will be assigned to the *errno* variable of the target.

The response is sent using the **SECCOMP_IOCTL_NOTIF_SEND** *ioctl*(2) operation, which is used to transmit a *seccomp_notif_resp* structure to the kernel. This structure includes a cookie value that the supervisor obtained in the *seccomp_notif* structure returned by the **SECCOMP_IOCTL_NOTIF_RECV** operation. This cookie value allows the kernel to associate the response with the target. This structure must include the cookie value that the supervisor obtained in the *seccomp_notif* structure returned by the **SECCOMP_IOCTL_NOTIF_RECV** operation; the cookie allows the kernel to associate the response with the target.

(9) Once the notification has been sent, the system call in the target thread unblocks, returning the information that was provided by the supervisor in the notification response.

As a variation on the last two steps, the supervisor can send a response that tells the kernel that it should execute the target thread's system call; see the discussion of **SECCOMP_USER_NOTIF_FLAG_CONTINUE**, below.

IOCTL OPERATIONS

The following *ioctl*(2) operations are supported by the seccomp user-space notification file descriptor. For each of these operations, the first (file descriptor) argument of *ioctl*(2) is the listening file descriptor returned by a call to *seccomp*(2) with the **SECCOMP_FILTER_FLAG_NEW_LISTENER** flag.

SECCOMP_IOCTL_NOTIF_RECV

The **SECCOMP_IOCTL_NOTIF_RECV** operation (available since Linux 5.0) is used to obtain a user-space notification event. If no such event is currently pending, the operation blocks until an event occurs. The third *ioctl*(2) argument is a pointer to a structure of the following form which contains information about the event. This structure must be zeroed out before the call.

```
struct seccomp_notif {
    __u64  id;              /* Cookie */
    __u32  pid;             /* TID of target thread */
    __u32  flags;           /* Currently unused (0) */
    struct seccomp_data data;   /* See seccomp(2) */
};
```

The fields in this structure are as follows:

id This is a cookie for the notification. Each such cookie is guaranteed to be unique for the corresponding seccomp filter.

- The cookie can be used with the **SECCOMP_IOCTL_NOTIF_ID_VALID** *ioctl*(2) operation described below.
- When returning a notification response to the kernel, the supervisor must include the cookie value in the *seccomp_notif_resp* structure that is specified as the argument of the **SECCOMP_IOCTL_NOTIF_SEND** operation.

pid This is the thread ID of the target thread that triggered the notification event.

flags This is a bit mask of flags providing further information on the event. In the current implementation, this field is always zero.

data This is a *seccomp_data* structure containing information about the system call that triggered the notification. This is the same structure that is passed to the seccomp filter. See *seccomp*(2) for details of this structure.

On success, this operation returns 0; on failure, −1 is returned, and *errno* is set to indicate the cause of the error. This operation can fail with the following errors:

EINVAL (since Linux 5.5)
The *seccomp_notif* structure that was passed to the call contained nonzero fields.

ENOENT
The target thread was killed by a signal as the notification information was being generated, or the target's (blocked) system call was interrupted by a signal handler.

SECCOMP_IOCTL_NOTIF_ID_VALID

The **SECCOMP_IOCTL_NOTIF_ID_VALID** operation (available since Linux 5.0) is used to check that a notification ID returned by an earlier **SECCOMP_IOCTL_NOTIF_RECV** operation is still valid (i.e., that the target still exists and its system call is still blocked waiting for a response).

The third *ioctl*(2) argument is a pointer to the cookie (*id*) returned by the **SECCOMP_IOCTL_NOTIF_RECV** operation.

This operation is necessary to avoid race conditions that can occur when the *pid* returned by the **SECCOMP_IOCTL_NOTIF_RECV** operation terminates, and that process ID is reused by another process. An example of this kind of race is the following

(1) A notification is generated on the listening file descriptor. The returned *seccomp_notif* contains the TID of the target thread (in the *pid* field of the structure).

(2) The target terminates.

(3) Another thread or process is created on the system that by chance reuses the TID that was freed when the target terminated.

(4) The supervisor *open*(2)s the */proc/*tid*/mem* file for the TID obtained in step 1, with the intention of (say) inspecting the memory location(s) that containing the argument(s) of the system call that triggered the notification in step 1.

In the above scenario, the risk is that the supervisor may try to access the memory of a process other than the target. This race can be avoided by following the call to *open*(2) with a **SECCOMP_IOCTL_NOTIF_ID_VALID** operation to verify that the process that generated the notification is still alive. (Note that if the target terminates after the latter step, a subsequent *read*(2) from the file descriptor may return 0, indicating end of file.)

See NOTES for a discussion of other cases where **SECCOMP_IOCTL_NOTIF_ID_VALID** checks must be performed.

On success (i.e., the notification ID is still valid), this operation returns 0. On failure (i.e., the notification ID is no longer valid), −1 is returned, and *errno* is set to **ENOENT**.

SECCOMP_IOCTL_NOTIF_SEND

The **SECCOMP_IOCTL_NOTIF_SEND** operation (available since Linux 5.0) is used to send a notification response back to the kernel. The third *ioctl*(2) argument of this structure is a pointer to a structure of the following form:

```
struct seccomp_notif_resp {
    __u64 id;           /* Cookie value */
    __s64 val;          /* Success return value */
    __s32 error;        /* 0 (success) or negative error number */
    __u32 flags;        /* See below */
};
```

The fields of this structure are as follows:

id This is the cookie value that was obtained using the **SECCOMP_IOCTL_NOTIF_RECV** operation. This cookie value allows the kernel to correctly associate this response with the system call that triggered the user-space notification.

val This is the value that will be used for a spoofed success return for the target's system call; see below.

error This is the value that will be used as the error number (*errno*) for a spoofed error return for the target's system call; see below.

flags This is a bit mask that includes zero or more of the following flags:

SECCOMP_USER_NOTIF_FLAG_CONTINUE (since Linux 5.5)
Tell the kernel to execute the target's system call.

Two kinds of response are possible:

- A response to the kernel telling it to execute the target's system call. In this case, the *flags* field includes **SECCOMP_USER_NOTIF_FLAG_CONTINUE** and the *error* and *val* fields must be zero.

  This kind of response can be useful in cases where the supervisor needs to do deeper analysis of the target's system call than is possible from a seccomp filter (e.g., examining the values of pointer arguments), and, having decided that the system call does not require emulation by the supervisor, the supervisor wants the system call to be executed normally in the target.

  The **SECCOMP_USER_NOTIF_FLAG_CONTINUE** flag should be used with caution; see NOTES.

- A spoofed return value for the target's system call. In this case, the kernel does not execute the target's system call, instead causing the system call to return a spoofed value as specified by fields of the *seccomp_notif_resp* structure. The supervisor should set the fields of this structure as follows:

  - *flags* does not contain **SECCOMP_USER_NOTIF_FLAG_CONTINUE**.
  - *error* is set either to 0 for a spoofed "success" return or to a negative error number for a spoofed "failure" return. In the former case, the kernel causes the target's system call to return the value specified in the *val* field. In the latter case, the kernel causes the target's system call to return −1, and *errno* is assigned the negated *error* value.

- *val* is set to a value that will be used as the return value for a spoofed "success" return for the target's system call. The value in this field is ignored if the *error* field contains a nonzero value.

On success, this operation returns 0; on failure, −1 is returned, and *errno* is set to indicate the cause of the error. This operation can fail with the following errors:

EINPROGRESS
A response to this notification has already been sent.

EINVAL
An invalid value was specified in the *flags field.*

EINVAL
The *flags* field contained **SECCOMP_USER_NOTIF_FLAG_CONTINUE**, and the *error* or *val* field was not zero.

ENOENT
The blocked system call in the target has been interrupted by a signal handler or the target has terminated.

SECCOMP_IOCTL_NOTIF_ADDFD
The **SECCOMP_IOCTL_NOTIF_ADDFD** operation (available since Linux 5.9) allows the supervisor to install a file descriptor into the target's file descriptor table. Much like the use of **SCM_RIGHTS** messages described in *unix*(7), this operation is semantically equivalent to duplicating a file descriptor from the supervisor's file descriptor table into the target's file descriptor table.

The **SECCOMP_IOCTL_NOTIF_ADDFD** operation permits the supervisor to emulate a target system call (such as *socket*(2) or *openat*(2)) that generates a file descriptor. The supervisor can perform the system call that generates the file descriptor (and associated open file description) and then use this operation to allocate a file descriptor that refers to the same open file description in the target. (For an explanation of open file descriptions, see *open*(2).)

Once this operation has been performed, the supervisor can close its copy of the file descriptor.

In the target, the received file descriptor is subject to the same Linux Security Module (LSM) checks as are applied to a file descriptor that is received in an **SCM_RIGHTS** ancillary message. If the file descriptor refers to a socket, it inherits the cgroup version 1 network controller settings (*classid* and *netprioidx*) of the target.

The third *ioctl*(2) argument is a pointer to a structure of the following form:

```
struct seccomp_notif_addfd {
    __u64 id;           /* Cookie value */
    __u32 flags;        /* Flags */
    __u32 srcfd;        /* Local file descriptor number */
    __u32 newfd;        /* 0 or desired file descriptor
                           number in target */
    __u32 newfd_flags;  /* Flags to set on target file
                           descriptor */
};
```

The fields in this structure are as follows:

id This field should be set to the notification ID (cookie value) that was obtained via **SECCOMP_IOCTL_NOTIF_RECV**.

flags This field is a bit mask of flags that modify the behavior of the operation. Currently, only one flag is supported:

SECCOMP_ADDFD_FLAG_SETFD
When allocating the file descriptor in the target, use the file descriptor number specified in the *newfd* field.

SECCOMP_ADDFD_FLAG_SEND (since Linux 5.14)
Perform the equivalent of **SECCOMP_IOCTL_NOTIF_ADDFD** plus **SECCOMP_IOCTL_NOTIF_SEND** as an atomic operation. On successful invocation, the target process's *errno* will be 0 and the return value will be the file descriptor number that was allocated in the target. If allocating the file descriptor in the target

fails, the target's system call continues to be blocked until a successful response is sent.

srcfd This field should be set to the number of the file descriptor in the supervisor that is to be duplicated.

newfd This field determines which file descriptor number is allocated in the target. If the **SECCOMP_ADDFD_FLAG_SETFD** flag is set, then this field specifies which file descriptor number should be allocated. If this file descriptor number is already open in the target, it is atomically closed and reused. If the descriptor duplication fails due to an LSM check, or if *srcfd* is not a valid file descriptor, the file descriptor *newfd* will not be closed in the target process.

If the **SECCOMP_ADDFD_FLAG_SETFD** flag it not set, then this field must be 0, and the kernel allocates the lowest unused file descriptor number in the target.

newfd_flags
This field is a bit mask specifying flags that should be set on the file descriptor that is received in the target process. Currently, only the following flag is implemented:

O_CLOEXEC
Set the close-on-exec flag on the received file descriptor.

On success, this *ioctl*(2) call returns the number of the file descriptor that was allocated in the target. Assuming that the emulated system call is one that returns a file descriptor as its function result (e.g., *socket*(2)), this value can be used as the return value (*resp.val*) that is supplied in the response that is subsequently sent with the **SECCOMP_IOCTL_NOTIF_SEND** operation.

On error, −1 is returned and *errno* is set to indicate the cause of the error.

This operation can fail with the following errors:

EBADF
Allocating the file descriptor in the target would cause the target's **RLIMIT_NOFILE** limit to be exceeded (see *getrlimit*(2)).

EBUSY
If the flag **SECCOMP_IOCTL_NOTIF_SEND** is used, this means the operation can't proceed until other **SECCOMP_IOCTL_NOTIF_ADDFD** requests are processed.

EINPROGRESS
The user-space notification specified in the *id* field exists but has not yet been fetched (by a **SECCOMP_IOCTL_NOTIF_RECV**) or has already been responded to (by a **SECCOMP_IOCTL_NOTIF_SEND**).

EINVAL
An invalid flag was specified in the *flags* or *newfd_flags* field, or the *newfd* field is nonzero and the **SECCOMP_ADDFD_FLAG_SETFD** flag was not specified in the *flags* field.

EMFILE
The file descriptor number specified in *newfd* exceeds the limit specified in */proc/sys/fs/nr_open*.

ENOENT
The blocked system call in the target has been interrupted by a signal handler or the target has terminated.

Here is some sample code (with error handling omitted) that uses the **SECCOMP_ADDFD_FLAG_SETFD** operation (here, to emulate a call to *openat*(2)):

```
int fd, removeFd;

fd = openat(req->data.args[0], path, req->data.args[2],
            req->data.args[3]);

struct seccomp_notif_addfd addfd;
addfd.id = req->id; /* Cookie from SECCOMP_IOCTL_NOTIF_RECV */
addfd.srcfd = fd;
```

```
        addfd.newfd = 0;
        addfd.flags = 0;
        addfd.newfd_flags = O_CLOEXEC;

        targetFd = ioctl(notifyFd, SECCOMP_IOCTL_NOTIF_ADDFD, &addfd);

        close(fd);          /* No longer needed in supervisor */

        struct seccomp_notif_resp *resp;
            /* Code to allocate 'resp' omitted */
        resp->id = req->id;
        resp->error = 0;        /* "Success" */
        resp->val = targetFd;
        resp->flags = 0;
        ioctl(notifyFd, SECCOMP_IOCTL_NOTIF_SEND, resp);
```

NOTES

One example use case for the user-space notification mechanism is to allow a container manager (a process which is typically running with more privilege than the processes inside the container) to mount block devices or create device nodes for the container. The mount use case provides an example of where the **SECCOMP_USER_NOTIF_FLAG_CONTINUE** *ioctl*(2) operation is useful. Upon receiving a notification for the *mount*(2) system call, the container manager (the "supervisor") can distinguish a request to mount a block filesystem (which would not be possible for a "target" process inside the container) and mount that file system. If, on the other hand, the container manager detects that the operation could be performed by the process inside the container (e.g., a mount of a *tmpfs*(5) filesystem), it can notify the kernel that the target process's *mount*(2) system call can continue.

select()/poll()/epoll semantics

The file descriptor returned when *seccomp*(2) is employed with the **SECCOMP_FILTER_FLAG_NEW_LISTENER** flag can be monitored using *poll*(2), *epoll*(7), and *select*(2). These interfaces indicate that the file descriptor is ready as follows:

- When a notification is pending, these interfaces indicate that the file descriptor is readable. Following such an indication, a subsequent **SECCOMP_IOCTL_NOTIF_RECV** *ioctl*(2) will not block, returning either information about a notification or else failing with the error **EINTR** if the target has been killed by a signal or its system call has been interrupted by a signal handler.
- After the notification has been received (i.e., by the **SECCOMP_IOCTL_NOTIF_RECV** *ioctl*(2) operation), these interfaces indicate that the file descriptor is writable, meaning that a notification response can be sent using the **SECCOMP_IOCTL_NOTIF_SEND** *ioctl*(2) operation.
- After the last thread using the filter has terminated and been reaped using *waitpid*(2) (or similar), the file descriptor indicates an end-of-file condition (readable in *select*(2); **POLLHUP**/**EPOLLHUP** in *poll*(2)/ *epoll_wait*(2)).

Design goals; use of SECCOMP_USER_NOTIF_FLAG_CONTINUE

The intent of the user-space notification feature is to allow system calls to be performed on behalf of the target. The target's system call should either be handled by the supervisor or allowed to continue normally in the kernel (where standard security policies will be applied).

Note well: this mechanism must not be used to make security policy decisions about the system call, which would be inherently race-prone for reasons described next.

The **SECCOMP_USER_NOTIF_FLAG_CONTINUE** flag must be used with caution. If set by the supervisor, the target's system call will continue. However, there is a time-of-check, time-of-use race here, since an attacker could exploit the interval of time where the target is blocked waiting on the "continue" response to do things such as rewriting the system call arguments.

Note furthermore that a user-space notifier can be bypassed if the existing filters allow the use of *seccomp*(2) or *prctl*(2) to install a filter that returns an action value with a higher precedence than **SECCOMP_RET_USER_NOTIF** (see *seccomp*(2)).

It should thus be absolutely clear that the seccomp user-space notification mechanism **can not** be used to implement a security policy! It should only ever be used in scenarios where a more privileged process supervises the system calls of a lesser privileged target to get around kernel-enforced security

restrictions when the supervisor deems this safe. In other words, in order to continue a system call, the supervisor should be sure that another security mechanism or the kernel itself will sufficiently block the system call if its arguments are rewritten to something unsafe.

Caveats regarding the use of */proc/*tid*/mem*

The discussion above noted the need to use the **SECCOMP_IOCTL_NOTIF_ID_VALID** *ioctl*(2) when opening the */proc/*tid*/mem* file of the target to avoid the possibility of accessing the memory of the wrong process in the event that the target terminates and its ID is recycled by another (unrelated) thread. However, the use of this *ioctl*(2) operation is also necessary in other situations, as explained in the following paragraphs.

Consider the following scenario, where the supervisor tries to read the pathname argument of a target's blocked *mount*(2) system call:

(1) From one of its functions (*func()*), the target calls *mount*(2), which triggers a user-space notification and causes the target to block.

(2) The supervisor receives the notification, opens */proc/*tid*/mem*, and (successfully) performs the **SECCOMP_IOCTL_NOTIF_ID_VALID** check.

(3) The target receives a signal, which causes the *mount*(2) to abort.

(4) The signal handler executes in the target, and returns.

(5) Upon return from the handler, the execution of *func()* resumes, and it returns (and perhaps other functions are called, overwriting the memory that had been used for the stack frame of *func()*).

(6) Using the address provided in the notification information, the supervisor reads from the target's memory location that used to contain the pathname.

(7) The supervisor now calls *mount*(2) with some arbitrary bytes obtained in the previous step.

The conclusion from the above scenario is this: since the target's blocked system call may be interrupted by a signal handler, the supervisor must be written to expect that the target may abandon its system call at **any** time; in such an event, any information that the supervisor obtained from the target's memory must be considered invalid.

To prevent such scenarios, every read from the target's memory must be separated from use of the bytes so obtained by a **SECCOMP_IOCTL_NOTIF_ID_VALID** check. In the above example, the check would be placed between the two final steps. An example of such a check is shown in EXAMPLES.

Following on from the above, it should be clear that a write by the supervisor into the target's memory can **never** be considered safe.

Caveats regarding blocking system calls

Suppose that the target performs a blocking system call (e.g., *accept*(2)) that the supervisor should handle. The supervisor might then in turn execute the same blocking system call.

In this scenario, it is important to note that if the target's system call is now interrupted by a signal, the supervisor is *not* informed of this. If the supervisor does not take suitable steps to actively discover that the target's system call has been canceled, various difficulties can occur. Taking the example of *accept*(2), the supervisor might remain blocked in its *accept*(2) holding a port number that the target (which, after the interruption by the signal handler, perhaps closed its listening socket) might expect to be able to reuse in a *bind*(2) call.

Therefore, when the supervisor wishes to emulate a blocking system call, it must do so in such a way that it gets informed if the target's system call is interrupted by a signal handler. For example, if the supervisor itself executes the same blocking system call, then it could employ a separate thread that uses the **SECCOMP_IOCTL_NOTIF_ID_VALID** operation to check if the target is still blocked in its system call. Alternatively, in the *accept*(2) example, the supervisor might use *poll*(2) to monitor both the notification file descriptor (so as to discover when the target's *accept*(2) call has been interrupted) and the listening file descriptor (so as to know when a connection is available).

If the target's system call is interrupted, the supervisor must take care to release resources (e.g., file descriptors) that it acquired on behalf of the target.

Interaction with SA_RESTART signal handlers

Consider the following scenario:

(1) The target process has used *sigaction*(2) to install a signal handler with the **SA_RESTART** flag.

(2) The target has made a system call that triggered a seccomp user-space notification and the target is currently blocked until the supervisor sends a notification response.

(3) A signal is delivered to the target and the signal handler is executed.

(4) When (if) the supervisor attempts to send a notification response, the **SECCOMP_IOCTL_NOTIF_SEND** *ioctl*(2)) operation will fail with the **ENOENT** error.

In this scenario, the kernel will restart the target's system call. Consequently, the supervisor will receive another user-space notification. Thus, depending on how many times the blocked system call is interrupted by a signal handler, the supervisor may receive multiple notifications for the same instance of a system call in the target.

One oddity is that system call restarting as described in this scenario will occur even for the blocking system calls listed in *signal*(7) that would **never** normally be restarted by the **SA_RESTART** flag.

Furthermore, if the supervisor response is a file descriptor added with **SECCOMP_IOCTL_NOTIF_ADDFD**, then the flag **SECCOMP_ADDFD_FLAG_SEND** can be used to atomically add the file descriptor and return that value, making sure no file descriptors are inadvertently leaked into the target.

BUGS

If a **SECCOMP_IOCTL_NOTIF_RECV** *ioctl*(2) operation is performed after the target terminates, then the *ioctl*(2) call simply blocks (rather than returning an error to indicate that the target no longer exists).

EXAMPLES

The (somewhat contrived) program shown below demonstrates the use of the interfaces described in this page. The program creates a child process that serves as the "target" process. The child process installs a seccomp filter that returns the **SECCOMP_RET_USER_NOTIF** action value if a call is made to *mkdir*(2). The child process then calls *mkdir*(2) once for each of the supplied command-line arguments, and reports the result returned by the call. After processing all arguments, the child process terminates.

The parent process acts as the supervisor, listening for the notifications that are generated when the target process calls *mkdir*(2). When such a notification occurs, the supervisor examines the memory of the target process (using */proc/*pid*/mem*) to discover the pathname argument that was supplied to the *mkdir*(2) call, and performs one of the following actions:

- If the pathname begins with the prefix "/tmp/", then the supervisor attempts to create the specified directory, and then spoofs a return for the target process based on the return value of the supervisor's *mkdir*(2) call. In the event that that call succeeds, the spoofed success return value is the length of the pathname.
- If the pathname begins with "./" (i.e., it is a relative pathname), the supervisor sends a **SECCOMP_USER_NOTIF_FLAG_CONTINUE** response to the kernel to say that the kernel should execute the target process's *mkdir*(2) call.
- If the pathname begins with some other prefix, the supervisor spoofs an error return for the target process, so that the target process's *mkdir*(2) call appears to fail with the error **EOPNOTSUPP** ("Operation not supported"). Additionally, if the specified pathname is exactly "/bye", then the supervisor terminates.

This program can be used to demonstrate various aspects of the behavior of the seccomp user-space notification mechanism. To help aid such demonstrations, the program logs various messages to show the operation of the target process (lines prefixed "T:") and the supervisor (indented lines prefixed "S:").

In the following example, the target attempts to create the directory */tmp/x*. Upon receiving the notification, the supervisor creates the directory on the target's behalf, and spoofs a success return to be received by the target process's *mkdir*(2) call.

```
$ ./seccomp_unotify /tmp/x
T: PID = 23168

T: about to mkdir("/tmp/x")
        S: got notification (ID 0x17445c4a0f4e0e3c) for PID 23168
```

```
            S: executing: mkdir("/tmp/x", 0700)
            S: success! spoofed return = 6
            S: sending response (flags = 0; val = 6; error = 0)
    T: SUCCESS: mkdir(2) returned 6

    T: terminating
            S: target has terminated; bye
```

In the above output, note that the spoofed return value seen by the target process is 6 (the length of the pathname */tmp/x*), whereas a normal *mkdir*(2) call returns 0 on success.

In the next example, the target attempts to create a directory using the relative pathname *./sub*. Since this pathname starts with "./", the supervisor sends a **SECCOMP_USER_NOTIF_FLAG_CONTINUE** response to the kernel, and the kernel then (successfully) executes the target process's *mkdir*(2) call.

```
    $ ./seccomp_unotify ./sub
    T: PID = 23204

    T: about to mkdir("./sub")
            S: got notification (ID 0xddb16abe25b4c12) for PID 23204
            S: target can execute system call
            S: sending response (flags = 0x1; val = 0; error = 0)
    T: SUCCESS: mkdir(2) returned 0

    T: terminating
            S: target has terminated; bye
```

If the target process attempts to create a directory with a pathname that doesn't start with "." and doesn't begin with the prefix "/tmp/", then the supervisor spoofs an error return (**EOPNOTSUPP**, "Operation not supported") for the target's *mkdir*(2) call (which is not executed):

```
    $ ./seccomp_unotify /xxx
    T: PID = 23178

    T: about to mkdir("/xxx")
            S: got notification (ID 0xe7dc095d1c524e80) for PID 23178
            S: spoofing error response (Operation not supported)
            S: sending response (flags = 0; val = 0; error = -95)
    T: ERROR: mkdir(2): Operation not supported

    T: terminating
            S: target has terminated; bye
```

In the next example, the target process attempts to create a directory with the pathname **/tmp/nosuchdir/b**. Upon receiving the notification, the supervisor attempts to create that directory, but the *mkdir*(2) call fails because the directory **/tmp/nosuchdir** does not exist. Consequently, the supervisor spoofs an error return that passes the error that it received back to the target process's *mkdir*(2) call.

```
    $ ./seccomp_unotify /tmp/nosuchdir/b
    T: PID = 23199

    T: about to mkdir("/tmp/nosuchdir/b")
            S: got notification (ID 0x8744454293506046) for PID 23199
            S: executing: mkdir("/tmp/nosuchdir/b", 0700)
            S: failure! (errno = 2; No such file or directory)
            S: sending response (flags = 0; val = 0; error = -2)
    T: ERROR: mkdir(2): No such file or directory

    T: terminating
            S: target has terminated; bye
```

If the supervisor receives a notification and sees that the argument of the target's *mkdir*(2) is the string

"/bye", then (as well as spoofing an **EOPNOTSUPP** error), the supervisor terminates. If the target process subsequently executes another *mkdir*(2) that triggers its seccomp filter to return the **SECCOMP_RET_USER_NOTIF** action value, then the kernel causes the target process's system call to fail with the error **ENOSYS** ("Function not implemented"). This is demonstrated by the following example:

```
$ ./seccomp_unotify /bye /tmp/y
T: PID = 23185

T: about to mkdir("/bye")
        S: got notification (ID 0xa81236b1d2f7b0f4) for PID 23185
        S: spoofing error response (Operation not supported)
        S: sending response (flags = 0; val = 0; error = -95)
        S: terminating **********
T: ERROR: mkdir(2): Operation not supported

T: about to mkdir("/tmp/y")
T: ERROR: mkdir(2): Function not implemented

T: terminating
```

           fd_set *_Nullable restrict writefds,
           fd_set *_Nullable restrict exceptfds,
           struct timeval *_Nullable restrict timeout);

void FD_CLR(int  fd, fd_set *set);
int  FD_ISSET(int  fd, fd_set *set);
void FD_SET(int  fd, fd_set *set);
void FD_ZERO(fd_set *set);

int pselect(int nfds, fd_set *_Nullable restrict readfds,
            fd_set *_Nullable restrict writefds,
            fd_set *_Nullable restrict exceptfds,
            const struct timespec *_Nullable restrict timeout,
            const sigset_t *_Nullable restrict sigmask);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

pselect():
_POSIX_C_SOURCE >= 200112L

DESCRIPTION

WARNING: **select**() can monitor only file descriptors numbers that are less than **FD_SETSIZE** (1024)—an unreasonably low limit for many modern applications—and this limitation will not change. All modern applications should instead use *poll*(2) or *epoll*(7), which do not suffer this limitation.

select() allows a program to monitor multiple file descriptors, waiting until one or more of the file descriptors become "ready" for some class of I/O operation (e.g., input possible). A file descriptor is considered ready if it is possible to perform a corresponding I/O operation (e.g., *read*(2), or a sufficiently small *write*(2)) without blocking.

fd_set

A structure type that can represent a set of file descriptors. According to POSIX, the maximum number of file descriptors in an *fd_set* structure is the value of the macro **FD_SETSIZE**.

File descriptor sets

The principal arguments of **select**() are three "sets" of file descriptors (declared with the type *fd_set*), which allow the caller to wait for three classes of events on the specified set of file descriptors. Each of the *fd_set* arguments may be specified as NULL if no file descriptors are to be watched for the corresponding class of events.

Note well: Upon return, each of the file descriptor sets is modified in place to indicate which file descriptors are currently "ready". Thus, if using **select**() within a loop, the sets *must be reinitialized* before each call.

The contents of a file descriptor set can be manipulated using the following macros:

FD_ZERO()
: This macro clears (removes all file descriptors from) *set*. It should be employed as the first step in initializing a file descriptor set.

FD_SET()
: This macro adds the file descriptor *fd* to *set*. Adding a file descriptor that is already present in the set is a no-op, and does not produce an error.

FD_CLR()
: This macro removes the file descriptor *fd* from *set*. Removing a file descriptor that is not present in the set is a no-op, and does not produce an error.

FD_ISSET()
select() modifies the contents of the sets according to the rules described below. After calling **select**(), the **FD_ISSET**() macro can be used to test if a file descriptor is still present in a set. **FD_ISSET**() returns nonzero if the file descriptor *fd* is present in *set*, and zero if it is not.

Arguments
The arguments of **select**() are as follows:

readfds The file descriptors in this set are watched to see if they are ready for reading. A file descriptor is ready for reading if a read operation will not block; in particular, a file descriptor is also ready on end-of-file.

After **select**() has returned, *readfds* will be cleared of all file descriptors except for those that are ready for reading.

writefds
The file descriptors in this set are watched to see if they are ready for writing. A file descriptor is ready for writing if a write operation will not block. However, even if a file descriptor indicates as writable, a large write may still block.

After **select**() has returned, *writefds* will be cleared of all file descriptors except for those that are ready for writing.

exceptfds
The file descriptors in this set are watched for "exceptional conditions". For examples of some exceptional conditions, see the discussion of **POLLPRI** in *poll*(2).

After **select**() has returned, *exceptfds* will be cleared of all file descriptors except for those for which an exceptional condition has occurred.

nfds This argument should be set to the highest-numbered file descriptor in any of the three sets, plus 1. The indicated file descriptors in each set are checked, up to this limit (but see BUGS).

timeout The *timeout* argument is a *timeval* structure (shown below) that specifies the interval that **select**() should block waiting for a file descriptor to become ready. The call will block until either:

- a file descriptor becomes ready;
- the call is interrupted by a signal handler; or
- the timeout expires.

Note that the *timeout* interval will be rounded up to the system clock granularity, and kernel scheduling delays mean that the blocking interval may overrun by a small amount.

If both fields of the *timeval* structure are zero, then **select**() returns immediately. (This is useful for polling.)

If *timeout* is specified as NULL, **select**() blocks indefinitely waiting for a file descriptor to become ready.

pselect()
The **pselect**() system call allows an application to safely wait until either a file descriptor becomes ready or until a signal is caught.

The operation of **select**() and **pselect**() is identical, other than these three differences:

- **select**() uses a timeout that is a *struct timeval* (with seconds and microseconds), while **pselect**() uses a *struct timespec* (with seconds and nanoseconds).
- **select**() may update the *timeout* argument to indicate how much time was left. **pselect**() does not change this argument.
- **select**() has no *sigmask* argument, and behaves as **pselect**() called with NULL *sigmask*.

sigmask is a pointer to a signal mask (see *sigprocmask*(2)); if it is not NULL, then **pselect**() first replaces the current signal mask by the one pointed to by *sigmask*, then does the "select" function, and then restores the original signal mask. (If *sigmask* is NULL, the signal mask is not modified during the **pselect**() call.)

Other than the difference in the precision of the *timeout* argument, the following **pselect**() call:

```
ready = pselect(nfds, &readfds, &writefds, &exceptfds,
                timeout, &sigmask);
```

is equivalent to *atomically* executing the following calls:

```
sigset_t origmask;

pthread_sigmask(SIG_SETMASK, &sigmask, &origmask);
ready = select(nfds, &readfds, &writefds, &exceptfds, timeout);
pthread_sigmask(SIG_SETMASK, &origmask, NULL);
```

The reason that **pselect**() is needed is that if one wants to wait for either a signal or for a file descriptor to become ready, then an atomic test is needed to prevent race conditions. (Suppose the signal handler sets a global flag and returns. Then a test of this global flag followed by a call of **select**() could hang indefinitely if the signal arrived just after the test but just before the call. By contrast, **pselect**() allows one to first block signals, handle the signals that have come in, then call **pselect**() with the desired *sigmask*, avoiding the race.)

The timeout

The *timeout* argument for **select**() is a structure of the following type:

```
struct timeval {
    time_t      tv_sec;         /* seconds */
    suseconds_t tv_usec;        /* microseconds */
};
```

The corresponding argument for **pselect**() is a *timespec*(3) structure.

On Linux, **select**() modifies *timeout* to reflect the amount of time not slept; most other implementations do not do this. (POSIX.1 permits either behavior.) This causes problems both when Linux code which reads *timeout* is ported to other operating systems, and when code is ported to Linux that reuses a *struct timeval* for multiple **select**()s in a loop without reinitializing it. Consider *timeout* to be undefined after **select**() returns.

RETURN VALUE

On success, **select**() and **pselect**() return the number of file descriptors contained in the three returned descriptor sets (that is, the total number of bits that are set in *readfds*, *writefds*, *exceptfds*). The return value may be zero if the timeout expired before any file descriptors became ready.

On error, −1 is returned, and *errno* is set to indicate the error; the file descriptor sets are unmodified, and *timeout* becomes undefined.

ERRORS

EBADF
: An invalid file descriptor was given in one of the sets. (Perhaps a file descriptor that was already closed, or one on which an error has occurred.) However, see BUGS.

EINTR
: A signal was caught; see *signal*(7).

EINVAL
: *nfds* is negative or exceeds the **RLIMIT_NOFILE** resource limit (see *getrlimit*(2)).

EINVAL
: The value contained within *timeout* is invalid.

ENOMEM
: Unable to allocate memory for internal tables.

VERSIONS

On some other UNIX systems, **select**() can fail with the error **EAGAIN** if the system fails to allocate kernel-internal resources, rather than **ENOMEM** as Linux does. POSIX specifies this error for *poll*(2), but not for **select**(). Portable programs may wish to check for **EAGAIN** and loop, just as with **EINTR**.

STANDARDS

POSIX.1-2008.

HISTORY

select() POSIX.1-2001, 4.4BSD (first appeared in 4.2BSD).

Generally portable to/from non-BSD systems supporting clones of the BSD socket layer (including System V variants). However, note that the System V variant typically sets the timeout variable before returning, but the BSD variant does not.

pselect()

Linux 2.6.16. POSIX.1g, POSIX.1-2001.

Prior to this, it was emulated in glibc (but see BUGS).

fd_set POSIX.1-2001.

NOTES

The following header also provides the *fd_set* type: <*sys/time.h*>.

An *fd_set* is a fixed size buffer. Executing **FD_CLR**() or **FD_SET**() with a value of *fd* that is negative or is equal to or larger than **FD_SETSIZE** will result in undefined behavior. Moreover, POSIX requires *fd* to be a valid file descriptor.

The operation of **select**() and **pselect**() is not affected by the **O_NONBLOCK** flag.

The self-pipe trick

On systems that lack **pselect**(), reliable (and more portable) signal trapping can be achieved using the self-pipe trick. In this technique, a signal handler writes a byte to a pipe whose other end is monitored by **select**() in the main program. (To avoid possibly blocking when writing to a pipe that may be full or reading from a pipe that may be empty, nonblocking I/O is used when reading from and writing to the pipe.)

Emulating usleep(3)

Before the advent of *usleep*(3), some code employed a call to **select**() with all three sets empty, *nfds* zero, and a non-NULL *timeout* as a fairly portable way to sleep with subsecond precision.

Correspondence between select() and poll() notifications

Within the Linux kernel source, we find the following definitions which show the correspondence between the readable, writable, and exceptional condition notifications of **select**() and the event notifications provided by *poll*(2) and *epoll*(7):

```
#define POLLIN_SET  (EPOLLRDNORM | EPOLLRDBAND | EPOLLIN |
                     EPOLLHUP | EPOLLERR)
                    /* Ready for reading */
#define POLLOUT_SET (EPOLLWRBAND | EPOLLWRNORM | EPOLLOUT |
                     EPOLLERR)
                    /* Ready for writing */
#define POLLEX_SET  (EPOLLPRI)
                    /* Exceptional condition */
```

Multithreaded applications

If a file descriptor being monitored by **select**() is closed in another thread, the result is unspecified. On some UNIX systems, **select**() unblocks and returns, with an indication that the file descriptor is ready (a subsequent I/O operation will likely fail with an error, unless another process reopens the file descriptor between the time **select**() returned and the I/O operation is performed). On Linux (and some other systems), closing the file descriptor in another thread has no effect on **select**(). In summary, any application that relies on a particular behavior in this scenario must be considered buggy.

C library/kernel differences

The Linux kernel allows file descriptor sets of arbitrary size, determining the length of the sets to be checked from the value of *nfds*. However, in the glibc implementation, the *fd_set* type is fixed in size. See also BUGS.

The **pselect**() interface described in this page is implemented by glibc. The underlying Linux system call is named **pselect6**(). This system call has somewhat different behavior from the glibc wrapper function.

The Linux **pselect6**() system call modifies its *timeout* argument. However, the glibc wrapper function hides this behavior by using a local variable for the timeout argument that is passed to the system call. Thus, the glibc **pselect**() function does not modify its *timeout* argument; this is the behavior required

by POSIX.1-2001.

The final argument of the **pselect6**() system call is not a *sigset_t* * pointer, but is instead a structure of the form:

```
struct {
    const kernel_sigset_t *ss;   /* Pointer to signal set */
    size_t ss_len;               /* Size (in bytes) of object
                                    pointed to by 'ss' */
};
```

This allows the system call to obtain both a pointer to the signal set and its size, while allowing for the fact that most architectures support a maximum of 6 arguments to a system call. See *sigprocmask*(2) for a discussion of the difference between the kernel and libc notion of the signal set.

Historical glibc details

glibc 2.0 provided an incorrect version of **pselect**() that did not take a *sigmask* argument.

From glibc 2.1 to glibc 2.2.1, one must define **_GNU_SOURCE** in order to obtain the declaration of **pselect**() from <*sys/select.h*>.

BUGS

POSIX allows an implementation to define an upper limit, advertised via the constant **FD_SETSIZE**, on the range of file descriptors that can be specified in a file descriptor set. The Linux kernel imposes no fixed limit, but the glibc implementation makes *fd_set* a fixed-size type, with **FD_SETSIZE** defined as 1024, and the **FD_***() macros operating according to that limit. To monitor file descriptors greater than 1023, use *poll*(2) or *epoll*(7) instead.

The implementation of the *fd_set* arguments as value-result arguments is a design error that is avoided in *poll*(2) and *epoll*(7).

According to POSIX, **select**() should check all specified file descriptors in the three file descriptor sets, up to the limit *nfds−1*. However, the current implementation ignores any file descriptor in these sets that is greater than the maximum file descriptor number that the process currently has open. According to POSIX, any such file descriptor that is specified in one of the sets should result in the error **EBADF**.

Starting with glibc 2.1, glibc provided an emulation of **pselect**() that was implemented using *sigprocmask*(2) and **select**(). This implementation remained vulnerable to the very race condition that **pselect**() was designed to prevent. Modern versions of glibc use the (race-free) **pselect**() system call on kernels where it is provided.

On Linux, **select**() may report a socket file descriptor as "ready for reading", while nevertheless a subsequent read blocks. This could for example happen when data has arrived but upon examination has the wrong checksum and is discarded. There may be other circumstances in which a file descriptor is spuriously reported as ready. Thus it may be safer to use **O_NONBLOCK** on sockets that should not block.

On Linux, **select**() also modifies *timeout* if the call is interrupted by a signal handler (i.e., the **EINTR** error return). This is not permitted by POSIX.1. The Linux **pselect**() system call has the same behavior, but the glibc wrapper hides this behavior by internally copying the *timeout* to a local variable and passing that variable to the system call.

EXAMPLES

```
#include <stdio.h>
#include <stdlib.h>
#include <sys/select.h>

int
main(void)
{
    int             retval;
    fd_set          rfds;
    struct timeval  tv;

    /* Watch stdin (fd 0) to see when it has input. */
```

```
        FD_ZERO(&rfds);
        FD_SET(0, &rfds);

        /* Wait up to five seconds. */

        tv.tv_sec = 5;
        tv.tv_usec = 0;

        retval = select(1, &rfds, NULL, NULL, &tv);
        /* Don't rely on the value of tv now! */

        if (retval == -1)
            perror("select()");
        else if (retval)
            printf("Data is available now.\n");
            /* FD_ISSET(0, &rfds) will be true. */
        else
            printf("No data within five seconds.\n");

        exit(EXIT_SUCCESS);
    }
```

NAME

select, pselect − synchronous I/O multiplexing

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

See *select*(2)

DESCRIPTION

The **select**() and **pselect**() system calls are used to efficiently monitor multiple file descriptors, to see if any of them is, or becomes, "ready"; that is, to see whether I/O becomes possible, or an "exceptional condition" has occurred on any of the file descriptors.

This page provides background and tutorial information on the use of these system calls. For details of the arguments and semantics of **select**() and **pselect**(), see *select*(2).

Combining signal and data events

pselect() is useful if you are waiting for a signal as well as for file descriptor(s) to become ready for I/O. Programs that receive signals normally use the signal handler only to raise a global flag. The global flag will indicate that the event must be processed in the main loop of the program. A signal will cause the **select**() (or *pselect*()) call to return with *errno* set to **EINTR**. This behavior is essential so that signals can be processed in the main loop of the program, otherwise **select**() would block indefinitely.

Now, somewhere in the main loop will be a conditional to check the global flag. So we must ask: what if a signal arrives after the conditional, but before the **select**() call? The answer is that **select**() would block indefinitely, even though an event is actually pending. This race condition is solved by the **pselect**() call. This call can be used to set the signal mask to a set of signals that are to be received only within the **pselect**() call. For instance, let us say that the event in question was the exit of a child process. Before the start of the main loop, we would block **SIGCHLD** using *sigprocmask*(2). Our **pselect**() call would enable **SIGCHLD** by using an empty signal mask. Our program would look like:

```
static volatile sig_atomic_t got_SIGCHLD = 0;

static void
child_sig_handler(int sig)
{
    got_SIGCHLD = 1;
}

int
main(int argc, char *argv[])
{
    sigset_t sigmask, empty_mask;
    struct sigaction sa;
    fd_set readfds, writefds, exceptfds;
    int r;

    sigemptyset(&sigmask);
    sigaddset(&sigmask, SIGCHLD);
    if (sigprocmask(SIG_BLOCK, &sigmask, NULL) == -1) {
        perror("sigprocmask");
        exit(EXIT_FAILURE);
    }

    sa.sa_flags = 0;
    sa.sa_handler = child_sig_handler;
    sigemptyset(&sa.sa_mask);
    if (sigaction(SIGCHLD, &sa, NULL) == -1) {
        perror("sigaction");
        exit(EXIT_FAILURE);
    }
```

```
        sigemptyset(&empty_mask);

        for (;;) {          /* main loop */
            /* Initialize readfds, writefds, and exceptfds
               before the pselect() call. (Code omitted.) */

            r = pselect(nfds, &readfds, &writefds, &exceptfds,
                        NULL, &empty_mask);
            if (r == -1 && errno != EINTR) {
                /* Handle error */
            }

            if (got_SIGCHLD) {
                got_SIGCHLD = 0;

                /* Handle signalled event here; e.g., wait() for all
                   terminated children. (Code omitted.) */
            }

            /* main body of program */
        }
    }
```

Practical

So what is the point of **select**()? Can't I just read and write to my file descriptors whenever I want? The point of **select**() is that it watches multiple descriptors at the same time and properly puts the process to sleep if there is no activity. UNIX programmers often find themselves in a position where they have to handle I/O from more than one file descriptor where the data flow may be intermittent. If you were to merely create a sequence of *read*(2) and *write*(2) calls, you would find that one of your calls may block waiting for data from/to a file descriptor, while another file descriptor is unused though ready for I/O. **select**() efficiently copes with this situation.

Select law

Many people who try to use **select**() come across behavior that is difficult to understand and produces nonportable or borderline results. For instance, the above program is carefully written not to block at any point, even though it does not set its file descriptors to nonblocking mode. It is easy to introduce subtle errors that will remove the advantage of using **select**(), so here is a list of essentials to watch for when using **select**().

1. You should always try to use **select**() without a timeout. Your program should have nothing to do if there is no data available. Code that depends on timeouts is not usually portable and is difficult to debug.
2. The value *nfds* must be properly calculated for efficiency as explained above.
3. No file descriptor must be added to any set if you do not intend to check its result after the **select**() call, and respond appropriately. See next rule.
4. After **select**() returns, all file descriptors in all sets should be checked to see if they are ready.
5. The functions *read*(2), *recv*(2), *write*(2), and *send*(2) do *not* necessarily read/write the full amount of data that you have requested. If they do read/write the full amount, it's because you have a low traffic load and a fast stream. This is not always going to be the case. You should cope with the case of your functions managing to send or receive only a single byte.
6. Never read/write only in single bytes at a time unless you are really sure that you have a small amount of data to process. It is extremely inefficient not to read/write as much data as you can buffer each time. The buffers in the example below are 1024 bytes although they could easily be made larger.
7. Calls to *read*(2), *recv*(2), *write*(2), *send*(2), and **select**() can fail with the error **EINTR**, and calls to *read*(2), *recv*(2), *write*(2), and *send*(2) can fail with *errno* set to **EAGAIN** (**EWOULDBLOCK**). These results must be properly managed (not done properly above). If your program is not going

to receive any signals, then it is unlikely you will get **EINTR**. If your program does not set non-blocking I/O, you will not get **EAGAIN**.

8. Never call *read*(2), *recv*(2), *write*(2), or *send*(2) with a buffer length of zero.
9. If the functions *read*(2), *recv*(2), *write*(2), and *send*(2) fail with errors other than those listed in **7.**, or one of the input functions returns 0, indicating end of file, then you should *not* pass that file descriptor to **select**() again. In the example below, I close the file descriptor immediately, and then set it to −1 to prevent it being included in a set.
10. The timeout value must be initialized with each new call to **select**(), since some operating systems modify the structure. **pselect**() however does not modify its timeout structure.
11. Since **select**() modifies its file descriptor sets, if the call is being used in a loop, then the sets must be reinitialized before each call.

RETURN VALUE

See *select*(2).

NOTES

Generally speaking, all operating systems that support sockets also support **select**(). **select**() can be used to solve many problems in a portable and efficient way that naive programmers try to solve in a more complicated manner using threads, forking, IPCs, signals, memory sharing, and so on.

The *poll*(2) system call has the same functionality as **select**(), and is somewhat more efficient when monitoring sparse file descriptor sets. It is nowadays widely available, but historically was less portable than **select**().

The Linux-specific *epoll*(7) API provides an interface that is more efficient than *select*(2) and *poll*(2) when monitoring large numbers of file descriptors.

EXAMPLES

Here is an example that better demonstrates the true utility of **select**(). The listing below is a TCP forwarding program that forwards from one TCP port to another.

```
#include <arpa/inet.h>
#include <errno.h>
#include <netinet/in.h>
#include <signal.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/select.h>
#include <sys/socket.h>
#include <unistd.h>

static int forward_port;

#undef max
#define max(x, y) ((x) > (y) ? (x) : (y))

static int
listen_socket(int listen_port)
{
    int                 lfd;
    int                 yes;
    struct sockaddr_in  addr;

    lfd = socket(AF_INET, SOCK_STREAM, 0);
    if (lfd == -1) {
        perror("socket");
        return -1;
    }

    yes = 1;
```

```
    if (setsockopt(lfd, SOL_SOCKET, SO_REUSEADDR,
                   &yes, sizeof(yes)) == -1)
    {
        perror("setsockopt");
        close(lfd);
        return -1;
    }

    memset(&addr, 0, sizeof(addr));
    addr.sin_port = htons(listen_port);
    addr.sin_family = AF_INET;
    if (bind(lfd, (struct sockaddr *) &addr, sizeof(addr)) == -1) {
        perror("bind");
        close(lfd);
        return -1;
    }

    printf("accepting connections on port %d\n", listen_port);
    listen(lfd, 10);
    return lfd;
}

static int
connect_socket(int connect_port, char *address)
{
    int                 cfd;
    struct sockaddr_in  addr;

    cfd = socket(AF_INET, SOCK_STREAM, 0);
    if (cfd == -1) {
        perror("socket");
        return -1;
    }

    memset(&addr, 0, sizeof(addr));
    addr.sin_port = htons(connect_port);
    addr.sin_family = AF_INET;

    if (!inet_aton(address, (struct in_addr *) &addr.sin_addr.s_addr)) {
        fprintf(stderr, "inet_aton(): bad IP address format\n");
        close(cfd);
        return -1;
    }

    if (connect(cfd, (struct sockaddr *) &addr, sizeof(addr)) == -1) {
        perror("connect()");
        shutdown(cfd, SHUT_RDWR);
        close(cfd);
        return -1;
    }
    return cfd;
}

#define SHUT_FD1 do {                                   \
                     if (fd1 >= 0) {                    \
                         shutdown(fd1, SHUT_RDWR);      \
                         close(fd1);                    \
                         fd1 = -1;                      \
                     }                                  \
```

```
                } while (0)

    }
    exit(EXIT_SUCCESS);
```

```
}
```

The above program properly forwards most kinds of TCP connections including OOB signal data transmitted by **telnet** servers. It handles the tricky problem of having data flow in both directions simultaneously. You might think it more efficient to use a *fork*(2) call and devote a thread to each stream. This becomes more tricky than you might suspect. Another idea is to set nonblocking I/O using *fcntl*(2). This also has its problems because you end up using inefficient timeouts.

The program does not handle more than one simultaneous connection at a time, although it could easily be extended to do this with a linked list of buffers—one for each connection. At the moment, new connections cause the current connection to be dropped.

NAME

semctl − System V semaphore control operations

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/sem.h>

int semctl(int *semid***, int** *semnum***, int** *op***, ...);**

DESCRIPTION

semctl() performs the control operation specified by *op* on the System V semaphore set identified by *semid*, or on the *semnum*-th semaphore of that set. (The semaphores in a set are numbered starting at 0.)

This function has three or four arguments, depending on *op*. When there are four, the fourth has the type *union semun*. The *calling program* must define this union as follows:

```
union semun {
    int              val;    /* Value for SETVAL */
    struct semid_ds *buf;    /* Buffer for IPC_STAT, IPC_SET */
    unsigned short  *array;  /* Array for GETALL, SETALL */
    struct seminfo  *__buf;  /* Buffer for IPC_INFO
                                (Linux-specific) */
};
```

The *semid_ds* data structure is defined in <*sys/sem.h*> as follows:

```
struct semid_ds {
    struct ipc_perm sem_perm;  /* Ownership and permissions */
    time_t          sem_otime; /* Last semop time */
    time_t          sem_ctime; /* Creation time/time of last
                                  modification via semctl() */
    unsigned long   sem_nsems; /* No. of semaphores in set */
};
```

The fields of the *semid_ds* structure are as follows:

sem_perm This is an *ipc_perm* structure (see below) that specifies the access permissions on the semaphore set.

sem_otime Time of last *semop*(2) system call.

sem_ctime Time of creation of semaphore set or time of last **semctl**() **IPCSET**, **SETVAL**, or **SETALL** operation.

sem_nsems Number of semaphores in the set. Each semaphore of the set is referenced by a nonnegative integer ranging from **0** to *sem_nsems−1*.

The *ipc_perm* structure is defined as follows (the highlighted fields are settable using **IPC_SET**):

```
struct ipc_perm {
    key_t          __key; /* Key supplied to semget(2) */
    uid_t          uid;   /* Effective UID of owner */
    gid_t          gid;   /* Effective GID of owner */
    uid_t          cuid;  /* Effective UID of creator */
    gid_t          cgid;  /* Effective GID of creator */
    unsigned short mode;  /* Permissions */
    unsigned short __seq; /* Sequence number */
};
```

The least significant 9 bits of the *mode* field of the *ipc_perm* structure define the access permissions for the shared memory segment. The permission bits are as follows:

0400 Read by user
0200 Write by user
0040 Read by group

0020 Write by group
0004 Read by others
0002 Write by others

In effect, "write" means "alter" for a semaphore set. Bits 0100, 0010, and 0001 (the execute bits) are unused by the system.

Valid values for *op* are:

IPC_STAT
Copy information from the kernel data structure associated with *semid* into the *semid_ds* structure pointed to by *arg.buf*. The argument *semnum* is ignored. The calling process must have read permission on the semaphore set.

IPC_SET
Write the values of some members of the *semid_ds* structure pointed to by *arg.buf* to the kernel data structure associated with this semaphore set, updating also its *sem_ctime* member.

The following members of the structure are updated: *sem_perm.uid*, *sem_perm.gid*, and (the least significant 9 bits of) *sem_perm.mode*.

The effective UID of the calling process must match the owner (*sem_perm.uid*) or creator (*sem_perm.cuid*) of the semaphore set, or the caller must be privileged. The argument *semnum* is ignored.

IPC_RMID
Immediately remove the semaphore set, awakening all processes blocked in *semop*(2) calls on the set (with an error return and *errno* set to **EIDRM**). The effective user ID of the calling process must match the creator or owner of the semaphore set, or the caller must be privileged. The argument *semnum* is ignored.

IPC_INFO (Linux-specific)
Return information about system-wide semaphore limits and parameters in the structure pointed to by *arg.__buf*. This structure is of type *seminfo*, defined in <*sys/sem.h*> if the **_GNU_SOURCE** feature test macro is defined:

```
struct  seminfo {
    int semmap;  /* Number of entries in semaphore
                    map; unused within kernel */
    int semmni;  /* Maximum number of semaphore sets */
    int semmns;  /* Maximum number of semaphores in all
                    semaphore sets */
    int semmnu;  /* System-wide maximum number of undo
                    structures; unused within kernel */
    int semmsl;  /* Maximum number of semaphores in a
                    set */
    int semopm;  /* Maximum number of operations for
                    semop(2) */
    int semume;  /* Maximum number of undo entries per
                    process; unused within kernel */
    int semusz;  /* Size of struct sem_undo */
    int semvmx;  /* Maximum semaphore value */
    int semaem;  /* Max. value that can be recorded for
                    semaphore adjustment (SEM_UNDO) */
};
```

The *semmsl*, *semmns*, *semopm*, and *semmni* settings can be changed via */proc/sys/kernel/sem*; see *proc*(5) for details.

SEM_INFO (Linux-specific)
Return a *seminfo* structure containing the same information as for **IPC_INFO**, except that the following fields are returned with information about system resources consumed by semaphores: the *semusz* field returns the number of semaphore sets that currently exist on the system; and the *semaem* field returns the total number of semaphores in all semaphore sets on the system.

SEM_STAT (Linux-specific)
Return a *semid_ds* structure as for **IPC_STAT**. However, the *semid* argument is not a semaphore identifier, but instead an index into the kernel's internal array that maintains information about all semaphore sets on the system.

SEM_STAT_ANY (Linux-specific, since Linux 4.17)
Return a *semid_ds* structure as for **SEM_STAT**. However, *sem_perm.mode* is not checked for read access for *semid* meaning that any user can employ this operation (just as any user may read */proc/sysvipc/sem* to obtain the same information).

GETALL
Return **semval** (i.e., the current value) for all semaphores of the set into *arg.array*. The argument *semnum* is ignored. The calling process must have read permission on the semaphore set.

GETNCNT
Return the **semncnt** value for the *semnum*−th semaphore of the set (i.e., the number of processes waiting for the semaphore's value to increase). The calling process must have read permission on the semaphore set.

GETPID
Return the **sempid** value for the *semnum*−th semaphore of the set. This is the PID of the process that last performed an operation on that semaphore (but see NOTES). The calling process must have read permission on the semaphore set.

GETVAL
Return **semval** (i.e., the semaphore value) for the *semnum*−th semaphore of the set. The calling process must have read permission on the semaphore set.

GETZCNT
Return the **semzcnt** value for the *semnum*−th semaphore of the set (i.e., the number of processes waiting for the semaphore value to become 0). The calling process must have read permission on the semaphore set.

SETALL
Set the **semval** values for all semaphores of the set using *arg.array*, updating also the *sem_ctime* member of the *semid_ds* structure associated with the set. Undo entries (see *semop*(2)) are cleared for altered semaphores in all processes. If the changes to semaphore values would permit blocked *semop*(2) calls in other processes to proceed, then those processes are woken up. The argument *semnum* is ignored. The calling process must have alter (write) permission on the semaphore set.

SETVAL
Set the semaphore value (**semval**) to *arg.val* for the *semnum*−th semaphore of the set, updating also the *sem_ctime* member of the *semid_ds* structure associated with the set. Undo entries are cleared for altered semaphores in all processes. If the changes to semaphore values would permit blocked *semop*(2) calls in other processes to proceed, then those processes are woken up. The calling process must have alter permission on the semaphore set.

RETURN VALUE
On success, **semctl**() returns a nonnegative value depending on *op* as follows:

GETNCNT
the value of **semncnt**.

GETPID
the value of **sempid**.

GETVAL
the value of **semval**.

GETZCNT
the value of **semzcnt**.

IPC_INFO
the index of the highest used entry in the kernel's internal array recording information about all semaphore sets. (This information can be used with repeated **SEM_STAT** or

SEM_STAT_ANY operations to obtain information about all semaphore sets on the system.)

SEM_INFO
as for **IPC_INFO**.

SEM_STAT
the identifier of the semaphore set whose index was given in *semid*.

SEM_STAT_ANY
as for **SEM_STAT**.

All other *op* values return 0 on success.

On failure, **semctl**() returns −1 and sets *errno* to indicate the error.

ERRORS

EACCES
The argument *op* has one of the values **GETALL**, **GETPID**, **GETVAL**, **GETNCNT**, **GETZCNT**, **IPC_STAT**, **SEM_STAT**, **SEM_STAT_ANY**, **SETALL**, or **SETVAL** and the calling process does not have the required permissions on the semaphore set and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EFAULT
The address pointed to by *arg.buf* or *arg.array* isn't accessible.

EIDRM
The semaphore set was removed.

EINVAL
Invalid value for *op* or *semid*. Or: for a **SEM_STAT** operation, the index value specified in *semid* referred to an array slot that is currently unused.

EPERM
The argument *op* has the value **IPC_SET** or **IPC_RMID** but the effective user ID of the calling process is not the creator (as found in *sem_perm.cuid*) or the owner (as found in *sem_perm.uid*) of the semaphore set, and the process does not have the **CAP_SYS_ADMIN** capability.

ERANGE
The argument *op* has the value **SETALL** or **SETVAL** and the value to which **semval** is to be set (for some semaphore of the set) is less than 0 or greater than the implementation limit **SEMVMX**.

VERSIONS

POSIX.1 specifies the *sem_nsems* field of the *semid_ds* structure as having the type *unsigned short*, and the field is so defined on most other systems. It was also so defined on Linux 2.2 and earlier, but, since Linux 2.4, the field has the type *unsigned long*.

The sempid value

POSIX.1 defines *sempid* as the "process ID of [the] last operation" on a semaphore, and explicitly notes that this value is set by a successful *semop*(2) call, with the implication that no other interface affects the *sempid* value.

While some implementations conform to the behavior specified in POSIX.1, others do not. (The fault here probably lies with POSIX.1 inasmuch as it likely failed to capture the full range of existing implementation behaviors.) Various other implementations also update *sempid* for the other operations that update the value of a semaphore: the **SETVAL** and **SETALL** operations, as well as the semaphore adjustments performed on process termination as a consequence of the use of the **SEM_UNDO** flag (see *semop*(2)).

Linux also updates *sempid* for **SETVAL** operations and semaphore adjustments. However, somewhat inconsistently, up to and including Linux 4.5, the kernel did not update *sempid* for **SETALL** operations. This was rectified in Linux 4.6.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

Various fields in a *struct semid_ds* were typed as *short* under Linux 2.2 and have become *long* under Linux 2.4. To take advantage of this, a recompilation under glibc-2.1.91 or later should suffice. (The kernel distinguishes old and new calls by an **IPC_64** flag in *op*.)

In some earlier versions of glibc, the *semun* union was defined in <*sys/sem.h*>, but POSIX.1 requires that the caller define this union. On versions of glibc where this union is *not* defined, the macro **_SEM_SEMUN_UNDEFINED** is defined in <*sys/sem.h*>.

NOTES

The **IPC_INFO**, **SEM_STAT**, and **SEM_INFO** operations are used by the *ipcs*(1) program to provide information on allocated resources. In the future these may modified or moved to a */proc* filesystem interface.

The following system limit on semaphore sets affects a **semctl**() call:

SEMVMX
Maximum value for **semval**: implementation dependent (32767).

For greater portability, it is best to always call **semctl**() with four arguments.

EXAMPLES

See *shmop*(2).

NAME

semget − get a System V semaphore set identifier

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/sem.h>

int semget(key_t *key***, int** *nsems***, int** *semflg***);**

DESCRIPTION

The **semget**() system call returns the System V semaphore set identifier associated with the argument *key*. It may be used either to obtain the identifier of a previously created semaphore set (when *semflg* is zero and *key* does not have the value **IPC_PRIVATE**), or to create a new set.

A new set of *nsems* semaphores is created if *key* has the value **IPC_PRIVATE** or if no existing semaphore set is associated with *key* and **IPC_CREAT** is specified in *semflg*.

If *semflg* specifies both **IPC_CREAT** and **IPC_EXCL** and a semaphore set already exists for *key*, then **semget**() fails with *errno* set to **EEXIST**. (This is analogous to the effect of the combination **O_CREAT | O_EXCL** for *open*(2).)

Upon creation, the least significant 9 bits of the argument *semflg* define the permissions (for owner, group, and others) for the semaphore set. These bits have the same format, and the same meaning, as the *mode* argument of *open*(2) (though the execute permissions are not meaningful for semaphores, and write permissions mean permission to alter semaphore values).

When creating a new semaphore set, **semget**() initializes the set's associated data structure, *semid_ds* (see *semctl*(2)), as follows:

- *sem_perm.cuid* and *sem_perm.uid* are set to the effective user ID of the calling process.
- *sem_perm.cgid* and *sem_perm.gid* are set to the effective group ID of the calling process.
- The least significant 9 bits of *sem_perm.mode* are set to the least significant 9 bits of *semflg*.
- *sem_nsems* is set to the value of *nsems*.
- *sem_otime* is set to 0.
- *sem_ctime* is set to the current time.

The argument *nsems* can be 0 (a don't care) when a semaphore set is not being created. Otherwise, *nsems* must be greater than 0 and less than or equal to the maximum number of semaphores per semaphore set (**SEMMSL**).

If the semaphore set already exists, the permissions are verified.

RETURN VALUE

On success, **semget**() returns the semaphore set identifier (a nonnegative integer). On failure, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
: A semaphore set exists for *key*, but the calling process does not have permission to access the set, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EEXIST
: **IPC_CREAT** and **IPC_EXCL** were specified in *semflg*, but a semaphore set already exists for *key*.

EINVAL
: *nsems* is less than 0 or greater than the limit on the number of semaphores per semaphore set (**SEMMSL**).

EINVAL
: A semaphore set corresponding to *key* already exists, but *nsems* is larger than the number of semaphores in that set.

ENOENT
No semaphore set exists for *key* and *semflg* did not specify **IPC_CREAT**.

ENOMEM
A semaphore set has to be created but the system does not have enough memory for the new data structure.

ENOSPC
A semaphore set has to be created but the system limit for the maximum number of semaphore sets (**SEMMNI**), or the system wide maximum number of semaphores (**SEMMNS**), would be exceeded.

STANDARDS
POSIX.1-2008.

HISTORY
SVr4, POSIX.1-2001.

NOTES
IPC_PRIVATE isn't a flag field but a *key_t* type. If this special value is used for *key*, the system call ignores all but the least significant 9 bits of *semflg* and creates a new semaphore set (on success).

Semaphore initialization
The values of the semaphores in a newly created set are indeterminate. (POSIX.1-2001 and POSIX.1-2008 are explicit on this point, although POSIX.1-2008 notes that a future version of the standard may require an implementation to initialize the semaphores to 0.) Although Linux, like many other implementations, initializes the semaphore values to 0, a portable application cannot rely on this: it should explicitly initialize the semaphores to the desired values.

Initialization can be done using *semctl*(2) **SETVAL** or **SETALL** operation. Where multiple peers do not know who will be the first to initialize the set, checking for a nonzero *sem_otime* in the associated data structure retrieved by a *semctl*(2) **IPC_STAT** operation can be used to avoid races.

Semaphore limits
The following limits on semaphore set resources affect the **semget**() call:

SEMMNI
System-wide limit on the number of semaphore sets. Before Linux 3.19, the default value for this limit was 128. Since Linux 3.19, the default value is 32,000. On Linux, this limit can be read and modified via the fourth field of */proc/sys/kernel/sem*.

SEMMSL
Maximum number of semaphores per semaphore ID. Before Linux 3.19, the default value for this limit was 250. Since Linux 3.19, the default value is 32,000. On Linux, this limit can be read and modified via the first field of */proc/sys/kernel/sem*.

SEMMNS
System-wide limit on the number of semaphores: policy dependent (on Linux, this limit can be read and modified via the second field of */proc/sys/kernel/sem*). Note that the number of semaphores system-wide is also limited by the product of **SEMMSL** and **SEMMNI**.

BUGS
The name choice **IPC_PRIVATE** was perhaps unfortunate, **IPC_NEW** would more clearly show its function.

EXAMPLES
The program shown below uses **semget**() to create a new semaphore set or retrieve the ID of an existing set. It generates the *key* for **semget**() using *ftok*(3). The first two command-line arguments are used as the *pathname* and *proj_id* arguments for *ftok*(3). The third command-line argument is an integer that specifies the *nsems* argument for **semget**(). Command-line options can be used to specify the **IPC_CREAT** (*−c*) and **IPC_EXCL** (*−x*) flags for the call to **semget**(). The usage of this program is demonstrated below.

We first create two files that will be used to generate keys using *ftok*(3), create two semaphore sets using those files, and then list the sets using *ipcs*(1):

```
$ touch mykey mykey2
$ ./t_semget -c mykey p 1
```

```
ID = 9
$ ./t_semget -c mykey2 p 2
ID = 10
$ ipcs -s

------ Semaphore Arrays --------
key        semid      owner      perms      nsems
0x7004136d 9          mtk        600        1
0x70041368 10         mtk        600        2
```

Next, we demonstrate that when *semctl*(2) is given the same *key* (as generated by the same arguments to *ftok*(3)), it returns the ID of the already existing semaphore set:

```
$ ./t_semget -c mykey p 1
ID = 9
```

Finally, we demonstrate the kind of collision that can occur when *ftok*(3) is given different *pathname* arguments that have the same inode number:

```
$ ln mykey link
$ ls -i1 link mykey
2233197 link
2233197 mykey
$ ./t_semget link p 1       # Generates same key as 'mykey'
ID = 9
```

*/
#include <stdio.h>
#include <stdlib.h>
#include <sys/ipc.h>
#include <sys/sem.h>
#include <unistd.h>

static void
usage(const char *pname)
{
    fprintf(stderr, "Usage: %s [-cx] pathname proj-id num-sems\n",
            pname);
    fprintf(stderr, "    -c           Use IPC_CREAT flag\n");
    fprintf(stderr, "    -x           Use IPC_EXCL flag\n");
    exit(EXIT_FAILURE);
}

int
main(int argc, char *argv[])
{
    int    semid, nsems, flags, opt;
    key_t  key;

    flags = 0;
    while ((opt = getopt(argc, argv, "cx")) != -1) {
        switch (opt) {
        case 'c': flags |= IPC_CREAT;   break;
        case 'x': flags |= IPC_EXCL;    break;
        default:  usage(argv[0]);
        }
    }
```

```
        if (argc != optind + 3)
            usage(argv[0]);

        key = ftok(argv[optind], argv[optind + 1][0]);
        if (key == -1) {
            perror("ftok");
            exit(EXIT_FAILURE);
        }

        nsems = atoi(argv[optind + 2]);

        semid = semget(key, nsems, flags | 0600);
        if (semid == -1) {
            perror("semget");
            exit(EXIT_FAILURE);
        }

        printf("ID = %d\n", semid);

        exit(EXIT_SUCCESS);
    }
```

NAME

semop, semtimedop − System V semaphore operations

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/sem.h>

int semop(int semid, struct sembuf *sops, size_t nsops);
int semtimedop(int semid, struct sembuf *sops, size_t nsops,
               const struct timespec *_Nullable timeout);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

semtimedop():
_GNU_SOURCE

DESCRIPTION

Each semaphore in a System V semaphore set has the following associated values:

```
unsigned short  semval;   /* semaphore value */
unsigned short  semzcnt;  /* # waiting for zero */
unsigned short  semncnt;  /* # waiting for increase */
pid_t           sempid;   /* PID of process that last
                             modified the semaphore value */
```

semop() performs operations on selected semaphores in the set indicated by *semid*. Each of the *nsops* elements in the array pointed to by *sops* is a structure that specifies an operation to be performed on a single semaphore. The elements of this structure are of type *struct sembuf*, containing the following members:

```
unsigned short sem_num;  /* semaphore number */
short          sem_op;   /* semaphore operation */
short          sem_flg;  /* operation flags */
```

Flags recognized in *sem_flg* are **IPC_NOWAIT** and **SEM_UNDO**. If an operation specifies **SEM_UNDO**, it will be automatically undone when the process terminates.

The set of operations contained in *sops* is performed in *array order*, and *atomically*, that is, the operations are performed either as a complete unit, or not at all. The behavior of the system call if not all operations can be performed immediately depends on the presence of the **IPC_NOWAIT** flag in the individual *sem_flg* fields, as noted below.

Each operation is performed on the *sem_num*−th semaphore of the semaphore set, where the first semaphore of the set is numbered 0. There are three types of operation, distinguished by the value of *sem_op*.

If *sem_op* is a positive integer, the operation adds this value to the semaphore value (*semval*). Furthermore, if **SEM_UNDO** is specified for this operation, the system subtracts the value *sem_op* from the semaphore adjustment (*semadj*) value for this semaphore. This operation can always proceed—it never forces a thread to wait. The calling process must have alter permission on the semaphore set.

If *sem_op* is zero, the process must have read permission on the semaphore set. This is a "wait-for-zero" operation: if *semval* is zero, the operation can immediately proceed. Otherwise, if **IPC_NOWAIT** is specified in *sem_flg*, **semop**() fails with *errno* set to **EAGAIN** (and none of the operations in *sops* is performed). Otherwise, *semzcnt* (the count of threads waiting until this semaphore's value becomes zero) is incremented by one and the thread sleeps until one of the following occurs:

- *semval* becomes 0, at which time the value of *semzcnt* is decremented.
- The semaphore set is removed: **semop**() fails, with *errno* set to **EIDRM**.
- The calling thread catches a signal: the value of *semzcnt* is decremented and **semop**() fails, with *errno* set to **EINTR**.

If *sem_op* is less than zero, the process must have alter permission on the semaphore set. If *semval* is greater than or equal to the absolute value of *sem_op*, the operation can proceed immediately: the absolute value of *sem_op* is subtracted from *semval*, and, if **SEM_UNDO** is specified for this operation,

the system adds the absolute value of *sem_op* to the semaphore adjustment (*semadj*) value for this semaphore. If the absolute value of *sem_op* is greater than *semval*, and **IPC_NOWAIT** is specified in *sem_flg*, **semop**() fails, with *errno* set to **EAGAIN** (and none of the operations in *sops* is performed). Otherwise, *semncnt* (the counter of threads waiting for this semaphore's value to increase) is incremented by one and the thread sleeps until one of the following occurs:

- *semval* becomes greater than or equal to the absolute value of *sem_op*: the operation now proceeds, as described above.
- The semaphore set is removed from the system: **semop**() fails, with *errno* set to **EIDRM**.
- The calling thread catches a signal: the value of *semncnt* is decremented and **semop**() fails, with *errno* set to **EINTR**.

On successful completion, the *sempid* value for each semaphore specified in the array pointed to by *sops* is set to the caller's process ID. In addition, the *sem_otime* is set to the current time.

semtimedop()

semtimedop() behaves identically to **semop**() except that in those cases where the calling thread would sleep, the duration of that sleep is limited by the amount of elapsed time specified by the *timespec* structure whose address is passed in the *timeout* argument. (This sleep interval will be rounded up to the system clock granularity, and kernel scheduling delays mean that the interval may overrun by a small amount.) If the specified time limit has been reached, **semtimedop**() fails with *errno* set to **EAGAIN** (and none of the operations in *sops* is performed). If the *timeout* argument is NULL, then **semtimedop**() behaves exactly like **semop**().

Note that if **semtimedop**() is interrupted by a signal, causing the call to fail with the error **EINTR**, the contents of *timeout* are left unchanged.

RETURN VALUE

On success, **semop**() and **semtimedop**() return 0. On failure, they return −1, and set *errno* to indicate the error.

ERRORS

E2BIG The argument *nsops* is greater than **SEMOPM**, the maximum number of operations allowed per system call.

EACCES
The calling process does not have the permissions required to perform the specified semaphore operations, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EAGAIN
An operation could not proceed immediately and either **IPC_NOWAIT** was specified in *sem_flg* or the time limit specified in *timeout* expired.

EFAULT
An address specified in either the *sops* or the *timeout* argument isn't accessible.

EFBIG
For some operation the value of *sem_num* is less than 0 or greater than or equal to the number of semaphores in the set.

EIDRM
The semaphore set was removed.

EINTR
While blocked in this system call, the thread caught a signal; see *signal*(7).

EINVAL
The semaphore set doesn't exist, or *semid* is less than zero, or *nsops* has a nonpositive value.

ENOMEM
The *sem_flg* of some operation specified **SEM_UNDO** and the system does not have enough memory to allocate the undo structure.

ERANGE
For some operation *sem_op*+*semval* is greater than **SEMVMX**, the implementation dependent maximum value for *semval*.

STANDARDS

POSIX.1-2008.

VERSIONS

Linux 2.5.52 (backported into Linux 2.4.22), glibc 2.3.3. POSIX.1-2001, SVr4.

NOTES

The *sem_undo* structures of a process aren't inherited by the child produced by *fork*(2), but they are inherited across an *execve*(2) system call.

semop() is never automatically restarted after being interrupted by a signal handler, regardless of the setting of the **SA_RESTART** flag when establishing a signal handler.

A semaphore adjustment (*semadj*) value is a per-process, per-semaphore integer that is the negated sum of all operations performed on a semaphore specifying the **SEM_UNDO** flag. Each process has a list of *semadj* values—one value for each semaphore on which it has operated using **SEM_UNDO**. When a process terminates, each of its per-semaphore *semadj* values is added to the corresponding semaphore, thus undoing the effect of that process's operations on the semaphore (but see BUGS below). When a semaphore's value is directly set using the **SETVAL** or **SETALL** request to *semctl*(2), the corresponding *semadj* values in all processes are cleared. The *clone*(2) **CLONE_SYSVSEM** flag allows more than one process to share a *semadj* list; see *clone*(2) for details.

The *semval*, *sempid*, *semzcnt*, and *semnct* values for a semaphore can all be retrieved using appropriate *semctl*(2) calls.

Semaphore limits

The following limits on semaphore set resources affect the **semop**() call:

SEMOPM
: Maximum number of operations allowed for one **semop**() call. Before Linux 3.19, the default value for this limit was 32. Since Linux 3.19, the default value is 500. On Linux, this limit can be read and modified via the third field of */proc/sys/kernel/sem*. *Note*: this limit should not be raised above 1000, because of the risk of that **semop**() fails due to kernel memory fragmentation when allocating memory to copy the *sops* array.

SEMVMX
: Maximum allowable value for *semval*: implementation dependent (32767).

The implementation has no intrinsic limits for the adjust on exit maximum value (**SEMAEM**), the system wide maximum number of undo structures (**SEMMNU**) and the per-process maximum number of undo entries system parameters.

BUGS

When a process terminates, its set of associated *semadj* structures is used to undo the effect of all of the semaphore operations it performed with the **SEM_UNDO** flag. This raises a difficulty: if one (or more) of these semaphore adjustments would result in an attempt to decrease a semaphore's value below zero, what should an implementation do? One possible approach would be to block until all the semaphore adjustments could be performed. This is however undesirable since it could force process termination to block for arbitrarily long periods. Another possibility is that such semaphore adjustments could be ignored altogether (somewhat analogously to failing when **IPC_NOWAIT** is specified for a semaphore operation). Linux adopts a third approach: decreasing the semaphore value as far as possible (i.e., to zero) and allowing process termination to proceed immediately.

In Linux 2.6.x, x <= 10, there is a bug that in some circumstances prevents a thread that is waiting for a semaphore value to become zero from being woken up when the value does actually become zero. This bug is fixed in Linux 2.6.11.

EXAMPLES

The following code segment uses **semop**() to atomically wait for the value of semaphore 0 to become zero, and then increment the semaphore value by one.

```
struct sembuf sops[2];
int semid;

/* Code to set semid omitted */
```

```
sops[0].sem_num = 0;        /* Operate on semaphore 0 */
sops[0].sem_op = 0;         /* Wait for value to equal 0 */
sops[0].sem_flg = 0;

sops[1].sem_num = 0;        /* Operate on semaphore 0 */
sops[1].sem_op = 1;         /* Increment value by one */
sops[1].sem_flg = 0;

if (semop(semid, sops, 2) == -1) {
    perror("semop");
    exit(EXIT_FAILURE);
}
```

A further example of the use of **semop**() can be found in *shmop*(2).

NAME

send, sendto, sendmsg − send a message on a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/socket.h>

ssize_t send(int *sockfd***, const void** *buf***[.***len***], size_t** *len***, int** *flags***);**
ssize_t sendto(int *sockfd***, const void** *buf***[.***len***], size_t** *len***, int** *flags***,**
const struct sockaddr ***dest_addr*, socklen_t** *addrlen***);**
ssize_t sendmsg(int *sockfd***, const struct msghdr ***msg***, int** *flags***);**

DESCRIPTION

The system calls **send**(), **sendto**(), and **sendmsg**() are used to transmit a message to another socket.

The **send**() call may be used only when the socket is in a *connected* state (so that the intended recipient is known). The only difference between **send**() and *write*(2) is the presence of *flags*. With a zero *flags* argument, **send**() is equivalent to *write*(2). Also, the following call

```
send(sockfd, buf, len, flags);
```

is equivalent to

```
sendto(sockfd, buf, len, flags, NULL, 0);
```

The argument *sockfd* is the file descriptor of the sending socket.

If **sendto**() is used on a connection-mode (**SOCK_STREAM**, **SOCK_SEQPACKET**) socket, the arguments *dest_addr* and *addrlen* are ignored (and the error **EISCONN** may be returned when they are not NULL and 0), and the error **ENOTCONN** is returned when the socket was not actually connected. Otherwise, the address of the target is given by *dest_addr* with *addrlen* specifying its size. For **sendmsg**(), the address of the target is given by *msg.msg_name*, with *msg.msg_namelen* specifying its size.

For **send**() and **sendto**(), the message is found in *buf* and has length *len*. For **sendmsg**(), the message is pointed to by the elements of the array *msg.msg_iov*. The **sendmsg**() call also allows sending ancillary data (also known as control information).

If the message is too long to pass atomically through the underlying protocol, the error **EMSGSIZE** is returned, and the message is not transmitted.

No indication of failure to deliver is implicit in a **send**(). Locally detected errors are indicated by a return value of −1.

When the message does not fit into the send buffer of the socket, **send**() normally blocks, unless the socket has been placed in nonblocking I/O mode. In nonblocking mode it would fail with the error **EAGAIN** or **EWOULDBLOCK** in this case. The *select*(2) call may be used to determine when it is possible to send more data.

The flags argument

The *flags* argument is the bitwise OR of zero or more of the following flags.

MSG_CONFIRM (since Linux 2.3.15)
: Tell the link layer that forward progress happened: you got a successful reply from the other side. If the link layer doesn't get this it will regularly reprobe the neighbor (e.g., via a unicast ARP). Valid only on **SOCK_DGRAM** and **SOCK_RAW** sockets and currently implemented only for IPv4 and IPv6. See *arp*(7) for details.

MSG_DONTROUTE
: Don't use a gateway to send out the packet, send to hosts only on directly connected networks. This is usually used only by diagnostic or routing programs. This is defined only for protocol families that route; packet sockets don't.

MSG_DONTWAIT (since Linux 2.2)
: Enables nonblocking operation; if the operation would block, **EAGAIN** or **EWOULDBLOCK** is returned. This provides similar behavior to setting the **O_NONBLOCK** flag (via the *fcntl*(2) **F_SETFL** operation), but differs in that **MSG_DONTWAIT** is a per-call option,

whereas **O_NONBLOCK** is a setting on the open file description (see *open*(2)), which will affect all threads in the calling process as well as other processes that hold file descriptors referring to the same open file description.

MSG_EOR (since Linux 2.2)
Terminates a record (when this notion is supported, as for sockets of type **SOCK_SEQPACKET**).

MSG_MORE (since Linux 2.4.4)
The caller has more data to send. This flag is used with TCP sockets to obtain the same effect as the **TCP_CORK** socket option (see *tcp*(7)), with the difference that this flag can be set on a per-call basis.

Since Linux 2.6, this flag is also supported for UDP sockets, and informs the kernel to package all of the data sent in calls with this flag set into a single datagram which is transmitted only when a call is performed that does not specify this flag. (See also the **UDP_CORK** socket option described in *udp*(7).)

MSG_NOSIGNAL (since Linux 2.2)
Don't generate a **SIGPIPE** signal if the peer on a stream-oriented socket has closed the connection. The **EPIPE** error is still returned. This provides similar behavior to using *sigaction*(2) to ignore **SIGPIPE**, but, whereas **MSG_NOSIGNAL** is a per-call feature, ignoring **SIGPIPE** sets a process attribute that affects all threads in the process.

MSG_OOB
Sends *out-of-band* data on sockets that support this notion (e.g., of type **SOCK_STREAM**); the underlying protocol must also support *out-of-band* data.

MSG_FASTOPEN (since Linux 3.7)
Attempts TCP Fast Open (RFC7413) and sends data in the SYN like a combination of *connect*(2) and *write*(2), by performing an implicit *connect*(2) operation. It blocks until the data is buffered and the handshake has completed. For a non-blocking socket, it returns the number of bytes buffered and sent in the SYN packet. If the cookie is not available locally, it returns **EINPROGRESS**, and sends a SYN with a Fast Open cookie request automatically. The caller needs to write the data again when the socket is connected. On errors, it sets the same *errno* as *connect*(2) if the handshake fails. This flag requires enabling TCP Fast Open client support on sysctl *net.ipv4.tcp_fastopen*.

Refer to **TCP_FASTOPEN_CONNECT** socket option in *tcp*(7) for an alternative approach.

sendmsg()
The definition of the *msghdr* structure employed by **sendmsg**() is as follows:

```
struct msghdr {
    void         *msg_name;       /* Optional address */
    socklen_t     msg_namelen;    /* Size of address */
    struct iovec *msg_iov;        /* Scatter/gather array */
    size_t        msg_iovlen;     /* # elements in msg_iov */
    void         *msg_control;    /* Ancillary data, see below */
    size_t        msg_controllen; /* Ancillary data buffer len */
    int           msg_flags;      /* Flags (unused) */
};
```

The *msg_name* field is used on an unconnected socket to specify the target address for a datagram. It points to a buffer containing the address; the *msg_namelen* field should be set to the size of the address. For a connected socket, these fields should be specified as NULL and 0, respectively.

The *msg_iov* and *msg_iovlen* fields specify scatter-gather locations, as for *writev*(2).

You may send control information (ancillary data) using the *msg_control* and *msg_controllen* members. The maximum control buffer length the kernel can process is limited per socket by the value in */proc/sys/net/core/optmem_max*; see *socket*(7). For further information on the use of ancillary data in various socket domains, see *unix*(7) and *ip*(7).

The *msg_flags* field is ignored.

RETURN VALUE

On success, these calls return the number of bytes sent. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

These are some standard errors generated by the socket layer. Additional errors may be generated and returned from the underlying protocol modules; see their respective manual pages.

EACCES

(For UNIX domain sockets, which are identified by pathname) Write permission is denied on the destination socket file, or search permission is denied for one of the directories the path prefix. (See *path_resolution*(7).)

(For UDP sockets) An attempt was made to send to a network/broadcast address as though it was a unicast address.

EAGAIN or **EWOULDBLOCK**

The socket is marked nonblocking and the requested operation would block. POSIX.1-2001 allows either error to be returned for this case, and does not require these constants to have the same value, so a portable application should check for both possibilities.

EAGAIN

(Internet domain datagram sockets) The socket referred to by *sockfd* had not previously been bound to an address and, upon attempting to bind it to an ephemeral port, it was determined that all port numbers in the ephemeral port range are currently in use. See the discussion of */proc/sys/net/ipv4/ip_local_port_range* in *ip*(7).

EALREADY

Another Fast Open is in progress.

EBADF

sockfd is not a valid open file descriptor.

ECONNRESET

Connection reset by peer.

EDESTADDRREQ

The socket is not connection-mode, and no peer address is set.

EFAULT

An invalid user space address was specified for an argument.

EINTR

A signal occurred before any data was transmitted; see *signal*(7).

EINVAL

Invalid argument passed.

EISCONN

The connection-mode socket was connected already but a recipient was specified. (Now either this error is returned, or the recipient specification is ignored.)

EMSGSIZE

The socket type requires that message be sent atomically, and the size of the message to be sent made this impossible.

ENOBUFS

The output queue for a network interface was full. This generally indicates that the interface has stopped sending, but may be caused by transient congestion. (Normally, this does not occur in Linux. Packets are just silently dropped when a device queue overflows.)

ENOMEM

No memory available.

ENOTCONN

The socket is not connected, and no target has been given.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

EOPNOTSUPP
Some bit in the *flags* argument is inappropriate for the socket type.

EPIPE The local end has been shut down on a connection oriented socket. In this case, the process will also receive a **SIGPIPE** unless **MSG_NOSIGNAL** is set.

VERSIONS

According to POSIX.1-2001, the *msg_controllen* field of the *msghdr* structure should be typed as *socklen_t*, and the *msg_iovlen* field should be typed as *int*, but glibc currently types both as *size_t*.

STANDARDS

POSIX.1-2008.

MSG_CONFIRM is a Linux extension.

HISTORY

4.4BSD, SVr4, POSIX.1-2001. (first appeared in 4.2BSD).

POSIX.1-2001 describes only the **MSG_OOB** and **MSG_EOR** flags. POSIX.1-2008 adds a specification of **MSG_NOSIGNAL**.

NOTES

See *sendmmsg*(2) for information about a Linux-specific system call that can be used to transmit multiple datagrams in a single call.

BUGS

Linux may return **EPIPE** instead of **ENOTCONN**.

EXAMPLES

An example of the use of **sendto**() is shown in *getaddrinfo*(3).

NAME

sendfile − transfer data between file descriptors

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/sendfile.h>

ssize_t sendfile(int *out_fd***, int** *in_fd***, off_t *_Nullable** *offset***,**
size_t *count***);**

DESCRIPTION

sendfile() copies data between one file descriptor and another. Because this copying is done within the kernel, **sendfile**() is more efficient than the combination of *read*(2) and *write*(2), which would require transferring data to and from user space.

in_fd should be a file descriptor opened for reading and *out_fd* should be a descriptor opened for writing.

If *offset* is not NULL, then it points to a variable holding the file offset from which **sendfile**() will start reading data from *in_fd*. When **sendfile**() returns, this variable will be set to the offset of the byte following the last byte that was read. If *offset* is not NULL, then **sendfile**() does not modify the file offset of *in_fd*; otherwise the file offset is adjusted to reflect the number of bytes read from *in_fd*.

If *offset* is NULL, then data will be read from *in_fd* starting at the file offset, and the file offset will be updated by the call.

count is the number of bytes to copy between the file descriptors.

The *in_fd* argument must correspond to a file which supports *mmap*(2)-like operations (i.e., it cannot be a socket). Except since Linux 5.12 and if *out_fd* is a pipe, in which case **sendfile**() desugars to a *splice*(2) and its restrictions apply.

Before Linux 2.6.33, *out_fd* must refer to a socket. Since Linux 2.6.33 it can be any file. If it's seekable, then **sendfile**() changes the file offset appropriately.

RETURN VALUE

If the transfer was successful, the number of bytes written to *out_fd* is returned. Note that a successful call to **sendfile**() may write fewer bytes than requested; the caller should be prepared to retry the call if there were unsent bytes. See also NOTES.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EAGAIN
Nonblocking I/O has been selected using **O_NONBLOCK** and the write would block.

EBADF
The input file was not opened for reading or the output file was not opened for writing.

EFAULT
Bad address.

EINVAL
Descriptor is not valid or locked, or an *mmap*(2)-like operation is not available for *in_fd*, or *count* is negative.

EINVAL
out_fd has the **O_APPEND** flag set. This is not currently supported by **sendfile**().

EIO Unspecified error while reading from *in_fd*.

ENOMEM
Insufficient memory to read from *in_fd*.

EOVERFLOW
count is too large, the operation would result in exceeding the maximum size of either the input file or the output file.

ESPIPE
offset is not NULL but the input file is not seekable.

VERSIONS

Other UNIX systems implement **sendfile**() with different semantics and prototypes. It should not be used in portable programs.

STANDARDS

None.

HISTORY

Linux 2.2, glibc 2.1.

In Linux 2.4 and earlier, *out_fd* could also refer to a regular file; this possibility went away in the Linux 2.6.x kernel series, but was restored in Linux 2.6.33.

The original Linux **sendfile**() system call was not designed to handle large file offsets. Consequently, Linux 2.4 added **sendfile64**(), with a wider type for the *offset* argument. The glibc **sendfile**() wrapper function transparently deals with the kernel differences.

NOTES

sendfile() will transfer at most 0x7ffff000 (2,147,479,552) bytes, returning the number of bytes actually transferred. (This is true on both 32-bit and 64-bit systems.)

If you plan to use **sendfile**() for sending files to a TCP socket, but need to send some header data in front of the file contents, you will find it useful to employ the **TCP_CORK** option, described in *tcp*(7), to minimize the number of packets and to tune performance.

Applications may wish to fall back to *read*(2) and *write*(2) in the case where **sendfile**() fails with **EINVAL** or **ENOSYS**.

If *out_fd* refers to a socket or pipe with zero-copy support, callers must ensure the transferred portions of the file referred to by *in_fd* remain unmodified until the reader on the other end of *out_fd* has consumed the transferred data.

The Linux-specific *splice*(2) call supports transferring data between arbitrary file descriptors provided one (or both) of them is a pipe.

SEE ALSO

copy_file_range(2), *mmap*(2), *open*(2), *socket*(2), *splice*(2)

NAME

sendmmsg − send multiple messages on a socket

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sys/socket.h>

int sendmmsg(int sockfd, struct mmsghdr *msgvec, unsigned int vlen,
             int flags);
```

DESCRIPTION

The **sendmmsg**() system call is an extension of *sendmsg*(2) that allows the caller to transmit multiple messages on a socket using a single system call. (This has performance benefits for some applications.)

The *sockfd* argument is the file descriptor of the socket on which data is to be transmitted.

The *msgvec* argument is a pointer to an array of *mmsghdr* structures. The size of this array is specified in *vlen*.

The *mmsghdr* structure is defined in <*sys/socket.h*> as:

```
struct mmsghdr {
    struct msghdr msg_hdr;  /* Message header */
    unsigned int  msg_len;  /* Number of bytes transmitted */
};
```

The *msg_hdr* field is a *msghdr* structure, as described in *sendmsg*(2). The *msg_len* field is used to return the number of bytes sent from the message in *msg_hdr* (i.e., the same as the return value from a single *sendmsg*(2) call).

The *flags* argument contains flags ORed together. The flags are the same as for *sendmsg*(2).

A blocking **sendmmsg**() call blocks until *vlen* messages have been sent. A nonblocking call sends as many messages as possible (up to the limit specified by *vlen*) and returns immediately.

On return from **sendmmsg**(), the *msg_len* fields of successive elements of *msgvec* are updated to contain the number of bytes transmitted from the corresponding *msg_hdr*. The return value of the call indicates the number of elements of *msgvec* that have been updated.

RETURN VALUE

On success, **sendmmsg**() returns the number of messages sent from *msgvec*; if this is less than *vlen*, the caller can retry with a further **sendmmsg**() call to send the remaining messages.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

Errors are as for *sendmsg*(2). An error is returned only if no datagrams could be sent. See also BUGS.

STANDARDS

Linux.

HISTORY

Linux 3.0, glibc 2.14.

NOTES

The value specified in *vlen* is capped to **UIO_MAXIOV** (1024).

BUGS

If an error occurs after at least one message has been sent, the call succeeds, and returns the number of messages sent. The error code is lost. The caller can retry the transmission, starting at the first failed message, but there is no guarantee that, if an error is returned, it will be the same as the one that was lost on the previous call.

EXAMPLES

The example below uses **sendmmsg**() to send *onetwo* and *three* in two distinct UDP datagrams using one system call. The contents of the first datagram originates from a pair of buffers.

```
#define _GNU_SOURCE
#include <arpa/inet.h>
#include <netinet/in.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/socket.h>
#include <sys/types.h>

int
main(void)
{
    int                 retval;
    int                 sockfd;
    struct iovec        msg1[2], msg2;
    struct mmsghdr      msg[2];
    struct sockaddr_in  addr;

    sockfd = socket(AF_INET, SOCK_DGRAM, 0);
    if (sockfd == -1) {
        perror("socket()");
        exit(EXIT_FAILURE);
    }

    addr.sin_family = AF_INET;
    addr.sin_addr.s_addr = htonl(INADDR_LOOPBACK);
    addr.sin_port = htons(1234);
    if (connect(sockfd, (struct sockaddr *) &addr, sizeof(addr)) == -1) {
        perror("connect()");
        exit(EXIT_FAILURE);
    }

    memset(msg1, 0, sizeof(msg1));
    msg1[0].iov_base = "one";
    msg1[0].iov_len = 3;
    msg1[1].iov_base = "two";
    msg1[1].iov_len = 3;

    memset(&msg2, 0, sizeof(msg2));
    msg2.iov_base = "three";
    msg2.iov_len = 5;

    memset(msg, 0, sizeof(msg));
    msg[0].msg_hdr.msg_iov = msg1;
    msg[0].msg_hdr.msg_iovlen = 2;

    msg[1].msg_hdr.msg_iov = &msg2;
    msg[1].msg_hdr.msg_iovlen = 1;

    retval = sendmmsg(sockfd, msg, 2, 0);
    if (retval == -1)
        perror("sendmmsg()");
    else
        printf("%d messages sent\n", retval);

    exit(0);
}
```

NAME

set_mempolicy − set default NUMA memory policy for a thread and its children

LIBRARY

NUMA (Non-Uniform Memory Access) policy library (*libnuma*, *−lnuma*)

SYNOPSIS

#include <numaif.h>

long set_mempolicy(int *mode***, const unsigned long ***_nodemask_**,**
unsigned long *maxnode***);**

DESCRIPTION

set_mempolicy() sets the NUMA memory policy of the calling thread, which consists of a policy mode and zero or more nodes, to the values specified by the *mode*, *nodemask*, and *maxnode* arguments.

A NUMA machine has different memory controllers with different distances to specific CPUs. The memory policy defines from which node memory is allocated for the thread.

This system call defines the default policy for the thread. The thread policy governs allocation of pages in the process's address space outside of memory ranges controlled by a more specific policy set by *mbind*(2). The thread default policy also controls allocation of any pages for memory-mapped files mapped using the *mmap*(2) call with the **MAP_PRIVATE** flag and that are only read (loaded) from by the thread and of memory-mapped files mapped using the *mmap*(2) call with the **MAP_SHARED** flag, regardless of the access type. The policy is applied only when a new page is allocated for the thread. For anonymous memory this is when the page is first touched by the thread.

The *mode* argument must specify one of **MPOL_DEFAULT**, **MPOL_BIND**, **MPOL_INTERLEAVE**, **MPOL_PREFERRED**, or **MPOL_LOCAL** (which are described in detail below). All modes except **MPOL_DEFAULT** require the caller to specify the node or nodes to which the mode applies, via the *nodemask* argument.

The *mode* argument may also include an optional *mode flag*. The supported *mode flags* are:

MPOL_F_NUMA_BALANCING (since Linux 5.12)
When *mode* is **MPOL_BIND**, enable the kernel NUMA balancing for the task if it is supported by the kernel. If the flag isn't supported by the kernel, or is used with *mode* other than **MPOL_BIND**, −1 is returned and *errno* is set to **EINVAL**.

MPOL_F_RELATIVE_NODES (since Linux 2.6.26)
A nonempty *nodemask* specifies node IDs that are relative to the set of node IDs allowed by the process's current cpuset.

MPOL_F_STATIC_NODES (since Linux 2.6.26)
A nonempty *nodemask* specifies physical node IDs. Linux will not remap the *nodemask* when the process moves to a different cpuset context, nor when the set of nodes allowed by the process's current cpuset context changes.

nodemask points to a bit mask of node IDs that contains up to *maxnode* bits. The bit mask size is rounded to the next multiple of *sizeof(unsigned long)*, but the kernel will use bits only up to *maxnode*. A NULL value of *nodemask* or a *maxnode* value of zero specifies the empty set of nodes. If the value of *maxnode* is zero, the *nodemask* argument is ignored.

Where a *nodemask* is required, it must contain at least one node that is on-line, allowed by the process's current cpuset context, (unless the **MPOL_F_STATIC_NODES** mode flag is specified), and contains memory. If the **MPOL_F_STATIC_NODES** is set in *mode* and a required *nodemask* contains no nodes that are allowed by the process's current cpuset context, the memory policy reverts to *local allocation*. This effectively overrides the specified policy until the process's cpuset context includes one or more of the nodes specified by *nodemask*.

The *mode* argument must include one of the following values:

MPOL_DEFAULT
This mode specifies that any nondefault thread memory policy be removed, so that the memory policy "falls back" to the system default policy. The system default policy is "local allocation"—that is, allocate memory on the node of the CPU that triggered the allocation. *nodemask* must be specified as NULL. If the "local node" contains no free memory, the system will attempt to allocate memory from a "near by" node.

MPOL_BIND
This mode defines a strict policy that restricts memory allocation to the nodes specified in *nodemask*. If *nodemask* specifies more than one node, page allocations will come from the node with the lowest numeric node ID first, until that node contains no free memory. Allocations will then come from the node with the next highest node ID specified in *nodemask* and so forth, until none of the specified nodes contain free memory. Pages will not be allocated from any node not specified in the *nodemask*.

MPOL_INTERLEAVE
This mode interleaves page allocations across the nodes specified in *nodemask* in numeric node ID order. This optimizes for bandwidth instead of latency by spreading out pages and memory accesses to those pages across multiple nodes. However, accesses to a single page will still be limited to the memory bandwidth of a single node.

MPOL_PREFERRED
This mode sets the preferred node for allocation. The kernel will try to allocate pages from this node first and fall back to "near by" nodes if the preferred node is low on free memory. If *nodemask* specifies more than one node ID, the first node in the mask will be selected as the preferred node. If the *nodemask* and *maxnode* arguments specify the empty set, then the policy specifies "local allocation" (like the system default policy discussed above).

MPOL_LOCAL (since Linux 3.8)
This mode specifies "local allocation"; the memory is allocated on the node of the CPU that triggered the allocation (the "local node"). The *nodemask* and *maxnode* arguments must specify the empty set. If the "local node" is low on free memory, the kernel will try to allocate memory from other nodes. The kernel will allocate memory from the "local node" whenever memory for this node is available. If the "local node" is not allowed by the process's current cpuset context, the kernel will try to allocate memory from other nodes. The kernel will allocate memory from the "local node" whenever it becomes allowed by the process's current cpuset context.

The thread memory policy is preserved across an *execve*(2), and is inherited by child threads created using *fork*(2) or *clone*(2).

RETURN VALUE
On success, **set_mempolicy**() returns 0; on error, −1 is returned and *errno* is set to indicate the error.

ERRORS
EFAULT
Part of all of the memory range specified by *nodemask* and *maxnode* points outside your accessible address space.

EINVAL
mode is invalid. Or, *mode* is **MPOL_DEFAULT** and *nodemask* is nonempty, or *mode* is **MPOL_BIND** or **MPOL_INTERLEAVE** and *nodemask* is empty. Or, *maxnode* specifies more than a page worth of bits. Or, *nodemask* specifies one or more node IDs that are greater than the maximum supported node ID. Or, none of the node IDs specified by *nodemask* are on-line and allowed by the process's current cpuset context, or none of the specified nodes contain memory. Or, the *mode* argument specified both **MPOL_F_STATIC_NODES** and **MPOL_F_RELATIVE_NODES**. Or, the **MPOL_F_NUMA_BALANCING** isn't supported by the kernel, or is used with *mode* other than **MPOL_BIND**.

ENOMEM
Insufficient kernel memory was available.

STANDARDS
Linux.

HISTORY
Linux 2.6.7.

NOTES
Memory policy is not remembered if the page is swapped out. When such a page is paged back in, it will use the policy of the thread or memory range that is in effect at the time the page is allocated.

For information on library support, see *numa*(7).

NAME

get_thread_area, set_thread_area − manipulate thread-local storage information

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

#if defined __i386__ || defined __x86_64__
# include <asm/ldt.h>         /* Definition of struct user_desc */

int syscall(SYS_get_thread_area, struct user_desc *u_info);
int syscall(SYS_set_thread_area, struct user_desc *u_info);

#elif defined __m68k__

int syscall(SYS_get_thread_area);
int syscall(SYS_set_thread_area, unsigned long tp);

#elif defined __mips__ || defined __csky__

int syscall(SYS_set_thread_area, unsigned long addr);

#endif
```

Note: glibc provides no wrappers for these system calls, necessitating the use of *syscall*(2).

DESCRIPTION

These calls provide architecture-specific support for a thread-local storage implementation. At the moment, **set_thread_area**() is available on m68k, MIPS, C-SKY, and x86 (both 32-bit and 64-bit variants); **get_thread_area**() is available on m68k and x86.

On m68k, MIPS and C-SKY, **set_thread_area**() allows storing an arbitrary pointer (provided in the **tp** argument on m68k and in the **addr** argument on MIPS and C-SKY) in the kernel data structure associated with the calling thread; this pointer can later be retrieved using **get_thread_area**() (see also NOTES for information regarding obtaining the thread pointer on MIPS).

On x86, Linux dedicates three global descriptor table (GDT) entries for thread-local storage. For more information about the GDT, see the Intel Software Developer's Manual or the AMD Architecture Programming Manual.

Both of these system calls take an argument that is a pointer to a structure of the following type:

```
struct user_desc {
    unsigned int  entry_number;
    unsigned int  base_addr;
    unsigned int  limit;
    unsigned int  seg_32bit:1;
    unsigned int  contents:2;
    unsigned int  read_exec_only:1;
    unsigned int  limit_in_pages:1;
    unsigned int  seg_not_present:1;
    unsigned int  useable:1;
#ifdef __x86_64__
    unsigned int  lm:1;
#endif
};
```

get_thread_area() reads the GDT entry indicated by *u_info->entry_number* and fills in the rest of the fields in *u_info*.

set_thread_area() sets a TLS entry in the GDT.

The TLS array entry set by **set_thread_area**() corresponds to the value of *u_info->entry_number* passed in by the user. If this value is in bounds, **set_thread_area**() writes the TLS descriptor pointed to by *u_info* into the thread's TLS array.

When **set_thread_area**() is passed an *entry_number* of −1, it searches for a free TLS entry. If

set_thread_area() finds a free TLS entry, the value of *u_info->entry_number* is set upon return to show which entry was changed.

A *user_desc* is considered "empty" if *read_exec_only* and *seg_not_present* are set to 1 and all of the other fields are 0. If an "empty" descriptor is passed to **set_thread_area**(), the corresponding TLS entry will be cleared. See BUGS for additional details.

Since Linux 3.19, **set_thread_area**() cannot be used to write non-present segments, 16-bit segments, or code segments, although clearing a segment is still acceptable.

RETURN VALUE

On x86, these system calls return 0 on success, and −1 on failure, with *errno* set to indicate the error.

On C-SKY, MIPS and m68k, **set_thread_area**() always returns 0. On m68k, **get_thread_area**() returns the thread area pointer value (previously set via *set_thread_area*())

ERRORS

EFAULT
u_info is an invalid pointer.

EINVAL
u_info->entry_number is out of bounds.

ENOSYS
get_thread_area() or **set_thread_area**() was invoked as a 64-bit system call.

ESRCH
(**set_thread_area**()) A free TLS entry could not be located.

STANDARDS

Linux.

HISTORY

set_thread_area()
Linux 2.5.29.

get_thread_area()
Linux 2.5.32.

NOTES

These system calls are generally intended for use only by threading libraries.

arch_prctl(2) can interfere with **set_thread_area**() on x86. See *arch_prctl*(2) for more details. This is not normally a problem, as *arch_prctl*(2) is normally used only by 64-bit programs.

On MIPS, the current value of the thread area pointer can be obtained using the instruction:

```
rdhwr dest, $29
```

This instruction traps and is handled by kernel.

BUGS

On 64-bit kernels before Linux 3.19, one of the padding bits in *user_desc*, if set, would prevent the descriptor from being considered empty (see *modify_ldt*(2)). As a result, the only reliable way to clear a TLS entry is to use *memset*(3) to zero the entire *user_desc* structure, including padding bits, and then to set the *read_exec_only* and *seg_not_present* bits. On Linux 3.19, a *user_desc* consisting entirely of zeros except for *entry_number* will also be interpreted as a request to clear a TLS entry, but this behaved differently on older kernels.

Prior to Linux 3.19, the DS and ES segment registers must not reference TLS entries.

NAME

set_tid_address − set pointer to thread ID

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

pid_t syscall(SYS_set_tid_address, int *****tidptr);

Note: glibc provides no wrapper for **set_tid_address**(), necessitating the use of *syscall*(2).

DESCRIPTION

For each thread, the kernel maintains two attributes (addresses) called *set_child_tid* and *clear_child_tid*. These two attributes contain the value NULL by default.

set_child_tid
: If a thread is started using *clone*(2) with the **CLONE_CHILD_SETTID** flag, *set_child_tid* is set to the value passed in the *ctid* argument of that system call.

  When *set_child_tid* is set, the very first thing the new thread does is to write its thread ID at this address.

clear_child_tid
: If a thread is started using *clone*(2) with the **CLONE_CHILD_CLEARTID** flag, *clear_child_tid* is set to the value passed in the *ctid* argument of that system call.

The system call **set_tid_address**() sets the *clear_child_tid* value for the calling thread to *tidptr*.

When a thread whose *clear_child_tid* is not NULL terminates, then, if the thread is sharing memory with other threads, then 0 is written at the address specified in *clear_child_tid* and the kernel performs the following operation:

```
futex(clear_child_tid, FUTEX_WAKE, 1, NULL, NULL, 0);
```

The effect of this operation is to wake a single thread that is performing a futex wait on the memory location. Errors from the futex wake operation are ignored.

RETURN VALUE

set_tid_address() always returns the caller's thread ID.

ERRORS

set_tid_address() always succeeds.

STANDARDS

Linux.

HISTORY

Linux 2.5.48.

Details as given here are valid since Linux 2.5.49.

SEE ALSO

clone(2), *futex*(2), *gettid*(2)

NAME

seteuid, setegid − set effective user or group ID

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int seteuid(uid_t euid);
int setegid(gid_t egid);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

seteuid(), **setegid**():
_POSIX_C_SOURCE >= 200112L
|| /* glibc <= 2.19: */ _BSD_SOURCE

DESCRIPTION

seteuid() sets the effective user ID of the calling process. Unprivileged processes may only set the effective user ID to the real user ID, the effective user ID or the saved set-user-ID.

Precisely the same holds for **setegid**() with "group" instead of "user".

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

Note: there are cases where **seteuid**() can fail even when the caller is UID 0; it is a grave security error to omit checking for a failure return from **seteuid**().

ERRORS

EINVAL
The target user or group ID is not valid in this user namespace.

EPERM
In the case of **seteuid**(): the calling process is not privileged (does not have the **CAP_SETUID** capability in its user namespace) and *euid* does not match the current real user ID, current effective user ID, or current saved set-user-ID.

In the case of **setegid**(): the calling process is not privileged (does not have the **CAP_SETGID** capability in its user namespace) and *egid* does not match the current real group ID, current effective group ID, or current saved set-group-ID.

VERSIONS

Setting the effective user (group) ID to the saved set-user-ID (saved set-group-ID) is possible since Linux 1.1.37 (1.1.38). On an arbitrary system one should check **_POSIX_SAVED_IDS**.

Under glibc 2.0, **seteuid(***euid***)** is equivalent to **setreuid(−1,** *euid***)** and hence may change the saved set-user-ID. Under glibc 2.1 and later, it is equivalent to **setresuid(−1,** *euid***, −1)** and hence does not change the saved set-user-ID. Analogous remarks hold for **setegid**(), with the difference that the change in implementation from **setregid(−1,** *egid***)** to **setresgid(−1,** *egid***, −1)** occurred in glibc 2.2 or 2.3 (depending on the hardware architecture).

According to POSIX.1, **seteuid**() (**setegid**()) need not permit *euid* (*egid*) to be the same value as the current effective user (group) ID, and some implementations do not permit this.

C library/kernel differences

On Linux, **seteuid**() and **setegid**() are implemented as library functions that call, respectively, *setresuid*(2) and *setresgid*(2).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.3BSD.

SEE ALSO

geteuid(2), *setresuid*(2), *setreuid*(2), *setuid*(2), *capabilities*(7), *credentials*(7), *user_namespaces*(7)

NAME

setfsgid − set group identity used for filesystem checks

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/fsuid.h>

[[deprecated]] int setfsgid(gid_t *fsgid***);**

DESCRIPTION

On Linux, a process has both a filesystem group ID and an effective group ID. The (Linux-specific) filesystem group ID is used for permissions checking when accessing filesystem objects, while the effective group ID is used for some other kinds of permissions checks (see *credentials*(7)).

Normally, the value of the process's filesystem group ID is the same as the value of its effective group ID. This is so, because whenever a process's effective group ID is changed, the kernel also changes the filesystem group ID to be the same as the new value of the effective group ID. A process can cause the value of its filesystem group ID to diverge from its effective group ID by using **setfsgid**() to change its filesystem group ID to the value given in *fsgid*.

setfsgid() will succeed only if the caller is the superuser or if *fsgid* matches either the caller's real group ID, effective group ID, saved set-group-ID, or current the filesystem user ID.

RETURN VALUE

On both success and failure, this call returns the previous filesystem group ID of the caller.

STANDARDS

Linux.

HISTORY

Linux 1.2.

C library/kernel differences

In glibc 2.15 and earlier, when the wrapper for this system call determines that the argument can't be passed to the kernel without integer truncation (because the kernel is old and does not support 32-bit group IDs), it will return −1 and set *errno* to **EINVAL** without attempting the system call.

NOTES

The filesystem group ID concept and the **setfsgid**() system call were invented for historical reasons that are no longer applicable on modern Linux kernels. See *setfsuid*(2) for a discussion of why the use of both *setfsuid*(2) and **setfsgid**() is nowadays unneeded.

The original Linux **setfsgid**() system call supported only 16-bit group IDs. Subsequently, Linux 2.4 added **setfsgid32**() supporting 32-bit IDs. The glibc **setfsgid**() wrapper function transparently deals with the variation across kernel versions.

BUGS

No error indications of any kind are returned to the caller, and the fact that both successful and unsuccessful calls return the same value makes it impossible to directly determine whether the call succeeded or failed. Instead, the caller must resort to looking at the return value from a further call such as *setfsgid(−1)* (which will always fail), in order to determine if a preceding call to **setfsgid**() changed the filesystem group ID. At the very least, **EPERM** should be returned when the call fails (because the caller lacks the **CAP_SETGID** capability).

SEE ALSO

kill(2), *setfsuid*(2), *capabilities*(7), *credentials*(7)

NAME

setfsuid − set user identity used for filesystem checks

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/fsuid.h>

[[deprecated]] int setfsuid(uid_t *fsuid***);**

DESCRIPTION

On Linux, a process has both a filesystem user ID and an effective user ID. The (Linux-specific) filesystem user ID is used for permissions checking when accessing filesystem objects, while the effective user ID is used for various other kinds of permissions checks (see *credentials*(7)).

Normally, the value of the process's filesystem user ID is the same as the value of its effective user ID. This is so, because whenever a process's effective user ID is changed, the kernel also changes the filesystem user ID to be the same as the new value of the effective user ID. A process can cause the value of its filesystem user ID to diverge from its effective user ID by using **setfsuid**() to change its filesystem user ID to the value given in *fsuid*.

Explicit calls to **setfsuid**() and *setfsgid*(2) are (were) usually used only by programs such as the Linux NFS server that need to change what user and group ID is used for file access without a corresponding change in the real and effective user and group IDs. A change in the normal user IDs for a program such as the NFS server is (was) a security hole that can expose it to unwanted signals. (However, this issue is historical; see below.)

setfsuid() will succeed only if the caller is the superuser or if *fsuid* matches either the caller's real user ID, effective user ID, saved set-user-ID, or current filesystem user ID.

RETURN VALUE

On both success and failure, this call returns the previous filesystem user ID of the caller.

STANDARDS

Linux.

HISTORY

Linux 1.2.

At the time when this system call was introduced, one process could send a signal to another process with the same effective user ID. This meant that if a privileged process changed its effective user ID for the purpose of file permission checking, then it could become vulnerable to receiving signals sent by another (unprivileged) process with the same user ID. The filesystem user ID attribute was thus added to allow a process to change its user ID for the purposes of file permission checking without at the same time becoming vulnerable to receiving unwanted signals. Since Linux 2.0, signal permission handling is different (see *kill*(2)), with the result that a process can change its effective user ID without being vulnerable to receiving signals from unwanted processes. Thus, **setfsuid**() is nowadays unneeded and should be avoided in new applications (likewise for *setfsgid*(2)).

The original Linux **setfsuid**() system call supported only 16-bit user IDs. Subsequently, Linux 2.4 added **setfsuid32**() supporting 32-bit IDs. The glibc **setfsuid**() wrapper function transparently deals with the variation across kernel versions.

C library/kernel differences

In glibc 2.15 and earlier, when the wrapper for this system call determines that the argument can't be passed to the kernel without integer truncation (because the kernel is old and does not support 32-bit user IDs), it will return −1 and set *errno* to **EINVAL** without attempting the system call.

BUGS

No error indications of any kind are returned to the caller, and the fact that both successful and unsuccessful calls return the same value makes it impossible to directly determine whether the call succeeded or failed. Instead, the caller must resort to looking at the return value from a further call such as *setfsuid(−1)* (which will always fail), in order to determine if a preceding call to **setfsuid**() changed the filesystem user ID. At the very least, **EPERM** should be returned when the call fails (because the caller lacks the **CAP_SETUID** capability).

SEE ALSO

kill(2), *setfsgid*(2), *capabilities*(7), *credentials*(7)

NAME

setgid − set group identity

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int setgid(gid_t *gid***);**

DESCRIPTION

setgid() sets the effective group ID of the calling process. If the calling process is privileged (more precisely: has the **CAP_SETGID** capability in its user namespace), the real GID and saved set-group-ID are also set.

Under Linux, **setgid**() is implemented like the POSIX version with the **_POSIX_SAVED_IDS** feature. This allows a set-group-ID program that is not set-user-ID-root to drop all of its group privileges, do some un-privileged work, and then reengage the original effective group ID in a secure manner.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EINVAL

The group ID specified in *gid* is not valid in this user namespace.

EPERM

The calling process is not privileged (does not have the **CAP_SETGID** capability in its user namespace), and *gid* does not match the real group ID or saved set-group-ID of the calling process.

VERSIONS

C library/kernel differences

At the kernel level, user IDs and group IDs are a per-thread attribute. However, POSIX requires that all threads in a process share the same credentials. The NPTL threading implementation handles the POSIX requirements by providing wrapper functions for the various system calls that change process UIDs and GIDs. These wrapper functions (including the one for *setgid*()) employ a signal-based technique to ensure that when one thread changes credentials, all of the other threads in the process also change their credentials. For details, see *nptl*(7).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

The original Linux **setgid**() system call supported only 16-bit group IDs. Subsequently, Linux 2.4 added **setgid32**() supporting 32-bit IDs. The glibc **setgid**() wrapper function transparently deals with the variation across kernel versions.

NAME

setns − reassociate thread with a namespace

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <sched.h>

int setns(int fd, int nstype);
```

DESCRIPTION

The **setns**() system call allows the calling thread to move into different namespaces. The *fd* argument is one of the following:

- a file descriptor referring to one of the magic links in a */proc/*pid*/ns/* directory (or a bind mount to such a link);
- a PID file descriptor (see *pidfd_open*(2)).

The *nstype* argument is interpreted differently in each case.

fd refers to a */proc/*pid*/ns/* link

If *fd* refers to a */proc/*pid*/ns/* link, then **setns**() reassociates the calling thread with the namespace associated with that link, subject to any constraints imposed by the *nstype* argument. In this usage, each call to **setns**() changes just one of the caller's namespace memberships.

The *nstype* argument specifies which type of namespace the calling thread may be reassociated with. This argument can have *one* of the following values:

0 Allow any type of namespace to be joined.

CLONE_NEWCGROUP (since Linux 4.6)
fd must refer to a cgroup namespace.

CLONE_NEWIPC (since Linux 3.0)
fd must refer to an IPC namespace.

CLONE_NEWNET (since Linux 3.0)
fd must refer to a network namespace.

CLONE_NEWNS (since Linux 3.8)
fd must refer to a mount namespace.

CLONE_NEWPID (since Linux 3.8)
fd must refer to a descendant PID namespace.

CLONE_NEWTIME (since Linux 5.8)
fd must refer to a time namespace.

CLONE_NEWUSER (since Linux 3.8)
fd must refer to a user namespace.

CLONE_NEWUTS (since Linux 3.0)
fd must refer to a UTS namespace.

Specifying *nstype* as 0 suffices if the caller knows (or does not care) what type of namespace is referred to by *fd*. Specifying a nonzero value for *nstype* is useful if the caller does not know what type of namespace is referred to by *fd* and wants to ensure that the namespace is of a particular type. (The caller might not know the type of the namespace referred to by *fd* if the file descriptor was opened by another process and, for example, passed to the caller via a UNIX domain socket.)

fd is a PID file descriptor

Since Linux 5.8, *fd* may refer to a PID file descriptor obtained from *pidfd_open*(2) or *clone*(2). In this usage, **setns**() atomically moves the calling thread into one or more of the same namespaces as the thread referred to by *fd*.

The *nstype* argument is a bit mask specified by ORing together *one or more* of the **CLONE_NEW*** namespace constants listed above. The caller is moved into each of the target thread's namespaces that is specified in *nstype*; the caller's memberships in the remaining namespaces are left unchanged.

For example, the following code would move the caller into the same user, network, and UTS namespaces as PID 1234, but would leave the caller's other namespace memberships unchanged:

```
int fd = pidfd_open(1234, 0);
setns(fd, CLONE_NEWUSER | CLONE_NEWNET | CLONE_NEWUTS);
```

Details for specific namespace types

Note the following details and restrictions when reassociating with specific namespace types:

User namespaces

A process reassociating itself with a user namespace must have the **CAP_SYS_ADMIN** capability in the target user namespace. (This necessarily implies that it is only possible to join a descendant user namespace.) Upon successfully joining a user namespace, a process is granted all capabilities in that namespace, regardless of its user and group IDs.

A multithreaded process may not change user namespace with **setns**().

It is not permitted to use **setns**() to reenter the caller's current user namespace. This prevents a caller that has dropped capabilities from regaining those capabilities via a call to **setns**().

For security reasons, a process can't join a new user namespace if it is sharing filesystem-related attributes (the attributes whose sharing is controlled by the *clone*(2) **CLONE_FS** flag) with another process.

For further details on user namespaces, see *user_namespaces*(7).

Mount namespaces

Changing the mount namespace requires that the caller possess both **CAP_SYS_CHROOT** and **CAP_SYS_ADMIN** capabilities in its own user namespace and **CAP_SYS_ADMIN** in the user namespace that owns the target mount namespace.

A process can't join a new mount namespace if it is sharing filesystem-related attributes (the attributes whose sharing is controlled by the *clone*(2) **CLONE_FS** flag) with another process.

See *user_namespaces*(7) for details on the interaction of user namespaces and mount namespaces.

PID namespaces

In order to reassociate itself with a new PID namespace, the caller must have the **CAP_SYS_ADMIN** capability both in its own user namespace and in the user namespace that owns the target PID namespace.

Reassociating the PID namespace has somewhat different from other namespace types. Reassociating the calling thread with a PID namespace changes only the PID namespace that subsequently created child processes of the caller will be placed in; it does not change the PID namespace of the caller itself.

Reassociating with a PID namespace is allowed only if the target PID namespace is a descendant (child, grandchild, etc.) of, or is the same as, the current PID namespace of the caller.

For further details on PID namespaces, see *pid_namespaces*(7).

Cgroup namespaces

In order to reassociate itself with a new cgroup namespace, the caller must have the **CAP_SYS_ADMIN** capability both in its own user namespace and in the user namespace that owns the target cgroup namespace.

Using **setns**() to change the caller's cgroup namespace does not change the caller's cgroup memberships.

Network, IPC, time, and UTS namespaces

In order to reassociate itself with a new network, IPC, time, or UTS namespace, the caller must have the **CAP_SYS_ADMIN** capability both in its own user namespace and in the user namespace that owns the target namespace.

RETURN VALUE

On success, **setns**() returns 0. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF
fd is not a valid file descriptor.

EINVAL
fd refers to a namespace whose type does not match that specified in *nstype*.

EINVAL
There is problem with reassociating the thread with the specified namespace.

EINVAL
The caller tried to join an ancestor (parent, grandparent, and so on) PID namespace.

EINVAL
The caller attempted to join the user namespace in which it is already a member.

EINVAL
The caller shares filesystem (**CLONE_FS**) state (in particular, the root directory) with other processes and tried to join a new user namespace.

EINVAL
The caller is multithreaded and tried to join a new user namespace.

EINVAL
fd is a PID file descriptor and *nstype* is invalid (e.g., it is 0).

ENOMEM
Cannot allocate sufficient memory to change the specified namespace.

EPERM
The calling thread did not have the required capability for this operation.

ESRCH
fd is a PID file descriptor but the process it refers to no longer exists (i.e., it has terminated and been waited on).

STANDARDS

Linux.

VERSIONS

Linux 3.0, glibc 2.14.

NOTES

For further information on the */proc/*pid*/ns/* magic links, see *namespaces*(7).

Not all of the attributes that can be shared when a new thread is created using *clone*(2) can be changed using **setns**().

EXAMPLES

The program below takes two or more arguments. The first argument specifies the pathname of a namespace file in an existing */proc/*pid*/ns/* directory. The remaining arguments specify a command and its arguments. The program opens the namespace file, joins that namespace using **setns**(), and executes the specified command inside that namespace.

The following shell session demonstrates the use of this program (compiled as a binary named *ns_exec*) in conjunction with the **CLONE_NEWUTS** example program in the *clone*(2) man page (complied as a binary named *newuts*).

We begin by executing the example program in *clone*(2) in the background. That program creates a child in a separate UTS namespace. The child changes the hostname in its namespace, and then both processes display the hostnames in their UTS namespaces, so that we can see that they are different.

```
$ su                    # Need privilege for namespace operations
Password:
# ./newuts bizarro &
[1] 3549
clone() returned 3550
uts.nodename in child:  bizarro
uts.nodename in parent: antero
```

```
# uname -n              # Verify hostname in the shell
antero
```

We then run the program shown below, using it to execute a shell. Inside that shell, we verify that the hostname is the one set by the child created by the first program:

```
# ./ns_exec /proc/3550/ns/uts /bin/bash
# uname -n              # Executed in shell started by ns_exec
bizarro
```

Program source

```
#define _GNU_SOURCE
#include <err.h>
#include <fcntl.h>
#include <sched.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

int
main(int argc, char *argv[])
{
    int fd;

    if (argc < 3) {
        fprintf(stderr, "%s /proc/PID/ns/FILE cmd args...\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    /* Get file descriptor for namespace; the file descriptor is opened
       with O_CLOEXEC so as to ensure that it is not inherited by the
       program that is later executed. */

    fd = open(argv[1], O_RDONLY | O_CLOEXEC);
    if (fd == -1)
        err(EXIT_FAILURE, "open");

    if (setns(fd, 0) == -1)       /* Join that namespace */
        err(EXIT_FAILURE, "setns");

    execvp(argv[2], &argv[2]);    /* Execute a command in namespace */
    err(EXIT_FAILURE, "execvp");
}
```

NAME

setpgid, getpgid, setpgrp, getpgrp − set/get process group

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int setpgid(pid_t pid, pid_t pgid);
pid_t getpgid(pid_t pid);

pid_t getpgrp(void);                    /* POSIX.1 version */
[[deprecated]] pid_t getpgrp(pid_t pid);    /* BSD version */

int setpgrp(void);                      /* System V version */
[[deprecated]] int setpgrp(pid_t pid, pid_t pgid);  /* BSD version */
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

getpgid():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L

setpgrp() (POSIX.1):
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _SVID_SOURCE

setpgrp() (BSD), **getpgrp**() (BSD):
[These are available only before glibc 2.19]
_BSD_SOURCE &&
! (_POSIX_SOURCE || _POSIX_C_SOURCE || _XOPEN_SOURCE
|| _GNU_SOURCE || _SVID_SOURCE)

DESCRIPTION

All of these interfaces are available on Linux, and are used for getting and setting the process group ID (PGID) of a process. The preferred, POSIX.1-specified ways of doing this are: *getpgrp*(void), for retrieving the calling process's PGID; and **setpgid**(), for setting a process's PGID.

setpgid() sets the PGID of the process specified by *pid* to *pgid*. If *pid* is zero, then the process ID of the calling process is used. If *pgid* is zero, then the PGID of the process specified by *pid* is made the same as its process ID. If **setpgid**() is used to move a process from one process group to another (as is done by some shells when creating pipelines), both process groups must be part of the same session (see *setsid*(2) and *credentials*(7)). In this case, the *pgid* specifies an existing process group to be joined and the session ID of that group must match the session ID of the joining process.

The POSIX.1 version of **getpgrp**(), which takes no arguments, returns the PGID of the calling process.

getpgid() returns the PGID of the process specified by *pid*. If *pid* is zero, the process ID of the calling process is used. (Retrieving the PGID of a process other than the caller is rarely necessary, and the POSIX.1 **getpgrp**() is preferred for that task.)

The System V-style **setpgrp**(), which takes no arguments, is equivalent to *setpgid(0, 0)*.

The BSD-specific **setpgrp**() call, which takes arguments *pid* and *pgid*, is a wrapper function that calls

```
setpgid(pid, pgid)
```

Since glibc 2.19, the BSD-specific **setpgrp**() function is no longer exposed by <*unistd.h*>; calls should be replaced with the **setpgid**() call shown above.

The BSD-specific **getpgrp**() call, which takes a single *pid* argument, is a wrapper function that calls

```
getpgid(pid)
```

Since glibc 2.19, the BSD-specific **getpgrp**() function is no longer exposed by <*unistd.h*>; calls should be replaced with calls to the POSIX.1 **getpgrp**() which takes no arguments (if the intent is to obtain the caller's PGID), or with the **getpgid**() call shown above.

RETURN VALUE

On success, **setpgid**() and **setpgrp**() return zero. On error, −1 is returned, and *errno* is set to indicate the error.

The POSIX.1 **getpgrp**() always returns the PGID of the caller.

getpgid(), and the BSD-specific **getpgrp**() return a process group on success. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
: An attempt was made to change the process group ID of one of the children of the calling process and the child had already performed an *execve*(2) (**setpgid**(), *setpgrp*())

EINVAL
: *pgid* is less than 0 (**setpgid**(), *setpgrp*())

EPERM
: An attempt was made to move a process into a process group in a different session, or to change the process group ID of one of the children of the calling process and the child was in a different session, or to change the process group ID of a session leader (**setpgid**(), *setpgrp*())

EPERM
: The target process group does not exist. (**setpgid**(), *setpgrp*())

ESRCH
: For **getpgid**(): *pid* does not match any process. For **setpgid**(): *pid* is not the calling process and not a child of the calling process.

STANDARDS

getpgid()
setpgid()
getpgrp() (no args)
setpgrp() (no args)
: POSIX.1-2008 (but see HISTORY).

setpgrp() (2 args)
getpgrp() (1 arg)
: None.

HISTORY

getpgid()
setpgid()
getpgrp() (no args)
: POSIX.1-2001.

setpgrp() (no args)
: POSIX.1-2001. POSIX.1-2008 marks it as obsolete.

setpgrp() (2 args)
getpgrp() (1 arg)
: 4.2BSD.

NOTES

A child created via *fork*(2) inherits its parent's process group ID. The PGID is preserved across an *execve*(2).

Each process group is a member of a session and each process is a member of the session of which its process group is a member. (See *credentials*(7).)

A session can have a controlling terminal. At any time, one (and only one) of the process groups in the session can be the foreground process group for the terminal; the remaining process groups are in the background. If a signal is generated from the terminal (e.g., typing the interrupt key to generate **SIGINT**), that signal is sent to the foreground process group. (See *termios*(3) for a description of the characters that generate signals.) Only the foreground process group may *read*(2) from the terminal; if a background process group tries to *read*(2) from the terminal, then the group is sent a **SIGTTIN** signal, which suspends it. The *tcgetpgrp*(3) and *tcsetpgrp*(3) functions are used to get/set the foreground process group of the controlling terminal.

The **setpgid**() and **getpgrp**() calls are used by programs such as *bash*(1) to create process groups in order to implement shell job control.

If the termination of a process causes a process group to become orphaned, and if any member of the newly orphaned process group is stopped, then a **SIGHUP** signal followed by a **SIGCONT** signal will be sent to each process in the newly orphaned process group. An orphaned process group is one in which the parent of every member of process group is either itself also a member of the process group or is a member of a process group in a different session (see also *credentials*(7)).

getuid(2), *setsid*(2), *tcgetpgrp*(3), *tcsetpgrp*(3), *termios*(3), *credentials*(7)

NAME

setresuid, setresgid − set real, effective, and saved user or group ID

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <unistd.h>

int setresuid(uid_t ruid, uid_t euid, uid_t suid);
int setresgid(gid_t rgid, gid_t egid, gid_t sgid);
```

DESCRIPTION

setresuid() sets the real user ID, the effective user ID, and the saved set-user-ID of the calling process.

An unprivileged process may change its real UID, effective UID, and saved set-user-ID, each to one of: the current real UID, the current effective UID, or the current saved set-user-ID.

A privileged process (on Linux, one having the **CAP_SETUID** capability) may set its real UID, effective UID, and saved set-user-ID to arbitrary values.

If one of the arguments equals −1, the corresponding value is not changed.

Regardless of what changes are made to the real UID, effective UID, and saved set-user-ID, the filesystem UID is always set to the same value as the (possibly new) effective UID.

Completely analogously, **setresgid**() sets the real GID, effective GID, and saved set-group-ID of the calling process (and always modifies the filesystem GID to be the same as the effective GID), with the same restrictions for unprivileged processes.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

Note: there are cases where **setresuid**() can fail even when the caller is UID 0; it is a grave security error to omit checking for a failure return from **setresuid**().

ERRORS

EAGAIN
: The call would change the caller's real UID (i.e., *ruid* does not match the caller's real UID), but there was a temporary failure allocating the necessary kernel data structures.

EAGAIN
: *ruid* does not match the caller's real UID and this call would bring the number of processes belonging to the real user ID *ruid* over the caller's **RLIMIT_NPROC** resource limit. Since Linux 3.1, this error case no longer occurs (but robust applications should check for this error); see the description of **EAGAIN** in *execve*(2).

EINVAL
: One or more of the target user or group IDs is not valid in this user namespace.

EPERM
: The calling process is not privileged (did not have the necessary capability in its user namespace) and tried to change the IDs to values that are not permitted. For **setresuid**(), the necessary capability is **CAP_SETUID**; for **setresgid**(), it is **CAP_SETGID**.

VERSIONS

C library/kernel differences

At the kernel level, user IDs and group IDs are a per-thread attribute. However, POSIX requires that all threads in a process share the same credentials. The NPTL threading implementation handles the POSIX requirements by providing wrapper functions for the various system calls that change process UIDs and GIDs. These wrapper functions (including those for **setresuid**() and *setresgid*()) employ a signal-based technique to ensure that when one thread changes credentials, all of the other threads in the process also change their credentials. For details, see *nptl*(7).

STANDARDS

None.

HISTORY

Linux 2.1.44, glibc 2.3.2. HP-UX, FreeBSD.

The original Linux **setresuid**() and **setresgid**() system calls supported only 16-bit user and group IDs. Subsequently, Linux 2.4 added **setresuid32**() and **setresgid32**(), supporting 32-bit IDs. The glibc **setresuid**() and **setresgid**() wrapper functions transparently deal with the variations across kernel versions.

SEE ALSO

getresuid(2), *getuid*(2), *setfsgid*(2), *setfsuid*(2), *setreuid*(2), *setuid*(2), *capabilities*(7), *credentials*(7), *user_namespaces*(7)

NAME

setreuid, setregid − set real and/or effective user or group ID

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int setreuid(uid_t *ruid***, uid_t** *euid***);**
int setregid(gid_t *rgid***, gid_t** *egid***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

setreuid(), **setregid**():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _BSD_SOURCE

DESCRIPTION

setreuid() sets real and effective user IDs of the calling process.

Supplying a value of −1 for either the real or effective user ID forces the system to leave that ID unchanged.

Unprivileged processes may only set the effective user ID to the real user ID, the effective user ID, or the saved set-user-ID.

Unprivileged users may only set the real user ID to the real user ID or the effective user ID.

If the real user ID is set (i.e., *ruid* is not −1) or the effective user ID is set to a value not equal to the previous real user ID, the saved set-user-ID will be set to the new effective user ID.

Completely analogously, **setregid**() sets real and effective group ID's of the calling process, and all of the above holds with "group" instead of "user".

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

Note: there are cases where **setreuid**() can fail even when the caller is UID 0; it is a grave security error to omit checking for a failure return from **setreuid**().

ERRORS

EAGAIN
The call would change the caller's real UID (i.e., *ruid* does not match the caller's real UID), but there was a temporary failure allocating the necessary kernel data structures.

EAGAIN
ruid does not match the caller's real UID and this call would bring the number of processes belonging to the real user ID *ruid* over the caller's **RLIMIT_NPROC** resource limit. Since Linux 3.1, this error case no longer occurs (but robust applications should check for this error); see the description of **EAGAIN** in *execve*(2).

EINVAL
One or more of the target user or group IDs is not valid in this user namespace.

EPERM
The calling process is not privileged (on Linux, does not have the necessary capability in its user namespace: **CAP_SETUID** in the case of **setreuid**(), or **CAP_SETGID** in the case of *setregid*()) and a change other than (i) swapping the effective user (group) ID with the real user (group) ID, or (ii) setting one to the value of the other or (iii) setting the effective user (group) ID to the value of the saved set-user-ID (saved set-group-ID) was specified.

VERSIONS

POSIX.1 does not specify all of the UID changes that Linux permits for an unprivileged process. For **setreuid**(), the effective user ID can be made the same as the real user ID or the saved set-user-ID, and it is unspecified whether unprivileged processes may set the real user ID to the real user ID, the effective user ID, or the saved set-user-ID. For **setregid**(), the real group ID can be changed to the value of the saved set-group-ID, and the effective group ID can be changed to the value of the real group ID or

the saved set-group-ID. The precise details of what ID changes are permitted vary across implementations.

POSIX.1 makes no specification about the effect of these calls on the saved set-user-ID and saved set-group-ID.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.3BSD (first appeared in 4.2BSD).

Setting the effective user (group) ID to the saved set-user-ID (saved set-group-ID) is possible since Linux 1.1.37 (1.1.38).

The original Linux **setreuid**() and **setregid**() system calls supported only 16-bit user and group IDs. Subsequently, Linux 2.4 added **setreuid32**() and **setregid32**(), supporting 32-bit IDs. The glibc **setreuid**() and **setregid**() wrapper functions transparently deal with the variations across kernel versions.

C library/kernel differences

At the kernel level, user IDs and group IDs are a per-thread attribute. However, POSIX requires that all threads in a process share the same credentials. The NPTL threading implementation handles the POSIX requirements by providing wrapper functions for the various system calls that change process UIDs and GIDs. These wrapper functions (including those for **setreuid**() and *setregid*()) employ a signal-based technique to ensure that when one thread changes credentials, all of the other threads in the process also change their credentials. For details, see *nptl*(7).

NAME

setsid − creates a session and sets the process group ID

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

pid_t setsid(void);

DESCRIPTION

setsid() creates a new session if the calling process is not a process group leader. The calling process is the leader of the new session (i.e., its session ID is made the same as its process ID). The calling process also becomes the process group leader of a new process group in the session (i.e., its process group ID is made the same as its process ID).

The calling process will be the only process in the new process group and in the new session.

Initially, the new session has no controlling terminal. For details of how a session acquires a controlling terminal, see *credentials*(7).

RETURN VALUE

On success, the (new) session ID of the calling process is returned. On error, *(pid_t) −1* is returned, and *errno* is set to indicate the error.

ERRORS

EPERM

The process group ID of any process equals the PID of the calling process. Thus, in particular, **setsid**() fails if the calling process is already a process group leader.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

NOTES

A child created via *fork*(2) inherits its parent's session ID. The session ID is preserved across an *execve*(2).

A process group leader is a process whose process group ID equals its PID. Disallowing a process group leader from calling **setsid**() prevents the possibility that a process group leader places itself in a new session while other processes in the process group remain in the original session; such a scenario would break the strict two-level hierarchy of sessions and process groups. In order to be sure that **setsid**() will succeed, call *fork*(2) and have the parent *_exit*(2), while the child (which by definition can't be a process group leader) calls **setsid**().

If a session has a controlling terminal, and the **CLOCAL** flag for that terminal is not set, and a terminal hangup occurs, then the session leader is sent a **SIGHUP** signal.

If a process that is a session leader terminates, then a **SIGHUP** signal is sent to each process in the foreground process group of the controlling terminal.

SEE ALSO

setsid(1), *getsid*(2), *setpgid*(2), *setpgrp*(2), *tcgetsid*(3), *credentials*(7), *sched*(7)

NAME

setuid − set user identity

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <unistd.h>

int setuid(uid_t *uid***);**

DESCRIPTION

setuid() sets the effective user ID of the calling process. If the calling process is privileged (more precisely: if the process has the **CAP_SETUID** capability in its user namespace), the real UID and saved set-user-ID are also set.

Under Linux, **setuid**() is implemented like the POSIX version with the **_POSIX_SAVED_IDS** feature. This allows a set-user-ID (other than root) program to drop all of its user privileges, do some un-privileged work, and then reengage the original effective user ID in a secure manner.

If the user is root or the program is set-user-ID-root, special care must be taken: **setuid**() checks the effective user ID of the caller and if it is the superuser, all process-related user ID's are set to *uid*. After this has occurred, it is impossible for the program to regain root privileges.

Thus, a set-user-ID-root program wishing to temporarily drop root privileges, assume the identity of an unprivileged user, and then regain root privileges afterward cannot use **setuid**(). You can accomplish this with *seteuid*(2).

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

Note: there are cases where **setuid**() can fail even when the caller is UID 0; it is a grave security error to omit checking for a failure return from **setuid**().

ERRORS

EAGAIN

The call would change the caller's real UID (i.e., *uid* does not match the caller's real UID), but there was a temporary failure allocating the necessary kernel data structures.

EAGAIN

uid does not match the real user ID of the caller and this call would bring the number of processes belonging to the real user ID *uid* over the caller's **RLIMIT_NPROC** resource limit. Since Linux 3.1, this error case no longer occurs (but robust applications should check for this error); see the description of **EAGAIN** in *execve*(2).

EINVAL

The user ID specified in *uid* is not valid in this user namespace.

EPERM

The user is not privileged (Linux: does not have the **CAP_SETUID** capability in its user namespace) and *uid* does not match the real UID or saved set-user-ID of the calling process.

VERSIONS

C library/kernel differences

At the kernel level, user IDs and group IDs are a per-thread attribute. However, POSIX requires that all threads in a process share the same credentials. The NPTL threading implementation handles the POSIX requirements by providing wrapper functions for the various system calls that change process UIDs and GIDs. These wrapper functions (including the one for *setuid*()) employ a signal-based technique to ensure that when one thread changes credentials, all of the other threads in the process also change their credentials. For details, see *nptl*(7).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

Not quite compatible with the 4.4BSD call, which sets all of the real, saved, and effective user IDs.

The original Linux **setuid**() system call supported only 16-bit user IDs. Subsequently, Linux 2.4 added **setuid32**() supporting 32-bit IDs. The glibc **setuid**() wrapper function transparently deals with the variation across kernel versions.

NOTES

Linux has the concept of the filesystem user ID, normally equal to the effective user ID. The **setuid**() call also sets the filesystem user ID of the calling process. See *setfsuid*(2).

If *uid* is different from the old effective UID, the process will be forbidden from leaving core dumps.

SEE ALSO

getuid(2), *seteuid*(2), *setfsuid*(2), *setreuid*(2), *capabilities*(7), *credentials*(7), *user_namespaces*(7)

NAME

setup − setup devices and filesystems, mount root filesystem

LIBRARY

Standard C library (*libc*, −*lc*)

SYNOPSIS

#include <unistd.h>

[[deprecated]] int setup(void);

DESCRIPTION

setup() is called once from within *linux/init/main.c*. It calls initialization functions for devices and filesystems configured into the kernel and then mounts the root filesystem.

No user process may call **setup**(). Any user process, even a process with superuser permission, will receive **EPERM**.

RETURN VALUE

setup() always returns −1 for a user process.

ERRORS

EPERM

Always, for a user process.

STANDARDS

Linux.

VERSIONS

Removed in Linux 2.1.121.

The calling sequence varied: at some times **setup**() has had a single argument *void *BIOS* and at other times a single argument *int magic*.

NAME

setxattr, lsetxattr, fsetxattr − set an extended attribute value

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/xattr.h>

int setxattr(const char *path, const char *name,
        const void value[.size], size_t size, int flags);
int lsetxattr(const char *path, const char *name,
        const void value[.size], size_t size, int flags);
int fsetxattr(int fd, const char *name,
        const void value[.size], size_t size, int flags);
```

DESCRIPTION

Extended attributes are *name*:*value* pairs associated with inodes (files, directories, symbolic links, etc.). They are extensions to the normal attributes which are associated with all inodes in the system (i.e., the *stat*(2) data). A complete overview of extended attributes concepts can be found in *xattr*(7).

setxattr() sets the *value* of the extended attribute identified by *name* and associated with the given *path* in the filesystem. The *size* argument specifies the size (in bytes) of *value*; a zero-length value is permitted.

lsetxattr() is identical to **setxattr**(), except in the case of a symbolic link, where the extended attribute is set on the link itself, not the file that it refers to.

fsetxattr() is identical to **setxattr**(), only the extended attribute is set on the open file referred to by *fd* (as returned by *open*(2)) in place of *path*.

An extended attribute name is a null-terminated string. The *name* includes a namespace prefix; there may be several, disjoint namespaces associated with an individual inode. The *value* of an extended attribute is a chunk of arbitrary textual or binary data of specified length.

By default (i.e., *flags* is zero), the extended attribute will be created if it does not exist, or the value will be replaced if the attribute already exists. To modify these semantics, one of the following values can be specified in *flags*:

XATTR_CREATE
: Perform a pure create, which fails if the named attribute exists already.

XATTR_REPLACE
: Perform a pure replace operation, which fails if the named attribute does not already exist.

RETURN VALUE

On success, zero is returned. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

EDQUOT
: Disk quota limits meant that there is insufficient space remaining to store the extended attribute.

EEXIST
: **XATTR_CREATE** was specified, and the attribute exists already.

ENODATA
: **XATTR_REPLACE** was specified, and the attribute does not exist.

ENOSPC
: There is insufficient space remaining to store the extended attribute.

ENOTSUP
: The namespace prefix of *name* is not valid.

ENOTSUP
: Extended attributes are not supported by the filesystem, or are disabled,

EPERM
The file is marked immutable or append-only. (See *ioctl_iflags*(2).)

In addition, the errors documented in *stat*(2) can also occur.

ERANGE
The size of *name* or *value* exceeds a filesystem-specific limit.

STANDARDS
Linux.

HISTORY
Linux 2.4, glibc 2.3.

SEE ALSO
getfattr(1), *setfattr*(1), *getxattr*(2), *listxattr*(2), *open*(2), *removexattr*(2), *stat*(2), *symlink*(7), *xattr*(7)

NAME

sgetmask, ssetmask − manipulation of signal mask (obsolete)

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/syscall.h>      /* Definition of SYS_* constants */
#include <unistd.h>

[[deprecated]] long syscall(SYS_sgetmask, void);
[[deprecated]] long syscall(SYS_ssetmask, long newmask);
```

DESCRIPTION

These system calls are obsolete. *Do not use them*; use *sigprocmask*(2) instead.

sgetmask() returns the signal mask of the calling process.

ssetmask() sets the signal mask of the calling process to the value given in *newmask*. The previous signal mask is returned.

The signal masks dealt with by these two system calls are plain bit masks (unlike the *sigset_t* used by *sigprocmask*(2)); use *sigmask*(3) to create and inspect these masks.

RETURN VALUE

sgetmask() always successfully returns the signal mask. **ssetmask**() always succeeds, and returns the previous signal mask.

ERRORS

These system calls always succeed.

STANDARDS

Linux.

HISTORY

Since Linux 3.16, support for these system calls is optional, depending on whether the kernel was built with the **CONFIG_SGETMASK_SYSCALL** option.

NOTES

These system calls are unaware of signal numbers greater than 31 (i.e., real-time signals).

These system calls do not exist on x86-64.

It is not possible to block **SIGSTOP** or **SIGKILL**.

SEE ALSO

sigprocmask(2), *signal*(7)

NAME

shmctl − System V shared memory control

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/shm.h>

int shmctl(int *shmid***, int** *op***, struct shmid_ds *****buf***);**

DESCRIPTION

shmctl() performs the control operation specified by *op* on the System V shared memory segment whose identifier is given in *shmid*.

The *buf* argument is a pointer to a *shmid_ds* structure, defined in <*sys/shm.h*> as follows:

```
struct shmid_ds {
    struct ipc_perm shm_perm;    /* Ownership and permissions */
    size_t          shm_segsz;   /* Size of segment (bytes) */
    time_t          shm_atime;   /* Last attach time */
    time_t          shm_dtime;   /* Last detach time */
    time_t          shm_ctime;   /* Creation time/time of last
                                    modification via shmctl() */
    pid_t           shm_cpid;    /* PID of creator */
    pid_t           shm_lpid;    /* PID of last shmat(2)/shmdt(2) */
    shmatt_t        shm_nattch;  /* No. of current attaches */
    ...
};
```

The fields of the *shmid_ds* structure are as follows:

shm_perm This is an *ipc_perm* structure (see below) that specifies the access permissions on the shared memory segment.

shm_segsz Size in bytes of the shared memory segment.

shm_atime Time of the last *shmat*(2) system call that attached this segment.

shm_dtime Time of the last *shmdt*(2) system call that detached tgis segment.

shm_ctime Time of creation of segment or time of the last **shmctl**() **IPC_SET** operation.

shm_cpid ID of the process that created the shared memory segment.

shm_lpid ID of the last process that executed a *shmat*(2) or *shmdt*(2) system call on this segment.

shm_nattch Number of processes that have this segment attached.

The *ipc_perm* structure is defined as follows (the highlighted fields are settable using **IPC_SET**):

```
struct ipc_perm {
    key_t          __key;    /* Key supplied to shmget(2) */
    uid_t          uid;      /* Effective UID of owner */
    gid_t          gid;      /* Effective GID of owner */
    uid_t          cuid;     /* Effective UID of creator */
    gid_t          cgid;     /* Effective GID of creator */
    unsigned short mode;     /* Permissions + SHM_DEST and
                                SHM_LOCKED flags */
    unsigned short __seq;    /* Sequence number */
};
```

The least significant 9 bits of the *mode* field of the *ipc_perm* structure define the access permissions for the shared memory segment. The permission bits are as follows:

0400 Read by user
0200 Write by user
0040 Read by group
0020 Write by group

0004 Read by others
0002 Write by others

Bits 0100, 0010, and 0001 (the execute bits) are unused by the system. (It is not necessary to have execute permission on a segment in order to perform a *shmat*(2) call with the **SHM_EXEC** flag.)

Valid values for *op* are:

IPC_STAT
Copy information from the kernel data structure associated with *shmid* into the *shmid_ds* structure pointed to by *buf*. The caller must have read permission on the shared memory segment.

IPC_SET
Write the values of some members of the *shmid_ds* structure pointed to by *buf* to the kernel data structure associated with this shared memory segment, updating also its *shm_ctime* member.

The following fields are updated: *shm_perm.uid*, *shm_perm.gid*, and (the least significant 9 bits of) *shm_perm.mode*.

The effective UID of the calling process must match the owner (*shm_perm.uid*) or creator (*shm_perm.cuid*) of the shared memory segment, or the caller must be privileged.

IPC_RMID
Mark the segment to be destroyed. The segment will actually be destroyed only after the last process detaches it (i.e., when the *shm_nattch* member of the associated structure *shmid_ds* is zero). The caller must be the owner or creator of the segment, or be privileged. The *buf* argument is ignored.

If a segment has been marked for destruction, then the (nonstandard) **SHM_DEST** flag of the *shm_perm.mode* field in the associated data structure retrieved by **IPC_STAT** will be set.

The caller *must* ensure that a segment is eventually destroyed; otherwise its pages that were faulted in will remain in memory or swap.

See also the description of */proc/sys/kernel/shm_rmid_forced* in *proc*(5).

IPC_INFO (Linux-specific)
Return information about system-wide shared memory limits and parameters in the structure pointed to by *buf*. This structure is of type *shminfo* (thus, a cast is required), defined in <*sys/shm.h*> if the **_GNU_SOURCE** feature test macro is defined:

```
struct shminfo {
    unsigned long shmmax; /* Maximum segment size */
    unsigned long shmmin; /* Minimum segment size;
                             always 1 */
    unsigned long shmmni; /* Maximum number of segments */
    unsigned long shmseg; /* Maximum number of segments
                             that a process can attach;
                             unused within kernel */
    unsigned long shmall; /* Maximum number of pages of
                             shared memory, system-wide */
};
```

The *shmmni*, *shmmax*, and *shmall* settings can be changed via */proc* files of the same name; see *proc*(5) for details.

SHM_INFO (Linux-specific)
Return a *shm_info* structure whose fields contain information about system resources consumed by shared memory. This structure is defined in <*sys/shm.h*> if the **_GNU_SOURCE** feature test macro is defined:

```
struct shm_info {
    int           used_ids; /* # of currently existing
                               segments */
    unsigned long shm_tot;  /* Total number of shared
                               memory pages */
```

```
            unsigned long shm_rss;  /* # of resident shared
                                       memory pages */
            unsigned long shm_swp;  /* # of swapped shared
                                       memory pages */
            unsigned long swap_attempts;
                                    /* Unused since Linux 2.4 */
            unsigned long swap_successes;
                                    /* Unused since Linux 2.4 */
        };
```

SHM_STAT (Linux-specific)
: Return a *shmid_ds* structure as for **IPC_STAT**. However, the *shmid* argument is not a segment identifier, but instead an index into the kernel's internal array that maintains information about all shared memory segments on the system.

SHM_STAT_ANY (Linux-specific, since Linux 4.17)
: Return a *shmid_ds* structure as for **SHM_STAT**. However, *shm_perm.mode* is not checked for read access for *shmid*, meaning that any user can employ this operation (just as any user may read */proc/sysvipc/shm* to obtain the same information).

The caller can prevent or allow swapping of a shared memory segment with the following *op* values:

SHM_LOCK (Linux-specific)
: Prevent swapping of the shared memory segment. The caller must fault in any pages that are required to be present after locking is enabled. If a segment has been locked, then the (non-standard) **SHM_LOCKED** flag of the *shm_perm.mode* field in the associated data structure retrieved by **IPC_STAT** will be set.

SHM_UNLOCK (Linux-specific)
: Unlock the segment, allowing it to be swapped out.

Before Linux 2.6.10, only a privileged process could employ **SHM_LOCK** and **SHM_UNLOCK**. Since Linux 2.6.10, an unprivileged process can employ these operations if its effective UID matches the owner or creator UID of the segment, and (for **SHM_LOCK**) the amount of memory to be locked falls within the **RLIMIT_MEMLOCK** resource limit (see *setrlimit*(2)).

RETURN VALUE

A successful **IPC_INFO** or **SHM_INFO** operation returns the index of the highest used entry in the kernel's internal array recording information about all shared memory segments. (This information can be used with repeated **SHM_STAT** or **SHM_STAT_ANY** operations to obtain information about all shared memory segments on the system.) A successful **SHM_STAT** operation returns the identifier of the shared memory segment whose index was given in *shmid*. Other operations return 0 on success.

On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
: **IPC_STAT** or **SHM_STAT** is requested and *shm_perm.mode* does not allow read access for *shmid*, and the calling process does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EFAULT
: The argument *op* has value **IPC_SET** or **IPC_STAT** but the address pointed to by *buf* isn't accessible.

EIDRM
: *shmid* points to a removed identifier.

EINVAL
: *shmid* is not a valid identifier, or *op* is not a valid operation. Or: for a **SHM_STAT** or **SHM_STAT_ANY** operation, the index value specified in *shmid* referred to an array slot that is currently unused.

ENOMEM
: (Since Linux 2.6.9), **SHM_LOCK** was specified and the size of the to-be-locked segment would mean that the total bytes in locked shared memory segments would exceed the limit for

the real user ID of the calling process. This limit is defined by the **RLIMIT_MEMLOCK** soft resource limit (see *setrlimit*(2)).

EOVERFLOW
IPC_STAT is attempted, and the GID or UID value is too large to be stored in the structure pointed to by *buf*.

EPERM
IPC_SET or **IPC_RMID** is attempted, and the effective user ID of the calling process is not that of the creator (found in *shm_perm.cuid*), or the owner (found in *shm_perm.uid*), and the process was not privileged (Linux: did not have the **CAP_SYS_ADMIN** capability).

Or (before Linux 2.6.9), **SHM_LOCK** or **SHM_UNLOCK** was specified, but the process was not privileged (Linux: did not have the **CAP_IPC_LOCK** capability). (Since Linux 2.6.9, this error can also occur if the **RLIMIT_MEMLOCK** is 0 and the caller is not privileged.)

VERSIONS

Linux permits a process to attach (**shmat**(2)) a shared memory segment that has already been marked for deletion using *shmctl(IPC_RMID)*. This feature is not available on other UNIX implementations; portable applications should avoid relying on it.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

Various fields in a *struct shmid_ds* were typed as *short* under Linux 2.2 and have become *long* under Linux 2.4. To take advantage of this, a recompilation under glibc-2.1.91 or later should suffice. (The kernel distinguishes old and new calls by an **IPC_64** flag in *op*.)

NOTES

The **IPC_INFO**, **SHM_STAT**, and **SHM_INFO** operations are used by the *ipcs*(1) program to provide information on allocated resources. In the future, these may modified or moved to a */proc* filesystem interface.

NAME

shmget − allocates a System V shared memory segment

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/shm.h>

int shmget(key_t *key***, size_t** *size***, int** *shmflg***);**

DESCRIPTION

shmget() returns the identifier of the System V shared memory segment associated with the value of the argument *key*. It may be used either to obtain the identifier of a previously created shared memory segment (when *shmflg* is zero and *key* does not have the value **IPC_PRIVATE**), or to create a new set.

A new shared memory segment, with size equal to the value of *size* rounded up to a multiple of **PAGE_SIZE**, is created if *key* has the value **IPC_PRIVATE** or *key* isn't **IPC_PRIVATE**, no shared memory segment corresponding to *key* exists, and **IPC_CREAT** is specified in *shmflg*.

If *shmflg* specifies both **IPC_CREAT** and **IPC_EXCL** and a shared memory segment already exists for *key*, then **shmget**() fails with *errno* set to **EEXIST**. (This is analogous to the effect of the combination **O_CREAT | O_EXCL** for *open*(2).)

The value *shmflg* is composed of:

IPC_CREAT
: Create a new segment. If this flag is not used, then **shmget**() will find the segment associated with *key* and check to see if the user has permission to access the segment.

IPC_EXCL
: This flag is used with **IPC_CREAT** to ensure that this call creates the segment. If the segment already exists, the call fails.

SHM_HUGETLB (since Linux 2.6)
: Allocate the segment using "huge" pages. See the Linux kernel source file *Documentation/admin−guide/mm/hugetlbpage.rst* for further information.

SHM_HUGE_2MB
SHM_HUGE_1GB (since Linux 3.8)
: Used in conjunction with **SHM_HUGETLB** to select alternative hugetlb page sizes (respectively, 2 MB and 1 GB) on systems that support multiple hugetlb page sizes.

  More generally, the desired huge page size can be configured by encoding the base-2 logarithm of the desired page size in the six bits at the offset **SHM_HUGE_SHIFT**. Thus, the above two constants are defined as:

```
#define SHM_HUGE_2MB    (21 << SHM_HUGE_SHIFT)
#define SHM_HUGE_1GB    (30 << SHM_HUGE_SHIFT)
```

  For some additional details, see the discussion of the similarly named constants in *mmap*(2).

SHM_NORESERVE (since Linux 2.6.15)
: This flag serves the same purpose as the *mmap*(2) **MAP_NORESERVE** flag. Do not reserve swap space for this segment. When swap space is reserved, one has the guarantee that it is possible to modify the segment. When swap space is not reserved one might get **SIGSEGV** upon a write if no physical memory is available. See also the discussion of the file */proc/sys/vm/overcommit_memory* in *proc*(5).

In addition to the above flags, the least significant 9 bits of *shmflg* specify the permissions granted to the owner, group, and others. These bits have the same format, and the same meaning, as the *mode* argument of *open*(2). Presently, execute permissions are not used by the system.

When a new shared memory segment is created, its contents are initialized to zero values, and its associated data structure, *shmid_ds* (see *shmctl*(2)), is initialized as follows:

- *shm_perm.cuid* and *shm_perm.uid* are set to the effective user ID of the calling process.

- *shm_perm.cgid* and *shm_perm.gid* are set to the effective group ID of the calling process.
- The least significant 9 bits of *shm_perm.mode* are set to the least significant 9 bit of *shmflg*.
- *shm_segsz* is set to the value of *size*.
- *shm_lpid*, *shm_nattch*, *shm_atime*, and *shm_dtime* are set to 0.
- *shm_ctime* is set to the current time.

If the shared memory segment already exists, the permissions are verified, and a check is made to see if it is marked for destruction.

RETURN VALUE

On success, a valid shared memory identifier is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
The user does not have permission to access the shared memory segment, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EEXIST
IPC_CREAT and **IPC_EXCL** were specified in *shmflg*, but a shared memory segment already exists for *key*.

EINVAL
A new segment was to be created and *size* is less than **SHMMIN** or greater than **SHMMAX**.

EINVAL
A segment for the given *key* exists, but *size* is greater than the size of that segment.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENOENT
No segment exists for the given *key*, and **IPC_CREAT** was not specified.

ENOMEM
No memory could be allocated for segment overhead.

ENOSPC
All possible shared memory IDs have been taken (**SHMMNI**), or allocating a segment of the requested *size* would cause the system to exceed the system-wide limit on shared memory (**SHMALL**).

EPERM
The **SHM_HUGETLB** flag was specified, but the caller was not privileged (did not have the **CAP_IPC_LOCK** capability) and is not a member of the *sysctl_hugetlb_shm_group* group; see the description of */proc/sys/vm/sysctl_hugetlb_shm_group* in *proc*(5).

STANDARDS

POSIX.1-2008.

SHM_HUGETLB and **SHM_NORESERVE** are Linux extensions.

HISTORY

POSIX.1-2001, SVr4.

NOTES

IPC_PRIVATE isn't a flag field but a *key_t* type. If this special value is used for *key*, the system call ignores all but the least significant 9 bits of *shmflg* and creates a new shared memory segment.

Shared memory limits

The following limits on shared memory segment resources affect the **shmget**() call:

SHMALL
System-wide limit on the total amount of shared memory, measured in units of the system page size.

On Linux, this limit can be read and modified via */proc/sys/kernel/shmall*. Since Linux 3.16, the default value for this limit is:

```
ULONG_MAX - 2^24
```

The effect of this value (which is suitable for both 32-bit and 64-bit systems) is to impose no limitation on allocations. This value, rather than **ULONG_MAX**, was chosen as the default to prevent some cases where historical applications simply raised the existing limit without first checking its current value. Such applications would cause the value to overflow if the limit was set at **ULONG_MAX**.

From Linux 2.4 up to Linux 3.15, the default value for this limit was:

```
SHMMAX / PAGE_SIZE * (SHMMNI / 16)
```

If **SHMMAX** and **SHMMNI** were not modified, then multiplying the result of this formula by the page size (to get a value in bytes) yielded a value of 8 GB as the limit on the total memory used by all shared memory segments.

SHMMAX
Maximum size in bytes for a shared memory segment.

On Linux, this limit can be read and modified via */proc/sys/kernel/shmmax*. Since Linux 3.16, the default value for this limit is:

```
ULONG_MAX - 2^24
```

The effect of this value (which is suitable for both 32-bit and 64-bit systems) is to impose no limitation on allocations. See the description of **SHMALL** for a discussion of why this default value (rather than **ULONG_MAX**) is used.

From Linux 2.2 up to Linux 3.15, the default value of this limit was 0x2000000 (32 MiB).

Because it is not possible to map just part of a shared memory segment, the amount of virtual memory places another limit on the maximum size of a usable segment: for example, on i386 the largest segments that can be mapped have a size of around 2.8 GB, and on x86-64 the limit is around 127 TB.

SHMMIN
Minimum size in bytes for a shared memory segment: implementation dependent (currently 1 byte, though **PAGE_SIZE** is the effective minimum size).

SHMMNI
System-wide limit on the number of shared memory segments. In Linux 2.2, the default value for this limit was 128; since Linux 2.4, the default value is 4096.

On Linux, this limit can be read and modified via */proc/sys/kernel/shmmni*.

The implementation has no specific limits for the per-process maximum number of shared memory segments (**SHMSEG**).

Linux notes
Until Linux 2.3.30, Linux would return **EIDRM** for a **shmget**() on a shared memory segment scheduled for deletion.

BUGS
The name choice **IPC_PRIVATE** was perhaps unfortunate, **IPC_NEW** would more clearly show its function.

EXAMPLES
See *shmop*(2).

NAME

shmat, shmdt − System V shared memory operations

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/shm.h>

void *shmat(int shmid, const void *_Nullable shmaddr, int shmflg);
int shmdt(const void *shmaddr);
```

DESCRIPTION

shmat()

shmat() attaches the System V shared memory segment identified by *shmid* to the address space of the calling process. The attaching address is specified by *shmaddr* with one of the following criteria:

- If *shmaddr* is NULL, the system chooses a suitable (unused) page-aligned address to attach the segment.
- If *shmaddr* isn't NULL and **SHM_RND** is specified in *shmflg*, the attach occurs at the address equal to *shmaddr* rounded down to the nearest multiple of **SHMLBA**.
- Otherwise, *shmaddr* must be a page-aligned address at which the attach occurs.

In addition to **SHM_RND**, the following flags may be specified in the *shmflg* bit-mask argument:

SHM_EXEC (Linux-specific; since Linux 2.6.9)
: Allow the contents of the segment to be executed. The caller must have execute permission on the segment.

SHM_RDONLY
: Attach the segment for read-only access. The process must have read permission for the segment. If this flag is not specified, the segment is attached for read and write access, and the process must have read and write permission for the segment. There is no notion of a write-only shared memory segment.

SHM_REMAP (Linux-specific)
: This flag specifies that the mapping of the segment should replace any existing mapping in the range starting at *shmaddr* and continuing for the size of the segment. (Normally, an **EINVAL** error would result if a mapping already exists in this address range.) In this case, *shmaddr* must not be NULL.

The *brk*(2) value of the calling process is not altered by the attach. The segment will automatically be detached at process exit. The same segment may be attached as a read and as a read-write one, and more than once, in the process's address space.

A successful **shmat**() call updates the members of the *shmid_ds* structure (see *shmctl*(2)) associated with the shared memory segment as follows:

- *shm_atime* is set to the current time.
- *shm_lpid* is set to the process-ID of the calling process.
- *shm_nattch* is incremented by one.

shmdt()

shmdt() detaches the shared memory segment located at the address specified by *shmaddr* from the address space of the calling process. The to-be-detached segment must be currently attached with *shmaddr* equal to the value returned by the attaching **shmat**() call.

On a successful **shmdt**() call, the system updates the members of the *shmid_ds* structure associated with the shared memory segment as follows:

- *shm_dtime* is set to the current time.
- *shm_lpid* is set to the process-ID of the calling process.
- *shm_nattch* is decremented by one. If it becomes 0 and the segment is marked for deletion, the segment is deleted.

RETURN VALUE

On success, **shmat**() returns the address of the attached shared memory segment; on error, *(void *) −1* is returned, and *errno* is set to indicate the error.

On success, **shmdt**() returns 0; on error −1 is returned, and *errno* is set to indicate the error.

ERRORS

shmat() can fail with one of the following errors:

EACCES
The calling process does not have the required permissions for the requested attach type, and does not have the **CAP_IPC_OWNER** capability in the user namespace that governs its IPC namespace.

EIDRM
shmid points to a removed identifier.

EINVAL
Invalid *shmid* value, unaligned (i.e., not page-aligned and **SHM_RND** was not specified) or invalid *shmaddr* value, or can't attach segment at *shmaddr*, or **SHM_REMAP** was specified and *shmaddr* was NULL.

ENOMEM
Could not allocate memory for the descriptor or for the page tables.

shmdt() can fail with one of the following errors:

EINVAL
There is no shared memory segment attached at *shmaddr*; or, *shmaddr* is not aligned on a page boundary.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

In SVID 3 (or perhaps earlier), the type of the *shmaddr* argument was changed from *char* * into *const void* *, and the returned type of **shmat**() from *char* * into *void* *.

NOTES

After a *fork*(2), the child inherits the attached shared memory segments.

After an *execve*(2), all attached shared memory segments are detached from the process.

Upon *_exit*(2), all attached shared memory segments are detached from the process.

Using **shmat**() with *shmaddr* equal to NULL is the preferred, portable way of attaching a shared memory segment. Be aware that the shared memory segment attached in this way may be attached at different addresses in different processes. Therefore, any pointers maintained within the shared memory must be made relative (typically to the starting address of the segment), rather than absolute.

On Linux, it is possible to attach a shared memory segment even if it is already marked to be deleted. However, POSIX.1 does not specify this behavior and many other implementations do not support it.

The following system parameter affects **shmat**():

SHMLBA
Segment low boundary address multiple. When explicitly specifying an attach address in a call to **shmat**(), the caller should ensure that the address is a multiple of this value. This is necessary on some architectures, in order either to ensure good CPU cache performance or to ensure that different attaches of the same segment have consistent views within the CPU cache. **SHMLBA** is normally some multiple of the system page size. (On many Linux architectures, **SHMLBA** is the same as the system page size.)

The implementation places no intrinsic per-process limit on the number of shared memory segments (**SHMSEG**).

EXAMPLES

The two programs shown below exchange a string using a shared memory segment. Further details about the programs are given below. First, we show a shell session demonstrating their use.

In one terminal window, we run the "reader" program, which creates a System V shared memory segment and a System V semaphore set. The program prints out the IDs of the created objects, and then waits for the semaphore to change value.

```
$ ./svshm_string_read
shmid = 1114194; semid = 15
```

In another terminal window, we run the "writer" program. The "writer" program takes three command-line arguments: the IDs of the shared memory segment and semaphore set created by the "reader", and a string. It attaches the existing shared memory segment, copies the string to the shared memory, and modifies the semaphore value.

```
$ ./svshm_string_write 1114194 15 'Hello, world'
```

Returning to the terminal where the "reader" is running, we see that the program has ceased waiting on the semaphore and has printed the string that was copied into the shared memory segment by the writer:

```
Hello, world
```

Program source: svshm_string.h

The following header file is included by the "reader" and "writer" programs:

```
/* svshm_string.h

   Licensed under GNU General Public License v2 or later.
*/
#include <sys/types.h>
#include <sys/ipc.h>
#include <sys/shm.h>
#include <sys/sem.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>

#define errExit(msg)    do { perror(msg); exit(EXIT_FAILURE); \
                        } while (0)

union semun {                   /* Used in calls to semctl() */
    int                 val;
    struct semid_ds *   buf;
    unsigned short *    array;
#if defined(__linux__)
    struct seminfo *    __buf;
#endif
};

#define MEM_SIZE 4096
```

Program source: svshm_string_read.c

The "reader" program creates a shared memory segment and a semaphore set containing one semaphore. It then attaches the shared memory object into its address space and initializes the semaphore value to 1. Finally, the program waits for the semaphore value to become 0, and afterwards prints the string that has been copied into the shared memory segment by the "writer".

```
/* svshm_string_read.c

   Licensed under GNU General Public License v2 or later.
*/
#include <stdio.h>
#include <stdlib.h>
#include <sys/ipc.h>
#include <sys/sem.h>
#include <sys/shm.h>
```

```
#include "svshm_string.h"

int
main(void)
{
    int            semid, shmid;
    char           *addr;
    union semun    arg, dummy;
    struct sembuf  sop;

    /* Create shared memory and semaphore set containing one
       semaphore. */

    shmid = shmget(IPC_PRIVATE, MEM_SIZE, IPC_CREAT | 0600);
    if (shmid == -1)
        errExit("shmget");

    semid = semget(IPC_PRIVATE, 1, IPC_CREAT | 0600);
    if (semid == -1)
        errExit("semget");

    /* Attach shared memory into our address space. */

    addr = shmat(shmid, NULL, SHM_RDONLY);
    if (addr == (void *) -1)
        errExit("shmat");

    /* Initialize semaphore 0 in set with value 1. */

    arg.val = 1;
    if (semctl(semid, 0, SETVAL, arg) == -1)
        errExit("semctl");

    printf("shmid = %d; semid = %d\n", shmid, semid);

    /* Wait for semaphore value to become 0. */

    sop.sem_num = 0;
    sop.sem_op = 0;
    sop.sem_flg = 0;

    if (semop(semid, &sop, 1) == -1)
        errExit("semop");

    /* Print the string from shared memory. */

    printf("%s\n", addr);

    /* Remove shared memory and semaphore set. */

    if (shmctl(shmid, IPC_RMID, NULL) == -1)
        errExit("shmctl");
    if (semctl(semid, 0, IPC_RMID, dummy) == -1)
        errExit("semctl");

    exit(EXIT_SUCCESS);
}
```

Program source: svshm_string_write.c

The writer program takes three command-line arguments: the IDs of the shared memory segment and semaphore set that have already been created by the "reader", and a string. It attaches the shared memory segment into its address space, and then decrements the semaphore value to 0 in order to inform the "reader" that it can now examine the contents of the shared memory.

*/
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/sem.h>
#include <sys/shm.h>

#include "svshm_string.h"

int
main(int argc, char *argv[])
{
    int            semid, shmid;
    char           *addr;
    size_t         len;
    struct sembuf  sop;

    if (argc != 4) {
        fprintf(stderr, "Usage: %s shmid semid string\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    len = strlen(argv[3]) + 1;  /* +1 to include trailing '\0' */
    if (len > MEM_SIZE) {
        fprintf(stderr, "String is too big!\n");
        exit(EXIT_FAILURE);
    }

    /* Get object IDs from command-line. */

    shmid = atoi(argv[1]);
    semid = atoi(argv[2]);

    /* Attach shared memory into our address space and copy string
       (including trailing null byte) into memory. */

    addr = shmat(shmid, NULL, 0);
    if (addr == (void *) -1)
        errExit("shmat");

    memcpy(addr, argv[3], len);

    /* Decrement semaphore to 0. */

    sop.sem_num = 0;
    sop.sem_op = -1;
    sop.sem_flg = 0;

    if (semop(semid, &sop, 1) == -1)
        errExit("semop");
```

```
            exit(EXIT_SUCCESS);
        }
```

NAME

shutdown − shut down part of a full-duplex connection

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/socket.h>

int shutdown(int *sockfd***, int** *how***);**

DESCRIPTION

The **shutdown**() call causes all or part of a full-duplex connection on the socket associated with *sockfd* to be shut down. If *how* is **SHUT_RD**, further receptions will be disallowed. If *how* is **SHUT_WR**, further transmissions will be disallowed. If *how* is **SHUT_RDWR**, further receptions and transmissions will be disallowed.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EBADF
sockfd is not a valid file descriptor.

EINVAL
An invalid value was specified in *how* (but see BUGS).

ENOTCONN
The specified socket is not connected.

ENOTSOCK
The file descriptor *sockfd* does not refer to a socket.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.4BSD (first appeared in 4.2BSD).

NOTES

The constants **SHUT_RD**, **SHUT_WR**, **SHUT_RDWR** have the value 0, 1, 2, respectively, and are defined in <*sys/socket.h*> since glibc-2.1.91.

BUGS

Checks for the validity of *how* are done in domain-specific code, and before Linux 3.7 not all domains performed these checks. Most notably, UNIX domain sockets simply ignored invalid values. This problem was fixed for UNIX domain sockets in Linux 3.7.

NAME

sigaction, rt_sigaction − examine and change a signal action

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <signal.h>

int sigaction(int signum,
              const struct sigaction *_Nullable restrict act,
              struct sigaction *_Nullable restrict oldact);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

sigaction():
_POSIX_C_SOURCE

siginfo_t:
_POSIX_C_SOURCE >= 199309L

DESCRIPTION

The **sigaction**() system call is used to change the action taken by a process on receipt of a specific signal. (See *signal*(7) for an overview of signals.)

signum specifies the signal and can be any valid signal except **SIGKILL** and **SIGSTOP**.

If *act* is non-NULL, the new action for signal *signum* is installed from *act*. If *oldact* is non-NULL, the previous action is saved in *oldact*.

The *sigaction* structure is defined as something like:

```
struct sigaction {
    void     (*sa_handler)(int);
    void     (*sa_sigaction)(int, siginfo_t *, void *);
    sigset_t   sa_mask;
    int        sa_flags;
    void     (*sa_restorer)(void);
};
```

On some architectures a union is involved: do not assign to both *sa_handler* and *sa_sigaction*.

The *sa_restorer* field is not intended for application use. (POSIX does not specify a *sa_restorer* field.) Some further details of the purpose of this field can be found in *sigreturn*(2).

sa_handler specifies the action to be associated with *signum* and can be one of the following:

- **SIG_DFL** for the default action.
- **SIG_IGN** to ignore this signal.
- A pointer to a signal handling function. This function receives the signal number as its only argument.

If **SA_SIGINFO** is specified in *sa_flags*, then *sa_sigaction* (instead of *sa_handler*) specifies the signal-handling function for *signum*. This function receives three arguments, as described below.

sa_mask specifies a mask of signals which should be blocked (i.e., added to the signal mask of the thread in which the signal handler is invoked) during execution of the signal handler. In addition, the signal which triggered the handler will be blocked, unless the **SA_NODEFER** flag is used.

sa_flags specifies a set of flags which modify the behavior of the signal. It is formed by the bitwise OR of zero or more of the following:

SA_NOCLDSTOP
: If *signum* is **SIGCHLD**, do not receive notification when child processes stop (i.e., when they receive one of **SIGSTOP**, **SIGTSTP**, **SIGTTIN**, or **SIGTTOU**) or resume (i.e., they receive **SIGCONT**) (see *wait*(2)). This flag is meaningful only when establishing a handler for **SIGCHLD**.

SA_NOCLDWAIT (since Linux 2.6)
If *signum* is **SIGCHLD**, do not transform children into zombies when they terminate. See also *waitpid*(2). This flag is meaningful only when establishing a handler for **SIGCHLD**, or when setting that signal's disposition to **SIG_DFL**.

If the **SA_NOCLDWAIT** flag is set when establishing a handler for **SIGCHLD**, POSIX.1 leaves it unspecified whether a **SIGCHLD** signal is generated when a child process terminates. On Linux, a **SIGCHLD** signal is generated in this case; on some other implementations, it is not.

SA_NODEFER
Do not add the signal to the thread's signal mask while the handler is executing, unless the signal is specified in *act.sa_mask*. Consequently, a further instance of the signal may be delivered to the thread while it is executing the handler. This flag is meaningful only when establishing a signal handler.

SA_NOMASK is an obsolete, nonstandard synonym for this flag.

SA_ONSTACK
Call the signal handler on an alternate signal stack provided by *sigaltstack*(2). If an alternate stack is not available, the default stack will be used. This flag is meaningful only when establishing a signal handler.

SA_RESETHAND
Restore the signal action to the default upon entry to the signal handler. This flag is meaningful only when establishing a signal handler.

SA_ONESHOT is an obsolete, nonstandard synonym for this flag.

SA_RESTART
Provide behavior compatible with BSD signal semantics by making certain system calls restartable across signals. This flag is meaningful only when establishing a signal handler. See *signal*(7) for a discussion of system call restarting.

SA_RESTORER
Not intended for application use. This flag is used by C libraries to indicate that the *sa_restorer* field contains the address of a "signal trampoline". See *sigreturn*(2) for more details.

SA_SIGINFO (since Linux 2.2)
The signal handler takes three arguments, not one. In this case, *sa_sigaction* should be set instead of *sa_handler*. This flag is meaningful only when establishing a signal handler.

SA_UNSUPPORTED (since Linux 5.11)
Used to dynamically probe for flag bit support.

If an attempt to register a handler succeeds with this flag set in *act->sa_flags* alongside other flags that are potentially unsupported by the kernel, and an immediately subsequent **sigaction**() call specifying the same signal number and with a non-NULL *oldact* argument yields **SA_UNSUPPORTED** *clear* in *oldact->sa_flags*, then *oldact->sa_flags* may be used as a bitmask describing which of the potentially unsupported flags are, in fact, supported. See the section "Dynamically probing for flag bit support" below for more details.

SA_EXPOSE_TAGBITS (since Linux 5.11)
Normally, when delivering a signal, an architecture-specific set of tag bits are cleared from the *si_addr* field of *siginfo_t*. If this flag is set, an architecture-specific subset of the tag bits will be preserved in *si_addr*.

Programs that need to be compatible with Linux versions older than 5.11 must use **SA_UNSUPPORTED** to probe for support.

The siginfo_t argument to a SA_SIGINFO handler

When the **SA_SIGINFO** flag is specified in *act.sa_flags*, the signal handler address is passed via the *act.sa_sigaction* field. This handler takes three arguments, as follows:

```
void
handler(int sig, siginfo_t *info, void *ucontext)
{
    ...
```

```
}
```

These three arguments are as follows

sig The number of the signal that caused invocation of the handler.

info A pointer to a *siginfo_t*, which is a structure containing further information about the signal, as described below.

ucontext

This is a pointer to a *ucontext_t* structure, cast to *void* *. The structure pointed to by this field contains signal context information that was saved on the user-space stack by the kernel; for details, see *sigreturn*(2). Further information about the *ucontext_t* structure can be found in *getcontext*(3) and *signal*(7). Commonly, the handler function doesn't make any use of the third argument.

The *siginfo_t* data type is a structure with the following fields:

```
siginfo_t {
    int      si_signo;     /* Signal number */
    int      si_errno;     /* An errno value */
    int      si_code;      /* Signal code */
    int      si_trapno;    /* Trap number that caused
                              hardware-generated signal
                              (unused on most architectures) */
    pid_t    si_pid;       /* Sending process ID */
    uid_t    si_uid;       /* Real user ID of sending process */
    int      si_status;    /* Exit value or signal */
    clock_t  si_utime;     /* User time consumed */
    clock_t  si_stime;     /* System time consumed */
    union sigval si_value; /* Signal value */
    int      si_int;       /* POSIX.1b signal */
    void    *si_ptr;       /* POSIX.1b signal */
    int      si_overrun;   /* Timer overrun count;
                              POSIX.1b timers */
    int      si_timerid;   /* Timer ID; POSIX.1b timers */
    void    *si_addr;      /* Memory location which caused fault */
    long     si_band;      /* Band event (was int in
                              glibc 2.3.2 and earlier) */
    int      si_fd;        /* File descriptor */
    short    si_addr_lsb;  /* Least significant bit of address
                              (since Linux 2.6.32) */
    void    *si_lower;     /* Lower bound when address violation
                              occurred (since Linux 3.19) */
    void    *si_upper;     /* Upper bound when address violation
                              occurred (since Linux 3.19) */
    int      si_pkey;      /* Protection key on PTE that caused
                              fault (since Linux 4.6) */
    void    *si_call_addr; /* Address of system call instruction
                              (since Linux 3.5) */
    int      si_syscall;   /* Number of attempted system call
                              (since Linux 3.5) */
    unsigned int si_arch;  /* Architecture of attempted system call
                              (since Linux 3.5) */
}
```

si_signo, *si_errno* and *si_code* are defined for all signals. (*si_errno* is generally unused on Linux.) The rest of the struct may be a union, so that one should read only the fields that are meaningful for the given signal:

- Signals sent with *kill*(2) and *sigqueue*(3) fill in *si_pid* and *si_uid*. In addition, signals sent with *sigqueue*(3) fill in *si_int* and *si_ptr* with the values specified by the sender of the signal; see *sigqueue*(3) for more details.

- Signals sent by POSIX.1b timers (since Linux 2.6) fill in *si_overrun* and *si_timerid*. The *si_timerid* field is an internal ID used by the kernel to identify the timer; it is not the same as the timer ID returned by *timer_create*(2). The *si_overrun* field is the timer overrun count; this is the same information as is obtained by a call to *timer_getoverrun*(2). These fields are nonstandard Linux extensions.
- Signals sent for message queue notification (see the description of **SIGEV_SIGNAL** in *mq_notify*(3)) fill in *si_int*/*si_ptr*, with the *sigev_value* supplied to *mq_notify*(3); *si_pid*, with the process ID of the message sender; and *si_uid*, with the real user ID of the message sender.
- **SIGCHLD** fills in *si_pid*, *si_uid*, *si_status*, *si_utime*, and *si_stime*, providing information about the child. The *si_pid* field is the process ID of the child; *si_uid* is the child's real user ID. The *si_status* field contains the exit status of the child (if *si_code* is **CLD_EXITED**), or the signal number that caused the process to change state. The *si_utime* and *si_stime* contain the user and system CPU time used by the child process; these fields do not include the times used by waited-for children (unlike *getrusage*(2) and *times*(2)). Up to Linux 2.6, and since Linux 2.6.27, these fields report CPU time in units of *sysconf(_SC_CLK_TCK)*. In Linux 2.6 kernels before Linux 2.6.27, a bug meant that these fields reported time in units of the (configurable) system jiffy (see *time*(7)).
- **SIGILL**, **SIGFPE**, **SIGSEGV**, **SIGBUS**, and **SIGTRAP** fill in *si_addr* with the address of the fault. On some architectures, these signals also fill in the *si_trapno* field.

  Some suberrors of **SIGBUS**, in particular **BUS_MCEERR_AO** and **BUS_MCEERR_AR**, also fill in *si_addr_lsb*. This field indicates the least significant bit of the reported address and therefore the extent of the corruption. For example, if a full page was corrupted, *si_addr_lsb* contains *log2(sysconf(_SC_PAGESIZE))*. When **SIGTRAP** is delivered in response to a *ptrace*(2) event (PTRACE_EVENT_foo), *si_addr* is not populated, but *si_pid* and *si_uid* are populated with the respective process ID and user ID responsible for delivering the trap. In the case of *seccomp*(2), the tracee will be shown as delivering the event. **BUS_MCEERR_*** and *si_addr_lsb* are Linux-specific extensions.

  The **SEGV_BNDERR** suberror of **SIGSEGV** populates *si_lower* and *si_upper*.

  The **SEGV_PKUERR** suberror of **SIGSEGV** populates *si_pkey*.
- **SIGIO**/**SIGPOLL** (the two names are synonyms on Linux) fills in *si_band* and *si_fd*. The *si_band* event is a bit mask containing the same values as are filled in the *revents* field by *poll*(2). The *si_fd* field indicates the file descriptor for which the I/O event occurred; for further details, see the description of **F_SETSIG** in *fcntl*(2).
- **SIGSYS**, generated (since Linux 3.5) when a seccomp filter returns **SECCOMP_RET_TRAP**, fills in *si_call_addr*, *si_syscall*, *si_arch*, *si_errno*, and other fields as described in *seccomp*(2).

The si_code field

The *si_code* field inside the *siginfo_t* argument that is passed to a **SA_SIGINFO** signal handler is a value (not a bit mask) indicating why this signal was sent. For a *ptrace*(2) event, *si_code* will contain **SIGTRAP** and have the ptrace event in the high byte:

```
(SIGTRAP | PTRACE_EVENT_foo << 8).
```

For a non-**ptrace**(2) event, the values that can appear in *si_code* are described in the remainder of this section. Since glibc 2.20, the definitions of most of these symbols are obtained from <*signal.h*> by defining feature test macros (before including *any* header file) as follows:

- **_XOPEN_SOURCE** with the value 500 or greater;
- **_XOPEN_SOURCE** and **_XOPEN_SOURCE_EXTENDED**; or
- **_POSIX_C_SOURCE** with the value 200809L or greater.

For the **TRAP_*** constants, the symbol definitions are provided only in the first two cases. Before glibc 2.20, no feature test macros were required to obtain these symbols.

For a regular signal, the following list shows the values which can be placed in *si_code* for any signal, along with the reason that the signal was generated.

SI_USER
: *kill*(2).

SI_KERNEL
Sent by the kernel.

SI_QUEUE
sigqueue(3).

SI_TIMER
POSIX timer expired.

SI_MESGQ (since Linux 2.6.6)
POSIX message queue state changed; see *mq_notify*(3).

SI_ASYNCIO
AIO completed.

SI_SIGIO
Queued **SIGIO** (only up to Linux 2.2; from Linux 2.4 onward **SIGIO**/**SIGPOLL** fills in *si_code* as described below).

SI_TKILL (since Linux 2.4.19)
tkill(2) or *tgkill*(2).

The following values can be placed in *si_code* for a **SIGILL** signal:

ILL_ILLOPC
Illegal opcode.

ILL_ILLOPN
Illegal operand.

ILL_ILLADR
Illegal addressing mode.

ILL_ILLTRP
Illegal trap.

ILL_PRVOPC
Privileged opcode.

ILL_PRVREG
Privileged register.

ILL_COPROC
Coprocessor error.

ILL_BADSTK
Internal stack error.

The following values can be placed in *si_code* for a **SIGFPE** signal:

FPE_INTDIV
Integer divide by zero.

FPE_INTOVF
Integer overflow.

FPE_FLTDIV
Floating-point divide by zero.

FPE_FLTOVF
Floating-point overflow.

FPE_FLTUND
Floating-point underflow.

FPE_FLTRES
Floating-point inexact result.

FPE_FLTINV
Floating-point invalid operation.

FPE_FLTSUB
Subscript out of range.

The following values can be placed in *si_code* for a **SIGSEGV** signal:

SEGV_MAPERR
Address not mapped to object.

SEGV_ACCERR
Invalid permissions for mapped object.

SEGV_BNDERR (since Linux 3.19)
Failed address bound checks.

SEGV_PKUERR (since Linux 4.6)
Access was denied by memory protection keys. See *pkeys*(7). The protection key which applied to this access is available via *si_pkey*.

The following values can be placed in *si_code* for a **SIGBUS** signal:

BUS_ADRALN
Invalid address alignment.

BUS_ADRERR
Nonexistent physical address.

BUS_OBJERR
Object-specific hardware error.

BUS_MCEERR_AR (since Linux 2.6.32)
Hardware memory error consumed on a machine check; action required.

BUS_MCEERR_AO (since Linux 2.6.32)
Hardware memory error detected in process but not consumed; action optional.

The following values can be placed in *si_code* for a **SIGTRAP** signal:

TRAP_BRKPT
Process breakpoint.

TRAP_TRACE
Process trace trap.

TRAP_BRANCH (since Linux 2.4, IA64 only)
Process taken branch trap.

TRAP_HWBKPT (since Linux 2.4, IA64 only)
Hardware breakpoint/watchpoint.

The following values can be placed in *si_code* for a **SIGCHLD** signal:

CLD_EXITED
Child has exited.

CLD_KILLED
Child was killed.

CLD_DUMPED
Child terminated abnormally.

CLD_TRAPPED
Traced child has trapped.

CLD_STOPPED
Child has stopped.

CLD_CONTINUED (since Linux 2.6.9)
Stopped child has continued.

The following values can be placed in *si_code* for a **SIGIO**/**SIGPOLL** signal:

POLL_IN
Data input available.

POLL_OUT
Output buffers available.

POLL_MSG
Input message available.

POLL_ERR
I/O error.

POLL_PRI
High priority input available.

POLL_HUP
Device disconnected.

The following value can be placed in *si_code* for a **SIGSYS** signal:

SYS_SECCOMP (since Linux 3.5)
Triggered by a *seccomp*(2) filter rule.

Dynamically probing for flag bit support

The **sigaction**() call on Linux accepts unknown bits set in *act->sa_flags* without error. The behavior of the kernel starting with Linux 5.11 is that a second **sigaction**() will clear unknown bits from *oldact->sa_flags*. However, historically, a second **sigaction**() call would typically leave those bits set in *oldact->sa_flags*.

This means that support for new flags cannot be detected simply by testing for a flag in *sa_flags*, and a program must test that **SA_UNSUPPORTED** has been cleared before relying on the contents of *sa_flags*.

Since the behavior of the signal handler cannot be guaranteed unless the check passes, it is wise to either block the affected signal while registering the handler and performing the check in this case, or where this is not possible, for example if the signal is synchronous, to issue the second **sigaction**() in the signal handler itself.

In kernels that do not support a specific flag, the kernel's behavior is as if the flag was not set, even if the flag was set in *act->sa_flags*.

The flags **SA_NOCLDSTOP**, **SA_NOCLDWAIT**, **SA_SIGINFO**, **SA_ONSTACK**, **SA_RESTART**, **SA_NODEFER**, **SA_RESETHAND**, and, if defined by the architecture, **SA_RESTORER** may not be reliably probed for using this mechanism, because they were introduced before Linux 5.11. However, in general, programs may assume that these flags are supported, since they have all been supported since Linux 2.6, which was released in the year 2003.

See EXAMPLES below for a demonstration of the use of **SA_UNSUPPORTED**.

RETURN VALUE

sigaction() returns 0 on success; on error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
act or *oldact* points to memory which is not a valid part of the process address space.

EINVAL
An invalid signal was specified. This will also be generated if an attempt is made to change the action for **SIGKILL** or **SIGSTOP**, which cannot be caught or ignored.

VERSIONS

C library/kernel differences

The glibc wrapper function for **sigaction**() gives an error (**EINVAL**) on attempts to change the disposition of the two real-time signals used internally by the NPTL threading implementation. See *nptl*(7) for details.

On architectures where the signal trampoline resides in the C library, the glibc wrapper function for **sigaction**() places the address of the trampoline code in the *act.sa_restorer* field and sets the **SA_RESTORER** flag in the *act.sa_flags* field. See *sigreturn*(2).

The original Linux system call was named **sigaction**(). However, with the addition of real-time signals in Linux 2.2, the fixed-size, 32-bit *sigset_t* type supported by that system call was no longer fit for

purpose. Consequently, a new system call, **rt_sigaction**(), was added to support an enlarged *sigset_t* type. The new system call takes a fourth argument, *size_t sigsetsize*, which specifies the size in bytes of the signal sets in *act.sa_mask* and *oldact.sa_mask*. This argument is currently required to have the value *sizeof(sigset_t)* (or the error **EINVAL** results). The glibc **sigaction**() wrapper function hides these details from us, transparently calling **rt_sigaction**() when the kernel provides it.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, SVr4.

POSIX.1-1990 disallowed setting the action for **SIGCHLD** to **SIG_IGN**. POSIX.1-2001 and later allow this possibility, so that ignoring **SIGCHLD** can be used to prevent the creation of zombies (see *wait*(2)). Nevertheless, the historical BSD and System V behaviors for ignoring **SIGCHLD** differ, so that the only completely portable method of ensuring that terminated children do not become zombies is to catch the **SIGCHLD** signal and perform a *wait*(2) or similar.

POSIX.1-1990 specified only **SA_NOCLDSTOP**. POSIX.1-2001 added **SA_NOCLDWAIT**, **SA_NODEFER**, **SA_ONSTACK**, **SA_RESETHAND**, **SA_RESTART**, and **SA_SIGINFO** as XSI extensions. POSIX.1-2008 moved **SA_NODEFER**, **SA_RESETHAND**, **SA_RESTART**, and **SA_SIGINFO** to the base specifications. Use of these latter values in *sa_flags* may be less portable in applications intended for older UNIX implementations.

The **SA_RESETHAND** flag is compatible with the SVr4 flag of the same name.

The **SA_NODEFER** flag is compatible with the SVr4 flag of the same name under kernels 1.3.9 and later. On older kernels the Linux implementation allowed the receipt of any signal, not just the one we are installing (effectively overriding any *sa_mask* settings).

NOTES

A child created via *fork*(2) inherits a copy of its parent's signal dispositions. During an *execve*(2), the dispositions of handled signals are reset to the default; the dispositions of ignored signals are left unchanged.

According to POSIX, the behavior of a process is undefined after it ignores a **SIGFPE**, **SIGILL**, or **SIGSEGV** signal that was not generated by *kill*(2) or *raise*(3). Integer division by zero has undefined result. On some architectures it will generate a **SIGFPE** signal. (Also dividing the most negative integer by −1 may generate **SIGFPE**.) Ignoring this signal might lead to an endless loop.

sigaction() can be called with a NULL second argument to query the current signal handler. It can also be used to check whether a given signal is valid for the current machine by calling it with NULL second and third arguments.

It is not possible to block **SIGKILL** or **SIGSTOP** (by specifying them in *sa_mask*). Attempts to do so are silently ignored.

See *sigsetops*(3) for details on manipulating signal sets.

See *signal-safety*(7) for a list of the async-signal-safe functions that can be safely called inside from inside a signal handler.

Undocumented

Before the introduction of **SA_SIGINFO**, it was also possible to get some additional information about the signal. This was done by providing an *sa_handler* signal handler with a second argument of type *struct sigcontext*, which is the same structure as the one that is passed in the *uc_mcontext* field of the *ucontext* structure that is passed (via a pointer) in the third argument of the *sa_sigaction* handler. See the relevant Linux kernel sources for details. This use is obsolete now.

BUGS

When delivering a signal with a **SA_SIGINFO** handler, the kernel does not always provide meaningful values for all of the fields of the *siginfo_t* that are relevant for that signal.

Up to and including Linux 2.6.13, specifying **SA_NODEFER** in *sa_flags* prevents not only the delivered signal from being masked during execution of the handler, but also the signals specified in *sa_mask*. This bug was fixed in Linux 2.6.14.

EXAMPLES

See *mprotect*(2).

Probing for flag support

The following example program exits with status **EXIT_SUCCESS** if **SA_EXPOSE_TAGBITS** is determined to be supported, and **EXIT_FAILURE** otherwise.

```
#include <signal.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

void
handler(int signo, siginfo_t *info, void *context)
{
    struct sigaction oldact;

    if (sigaction(SIGSEGV, NULL, &oldact) == -1
        || (oldact.sa_flags & SA_UNSUPPORTED)
        || !(oldact.sa_flags & SA_EXPOSE_TAGBITS))
    {
        _exit(EXIT_FAILURE);
    }
    _exit(EXIT_SUCCESS);
}

int
main(void)
{
    struct sigaction act = { 0 };

    act.sa_flags = SA_SIGINFO | SA_UNSUPPORTED | SA_EXPOSE_TAGBITS;
    act.sa_sigaction = &handler;
    if (sigaction(SIGSEGV, &act, NULL) == -1) {
        perror("sigaction");
        exit(EXIT_FAILURE);
    }

    raise(SIGSEGV);
}
```

NAME

sigaltstack − set and/or get signal stack context

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <signal.h>

int sigaltstack(const stack_t *_Nullable restrict *ss*,
stack_t *_Nullable restrict *old_ss*);

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

sigaltstack():
_XOPEN_SOURCE >= 500
|| /* Since glibc 2.12: */ _POSIX_C_SOURCE >= 200809L
|| /* glibc <= 2.19: */ _BSD_SOURCE

DESCRIPTION

sigaltstack() allows a thread to define a new alternate signal stack and/or retrieve the state of an existing alternate signal stack. An alternate signal stack is used during the execution of a signal handler if the establishment of that handler (see *sigaction*(2)) requested it.

The normal sequence of events for using an alternate signal stack is the following:

1. Allocate an area of memory to be used for the alternate signal stack.
2. Use **sigaltstack**() to inform the system of the existence and location of the alternate signal stack.
3. When establishing a signal handler using *sigaction*(2), inform the system that the signal handler should be executed on the alternate signal stack by specifying the **SA_ONSTACK** flag.

The *ss* argument is used to specify a new alternate signal stack, while the *old_ss* argument is used to retrieve information about the currently established signal stack. If we are interested in performing just one of these tasks, then the other argument can be specified as NULL.

The *stack_t* type used to type the arguments of this function is defined as follows:

```
typedef struct {
    void  *ss_sp;     /* Base address of stack */
    int    ss_flags;  /* Flags */
    size_t ss_size;   /* Number of bytes in stack */
} stack_t;
```

To establish a new alternate signal stack, the fields of this structure are set as follows:

ss.ss_flags
: This field contains either 0, or the following flag:

  SS_AUTODISARM (since Linux 4.7)
  : Clear the alternate signal stack settings on entry to the signal handler. When the signal handler returns, the previous alternate signal stack settings are restored.

    This flag was added in order to make it safe to switch away from the signal handler with *swapcontext*(3). Without this flag, a subsequently handled signal will corrupt the state of the switched-away signal handler. On kernels where this flag is not supported, **sigaltstack**() fails with the error **EINVAL** when this flag is supplied.

ss.ss_sp
: This field specifies the starting address of the stack. When a signal handler is invoked on the alternate stack, the kernel automatically aligns the address given in *ss.ss_sp* to a suitable address boundary for the underlying hardware architecture.

ss.ss_size
: This field specifies the size of the stack. The constant **SIGSTKSZ** is defined to be large enough to cover the usual size requirements for an alternate signal stack, and the constant **MINSIGSTKSZ** defines the minimum size required to execute a signal handler.

To disable an existing stack, specify *ss.ss_flags* as **SS_DISABLE**. In this case, the kernel ignores any other flags in *ss.ss_flags* and the remaining fields in *ss*.

If *old_ss* is not NULL, then it is used to return information about the alternate signal stack which was in effect prior to the call to **sigaltstack**(). The *old_ss.ss_sp* and *old_ss.ss_size* fields return the starting address and size of that stack. The *old_ss.ss_flags* may return either of the following values:

SS_ONSTACK
The thread is currently executing on the alternate signal stack. (Note that it is not possible to change the alternate signal stack if the thread is currently executing on it.)

SS_DISABLE
The alternate signal stack is currently disabled.

Alternatively, this value is returned if the thread is currently executing on an alternate signal stack that was established using the **SS_AUTODISARM** flag. In this case, it is safe to switch away from the signal handler with *swapcontext*(3). It is also possible to set up a different alternative signal stack using a further call to **sigaltstack**().

SS_AUTODISARM
The alternate signal stack has been marked to be autodisarmed as described above.

By specifying *ss* as NULL, and *old_ss* as a non-NULL value, one can obtain the current settings for the alternate signal stack without changing them.

RETURN VALUE

sigaltstack() returns 0 on success, or −1 on failure with *errno* set to indicate the error.

ERRORS

EFAULT
Either *ss* or *old_ss* is not NULL and points to an area outside of the process's address space.

EINVAL
ss is not NULL and the *ss_flags* field contains an invalid flag.

ENOMEM
The specified size of the new alternate signal stack *ss.ss_size* was less than **MINSIGSTKSZ**.

EPERM
An attempt was made to change the alternate signal stack while it was active (i.e., the thread was already executing on the current alternate signal stack).

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
sigaltstack()	Thread safety	MT-Safe

STANDARDS

POSIX.1-2008.

SS_AUTODISARM is a Linux extension.

HISTORY

POSIX.1-2001, SUSv2, SVr4.

NOTES

The most common usage of an alternate signal stack is to handle the **SIGSEGV** signal that is generated if the space available for the standard stack is exhausted: in this case, a signal handler for **SIGSEGV** cannot be invoked on the standard stack; if we wish to handle it, we must use an alternate signal stack.

Establishing an alternate signal stack is useful if a thread expects that it may exhaust its standard stack. This may occur, for example, because the stack grows so large that it encounters the upwardly growing heap, or it reaches a limit established by a call to **setrlimit(RLIMIT_STACK, &rlim)**. If the standard stack is exhausted, the kernel sends the thread a **SIGSEGV** signal. In these circumstances the only way to catch this signal is on an alternate signal stack.

On most hardware architectures supported by Linux, stacks grow downward. **sigaltstack**() automatically takes account of the direction of stack growth.

Functions called from a signal handler executing on an alternate signal stack will also use the alternate signal stack. (This also applies to any handlers invoked for other signals while the thread is executing on the alternate signal stack.) Unlike the standard stack, the system does not automatically extend the

alternate signal stack. Exceeding the allocated size of the alternate signal stack will lead to unpredictable results.

A successful call to *execve*(2) removes any existing alternate signal stack. A child process created via *fork*(2) inherits a copy of its parent's alternate signal stack settings. The same is also true for a child process created using *clone*(2), unless the clone flags include **CLONE_VM** and do not include **CLONE_VFORK**, in which case any alternate signal stack that was established in the parent is disabled in the child process.

sigaltstack() supersedes the older **sigstack**() call. For backward compatibility, glibc also provides **sigstack**(). All new applications should be written using **sigaltstack**().

History

4.2BSD had a **sigstack**() system call. It used a slightly different struct, and had the major disadvantage that the caller had to know the direction of stack growth.

BUGS

In Linux 2.2 and earlier, the only flag that could be specified in *ss.sa_flags* was **SS_DISABLE**. In the lead up to the release of the Linux 2.4 kernel, a change was made to allow **sigaltstack**() to allow *ss.ss_flags==SS_ONSTACK* with the same meaning as *ss.ss_flags==0* (i.e., the inclusion of **SS_ONSTACK** in *ss.ss_flags* is a no-op). On other implementations, and according to POSIX.1, **SS_ONSTACK** appears only as a reported flag in *old_ss.ss_flags*. On Linux, there is no need ever to specify **SS_ONSTACK** in *ss.ss_flags*, and indeed doing so should be avoided on portability grounds: various other systems give an error if **SS_ONSTACK** is specified in *ss.ss_flags*.

EXAMPLES

The following code segment demonstrates the use of **sigaltstack**() (and *sigaction*(2)) to install an alternate signal stack that is employed by a handler for the **SIGSEGV** signal:

```
stack_t ss;

ss.ss_sp = malloc(SIGSTKSZ);
if (ss.ss_sp == NULL) {
    perror("malloc");
    exit(EXIT_FAILURE);
}

ss.ss_size = SIGSTKSZ;
ss.ss_flags = 0;
if (sigaltstack(&ss, NULL) == -1) {
    perror("sigaltstack");
    exit(EXIT_FAILURE);
}

sa.sa_flags = SA_ONSTACK;
sa.sa_handler = handler();      /* Address of a signal handler */
sigemptyset(&sa.sa_mask);
if (sigaction(SIGSEGV, &sa, NULL) == -1) {
    perror("sigaction");
    exit(EXIT_FAILURE);
}
```

NAME

signal − ANSI C signal handling

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <signal.h>

typedef void (*sighandler_t)(int);

sighandler_t signal(int *signum***, sighandler_t** *handler***);**

DESCRIPTION

WARNING: the behavior of **signal**() varies across UNIX versions, and has also varied historically across different versions of Linux. **Avoid its use**: use *sigaction*(2) instead. See *Portability* below.

signal() sets the disposition of the signal *signum* to *handler*, which is either **SIG_IGN**, **SIG_DFL**, or the address of a programmer-defined function (a "signal handler").

If the signal *signum* is delivered to the process, then one of the following happens:

* If the disposition is set to **SIG_IGN**, then the signal is ignored.
* If the disposition is set to **SIG_DFL**, then the default action associated with the signal (see *signal*(7)) occurs.
* If the disposition is set to a function, then first either the disposition is reset to **SIG_DFL**, or the signal is blocked (see *Portability* below), and then *handler* is called with argument *signum*. If invocation of the handler caused the signal to be blocked, then the signal is unblocked upon return from the handler.

The signals **SIGKILL** and **SIGSTOP** cannot be caught or ignored.

RETURN VALUE

signal() returns the previous value of the signal handler. On failure, it returns **SIG_ERR**, and *errno* is set to indicate the error.

ERRORS

EINVAL

signum is invalid.

VERSIONS

The use of *sighandler_t* is a GNU extension, exposed if **_GNU_SOURCE** is defined; glibc also defines (the BSD-derived) *sig_t* if **_BSD_SOURCE** (glibc 2.19 and earlier) or **_DEFAULT_SOURCE** (glibc 2.19 and later) is defined. Without use of such a type, the declaration of **signal**() is the somewhat harder to read:

```
void ( *signal(int signum, void (*handler)(int)) ) (int);
```

Portability

The only portable use of **signal**() is to set a signal's disposition to **SIG_DFL** or **SIG_IGN**. The semantics when using **signal**() to establish a signal handler vary across systems (and POSIX.1 explicitly permits this variation); **do not use it for this purpose.**

POSIX.1 solved the portability mess by specifying *sigaction*(2), which provides explicit control of the semantics when a signal handler is invoked; use that interface instead of **signal**().

STANDARDS

C11, POSIX.1-2008.

HISTORY

C89, POSIX.1-2001.

In the original UNIX systems, when a handler that was established using **signal**() was invoked by the delivery of a signal, the disposition of the signal would be reset to **SIG_DFL**, and the system did not block delivery of further instances of the signal. This is equivalent to calling *sigaction*(2) with the following flags:

```
sa.sa_flags = SA_RESETHAND | SA_NODEFER;
```

System V also provides these semantics for **signal**(). This was bad because the signal might be

delivered again before the handler had a chance to reestablish itself. Furthermore, rapid deliveries of the same signal could result in recursive invocations of the handler.

BSD improved on this situation, but unfortunately also changed the semantics of the existing **signal**() interface while doing so. On BSD, when a signal handler is invoked, the signal disposition is not reset, and further instances of the signal are blocked from being delivered while the handler is executing. Furthermore, certain blocking system calls are automatically restarted if interrupted by a signal handler (see *signal*(7)). The BSD semantics are equivalent to calling *sigaction*(2) with the following flags:

```
sa.sa_flags = SA_RESTART;
```

The situation on Linux is as follows:

- The kernel's **signal**() system call provides System V semantics.
- By default, in glibc 2 and later, the **signal**() wrapper function does not invoke the kernel system call. Instead, it calls *sigaction*(2) using flags that supply BSD semantics. This default behavior is provided as long as a suitable feature test macro is defined: **_BSD_SOURCE** on glibc 2.19 and earlier or **_DEFAULT_SOURCE** in glibc 2.19 and later. (By default, these macros are defined; see *feature_test_macros*(7) for details.) If such a feature test macro is not defined, then **signal**() provides System V semantics.

NOTES

The effects of **signal**() in a multithreaded process are unspecified.

According to POSIX, the behavior of a process is undefined after it ignores a **SIGFPE**, **SIGILL**, or **SIGSEGV** signal that was not generated by *kill*(2) or *raise*(3). Integer division by zero has undefined result. On some architectures it will generate a **SIGFPE** signal. (Also dividing the most negative integer by −1 may generate **SIGFPE**.) Ignoring this signal might lead to an endless loop.

See *sigaction*(2) for details on what happens when the disposition **SIGCHLD** is set to **SIG_IGN**.

See *signal-safety*(7) for a list of the async-signal-safe functions that can be safely called from inside a signal handler.

NAME

signalfd − create a file descriptor for accepting signals

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/signalfd.h>

int signalfd(int *fd***, const sigset_t ****mask***, int** *flags***);**

DESCRIPTION

signalfd() creates a file descriptor that can be used to accept signals targeted at the caller. This provides an alternative to the use of a signal handler or *sigwaitinfo*(2), and has the advantage that the file descriptor may be monitored by *select*(2), *poll*(2), and *epoll*(7).

The *mask* argument specifies the set of signals that the caller wishes to accept via the file descriptor. This argument is a signal set whose contents can be initialized using the macros described in *sigsetops*(3). Normally, the set of signals to be received via the file descriptor should be blocked using *sigprocmask*(2), to prevent the signals being handled according to their default dispositions. It is not possible to receive **SIGKILL** or **SIGSTOP** signals via a signalfd file descriptor; these signals are silently ignored if specified in *mask*.

If the *fd* argument is −1, then the call creates a new file descriptor and associates the signal set specified in *mask* with that file descriptor. If *fd* is not −1, then it must specify a valid existing signalfd file descriptor, and *mask* is used to replace the signal set associated with that file descriptor.

Starting with Linux 2.6.27, the following values may be bitwise ORed in *flags* to change the behavior of **signalfd**():

SFD_NONBLOCK
: Set the **O_NONBLOCK** file status flag on the open file description (see *open*(2)) referred to by the new file descriptor. Using this flag saves extra calls to *fcntl*(2) to achieve the same result.

SFD_CLOEXEC
: Set the close-on-exec (**FD_CLOEXEC**) flag on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

Up to Linux 2.6.26, the *flags* argument is unused, and must be specified as zero.

signalfd() returns a file descriptor that supports the following operations:

read(2)
: If one or more of the signals specified in *mask* is pending for the process, then the buffer supplied to *read*(2) is used to return one or more *signalfd_siginfo* structures (see below) that describe the signals. The *read*(2) returns information for as many signals as are pending and will fit in the supplied buffer. The buffer must be at least *sizeof(struct signalfd_siginfo)* bytes. The return value of the *read*(2) is the total number of bytes read.

  As a consequence of the *read*(2), the signals are consumed, so that they are no longer pending for the process (i.e., will not be caught by signal handlers, and cannot be accepted using *sigwaitinfo*(2)).

  If none of the signals in *mask* is pending for the process, then the *read*(2) either blocks until one of the signals in *mask* is generated for the process, or fails with the error **EAGAIN** if the file descriptor has been made nonblocking.

poll(2)
select(2)
(and similar)
: The file descriptor is readable (the *select*(2) *readfds* argument; the *poll*(2) **POLLIN** flag) if one or more of the signals in *mask* is pending for the process.

  The signalfd file descriptor also supports the other file-descriptor multiplexing APIs: *pselect*(2), *ppoll*(2), and *epoll*(7).

close(2)
: When the file descriptor is no longer required it should be closed. When all file descriptors associated with the same signalfd object have been closed, the resources for object are freed by

the kernel.

The signalfd_siginfo structure

The format of the *signalfd_siginfo* structure(s) returned by *read*(2)s from a signalfd file descriptor is as follows:

```
struct signalfd_siginfo {
    uint32_t ssi_signo;    /* Signal number */
    int32_t  ssi_errno;    /* Error number (unused) */
    int32_t  ssi_code;     /* Signal code */
    uint32_t ssi_pid;      /* PID of sender */
    uint32_t ssi_uid;      /* Real UID of sender */
    int32_t  ssi_fd;       /* File descriptor (SIGIO) */
    uint32_t ssi_tid;      /* Kernel timer ID (POSIX timers)
    uint32_t ssi_band;     /* Band event (SIGIO) */
    uint32_t ssi_overrun;  /* POSIX timer overrun count */
    uint32_t ssi_trapno;   /* Trap number that caused signal */
    int32_t  ssi_status;   /* Exit status or signal (SIGCHLD) */
    int32_t  ssi_int;      /* Integer sent by sigqueue(3) */
    uint64_t ssi_ptr;      /* Pointer sent by sigqueue(3) */
    uint64_t ssi_utime;    /* User CPU time consumed (SIGCHLD) */
    uint64_t ssi_stime;    /* System CPU time consumed
                              (SIGCHLD) */
    uint64_t ssi_addr;     /* Address that generated signal
                              (for hardware-generated signals) */
    uint16_t ssi_addr_lsb; /* Least significant bit of address
                              (SIGBUS; since Linux 2.6.37) */
    uint8_t  pad[X];       /* Pad size to 128 bytes (allow for
                              additional fields in the future) */
};
```

Each of the fields in this structure is analogous to the similarly named field in the *siginfo_t* structure. The *siginfo_t* structure is described in *sigaction*(2). Not all fields in the returned *signalfd_siginfo* structure will be valid for a specific signal; the set of valid fields can be determined from the value returned in the *ssi_code* field. This field is the analog of the *siginfo_t si_code* field; see *sigaction*(2) for details.

fork(2) semantics

After a *fork*(2), the child inherits a copy of the signalfd file descriptor. A *read*(2) from the file descriptor in the child will return information about signals queued to the child.

Semantics of file descriptor passing

As with other file descriptors, signalfd file descriptors can be passed to another process via a UNIX domain socket (see *unix*(7)). In the receiving process, a *read*(2) from the received file descriptor will return information about signals queued to that process.

execve(2) semantics

Just like any other file descriptor, a signalfd file descriptor remains open across an *execve*(2), unless it has been marked for close-on-exec (see *fcntl*(2)). Any signals that were available for reading before the *execve*(2) remain available to the newly loaded program. (This is analogous to traditional signal semantics, where a blocked signal that is pending remains pending across an *execve*(2).)

Thread semantics

The semantics of signalfd file descriptors in a multithreaded program mirror the standard semantics for signals. In other words, when a thread reads from a signalfd file descriptor, it will read the signals that are directed to the thread itself and the signals that are directed to the process (i.e., the entire thread group). (A thread will not be able to read signals that are directed to other threads in the process.)

epoll(7) semantics

If a process adds (via *epoll_ctl*(2)) a signalfd file descriptor to an *epoll*(7) instance, then *epoll_wait*(2) returns events only for signals sent to that process. In particular, if the process then uses *fork*(2) to create a child process, then the child will be able to *read*(2) signals that are sent to it using the signalfd file descriptor, but *epoll_wait*(2) will **not** indicate that the signalfd file descriptor is ready. In this scenario,

a possible workaround is that after the *fork*(2), the child process can close the signalfd file descriptor that it inherited from the parent process and then create another signalfd file descriptor and add it to the epoll instance. Alternatively, the parent and the child could delay creating their (separate) signalfd file descriptors and adding them to the epoll instance until after the call to *fork*(2).

RETURN VALUE

On success, **signalfd**() returns a signalfd file descriptor; this is either a new file descriptor (if *fd* was −1), or *fd* if *fd* was a valid signalfd file descriptor. On error, −1 is returned and *errno* is set to indicate the error.

ERRORS

EBADF
The *fd* file descriptor is not a valid file descriptor.

EINVAL
fd is not a valid signalfd file descriptor.

EINVAL
flags is invalid; or, in Linux 2.6.26 or earlier, *flags* is nonzero.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENODEV
Could not mount (internal) anonymous inode device.

ENOMEM
There was insufficient memory to create a new signalfd file descriptor.

VERSIONS

C library/kernel differences

The underlying Linux system call requires an additional argument, *size_t sizemask*, which specifies the size of the *mask* argument. The glibc **signalfd**() wrapper function does not include this argument, since it provides the required value for the underlying system call.

There are two underlying Linux system calls: **signalfd**() and the more recent **signalfd4**(). The former system call does not implement a *flags* argument. The latter system call implements the *flags* values described above. Starting with glibc 2.9, the **signalfd**() wrapper function will use **signalfd4**() where it is available.

STANDARDS

Linux.

HISTORY

signalfd()
Linux 2.6.22, glibc 2.8.

signalfd4()
Linux 2.6.27.

NOTES

A process can create multiple signalfd file descriptors. This makes it possible to accept different signals on different file descriptors. (This may be useful if monitoring the file descriptors using *select*(2), *poll*(2), or *epoll*(7): the arrival of different signals will make different file descriptors ready.) If a signal appears in the *mask* of more than one of the file descriptors, then occurrences of that signal can be read (once) from any one of the file descriptors.

Attempts to include **SIGKILL** and **SIGSTOP** in *mask* are silently ignored.

The signal mask employed by a signalfd file descriptor can be viewed via the entry for the corresponding file descriptor in the process's */proc/*pid*/fdinfo* directory. See *proc*(5) for further details.

Limitations

The signalfd mechanism can't be used to receive signals that are synchronously generated, such as the **SIGSEGV** signal that results from accessing an invalid memory address or the **SIGFPE** signal that results from an arithmetic error. Such signals can be caught only via signal handler.

As described above, in normal usage one blocks the signals that will be accepted via **signalfd**(). If spawning a child process to execute a helper program (that does not need the signalfd file descriptor), then, after the call to *fork*(2), you will normally want to unblock those signals before calling *execve*(2), so that the helper program can see any signals that it expects to see. Be aware, however, that this won't be possible in the case of a helper program spawned behind the scenes by any library function that the program may call. In such cases, one must fall back to using a traditional signal handler that writes to a file descriptor monitored by *select*(2), *poll*(2), or *epoll*(7).

BUGS

Before Linux 2.6.25, the *ssi_ptr* and *ssi_int* fields are not filled in with the data accompanying a signal sent by *sigqueue*(3).

EXAMPLES

The program below accepts the signals **SIGINT** and **SIGQUIT** via a signalfd file descriptor. The program terminates after accepting a **SIGQUIT** signal. The following shell session demonstrates the use of the program:

```
$ ./signalfd_demo
^C                    # Control-C generates SIGINT
Got SIGINT
^C
Got SIGINT
^\                     # Control-\ generates SIGQUIT
Got SIGQUIT
$
```

Program source

```
#include <err.h>
#include <signal.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/signalfd.h>
#include <unistd.h>

int

NAME

sigpending, rt_sigpending − examine pending signals

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <signal.h>

int sigpending(sigset_t *set);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

sigpending():
_POSIX_C_SOURCE

DESCRIPTION

sigpending() returns the set of signals that are pending for delivery to the calling thread (i.e., the signals which have been raised while blocked). The mask of pending signals is returned in *set*.

RETURN VALUE

sigpending() returns 0 on success. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
set points to memory which is not a valid part of the process address space.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

C library/kernel differences

The original Linux system call was named **sigpending**(). However, with the addition of real-time signals in Linux 2.2, the fixed-size, 32-bit *sigset_t* argument supported by that system call was no longer fit for purpose. Consequently, a new system call, **rt_sigpending**(), was added to support an enlarged *sigset_t* type. The new system call takes a second argument, *size_t sigsetsize*, which specifies the size in bytes of the signal set in *set*. The glibc **sigpending**() wrapper function hides these details from us, transparently calling **rt_sigpending**() when the kernel provides it.

NOTES

See *sigsetops*(3) for details on manipulating signal sets.

If a signal is both blocked and has a disposition of "ignored", it is *not* added to the mask of pending signals when generated.

The set of signals that is pending for a thread is the union of the set of signals that is pending for that thread and the set of signals that is pending for the process as a whole; see *signal*(7).

A child created via *fork*(2) initially has an empty pending signal set; the pending signal set is preserved across an *execve*(2).

BUGS

Up to and including glibc 2.2.1, there is a bug in the wrapper function for **sigpending**() which means that information about pending real-time signals is not correctly returned.

NAME

sigprocmask, rt_sigprocmask − examine and change blocked signals

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <signal.h>

/* Prototype for the glibc wrapper function */
int sigprocmask(int how, const sigset_t *_Nullable restrict set,
                sigset_t *_Nullable restrict oldset);

#include <signal.h>          /* Definition of SIG_* constants */
#include <sys/syscall.h>     /* Definition of SYS_* constants */
#include <unistd.h>

/* Prototype for the underlying system call */
int syscall(SYS_rt_sigprocmask, int how,
                const kernel_sigset_t *_Nullable set,
                kernel_sigset_t *_Nullable oldset,
                size_t sigsetsize);

/* Prototype for the legacy system call */
[[deprecated]] int syscall(SYS_sigprocmask, int how,
                const old_kernel_sigset_t *_Nullable set,
                old_kernel_sigset_t *_Nullable oldset);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

sigprocmask():
_POSIX_C_SOURCE

DESCRIPTION

sigprocmask() is used to fetch and/or change the signal mask of the calling thread. The signal mask is the set of signals whose delivery is currently blocked for the caller (see also *signal*(7) for more details).

The behavior of the call is dependent on the value of *how*, as follows.

SIG_BLOCK
The set of blocked signals is the union of the current set and the *set* argument.

SIG_UNBLOCK
The signals in *set* are removed from the current set of blocked signals. It is permissible to attempt to unblock a signal which is not blocked.

SIG_SETMASK
The set of blocked signals is set to the argument *set*.

If *oldset* is non-NULL, the previous value of the signal mask is stored in *oldset*.

If *set* is NULL, then the signal mask is unchanged (i.e., *how* is ignored), but the current value of the signal mask is nevertheless returned in *oldset* (if it is not NULL).

A set of functions for modifying and inspecting variables of type *sigset_t* ("signal sets") is described in *sigsetops*(3).

The use of **sigprocmask**() is unspecified in a multithreaded process; see *pthread_sigmask*(3).

RETURN VALUE

sigprocmask() returns 0 on success. On failure, −1 is returned and *errno* is set to indicate the error.

ERRORS

EFAULT
The *set* or *oldset* argument points outside the process's allocated address space.

EINVAL
Either the value specified in *how* was invalid or the kernel does not support the size passed in *sigsetsize.*

VERSIONS

C library/kernel differences

The kernel's definition of *sigset_t* differs in size from that used by the C library. In this manual page, the former is referred to as *kernel_sigset_t* (it is nevertheless named *sigset_t* in the kernel sources).

The glibc wrapper function for **sigprocmask**() silently ignores attempts to block the two real-time signals that are used internally by the NPTL threading implementation. See *nptl*(7) for details.

The original Linux system call was named **sigprocmask**(). However, with the addition of real-time signals in Linux 2.2, the fixed-size, 32-bit *sigset_t* (referred to as *old_kernel_sigset_t* in this manual page) type supported by that system call was no longer fit for purpose. Consequently, a new system call, **rt_sigprocmask**(), was added to support an enlarged *sigset_t* type (referred to as *kernel_sigset_t* in this manual page). The new system call takes a fourth argument, *size_t sigsetsize*, which specifies the size in bytes of the signal sets in *set* and *oldset*. This argument is currently required to have a fixed architecture specific value (equal to *sizeof(kernel_sigset_t)*).

The glibc **sigprocmask**() wrapper function hides these details from us, transparently calling **rt_sigprocmask**() when the kernel provides it.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

NOTES

It is not possible to block **SIGKILL** or **SIGSTOP**. Attempts to do so are silently ignored.

Each of the threads in a process has its own signal mask.

A child created via *fork*(2) inherits a copy of its parent's signal mask; the signal mask is preserved across *execve*(2).

If **SIGBUS**, **SIGFPE**, **SIGILL**, or **SIGSEGV** are generated while they are blocked, the result is undefined, unless the signal was generated by *kill*(2), *sigqueue*(3), or *raise*(3).

See *sigsetops*(3) for details on manipulating signal sets.

Note that it is permissible (although not very useful) to specify both *set* and *oldset* as NULL.

SEE ALSO

kill(2), *pause*(2), *sigaction*(2), *signal*(2), *sigpending*(2), *sigsuspend*(2), *pthread_sigmask*(3), *sigqueue*(3), *sigsetops*(3), *signal*(7)

NAME

sigreturn, rt_sigreturn − return from signal handler and cleanup stack frame

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

int sigreturn(...);

DESCRIPTION

If the Linux kernel determines that an unblocked signal is pending for a process, then, at the next transition back to user mode in that process (e.g., upon return from a system call or when the process is rescheduled onto the CPU), it creates a new frame on the user-space stack where it saves various pieces of process context (processor status word, registers, signal mask, and signal stack settings).

The kernel also arranges that, during the transition back to user mode, the signal handler is called, and that, upon return from the handler, control passes to a piece of user-space code commonly called the "signal trampoline". The signal trampoline code in turn calls **sigreturn**().

This **sigreturn**() call undoes everything that was done—changing the process's signal mask, switching signal stacks (see **sigaltstack**(2))—in order to invoke the signal handler. Using the information that was earlier saved on the user-space stack **sigreturn**() restores the process's signal mask, switches stacks, and restores the process's context (processor flags and registers, including the stack pointer and instruction pointer), so that the process resumes execution at the point where it was interrupted by the signal.

RETURN VALUE

sigreturn() never returns.

VERSIONS

Many UNIX-type systems have a **sigreturn**() system call or near equivalent. However, this call is not specified in POSIX, and details of its behavior vary across systems.

STANDARDS

None.

NOTES

sigreturn() exists only to allow the implementation of signal handlers. It should **never** be called directly. (Indeed, a simple **sigreturn**() wrapper in the GNU C library simply returns −1, with *errno* set to **ENOSYS**.) Details of the arguments (if any) passed to **sigreturn**() vary depending on the architecture. (On some architectures, such as x86-64, **sigreturn**() takes no arguments, since all of the information that it requires is available in the stack frame that was previously created by the kernel on the user-space stack.)

Once upon a time, UNIX systems placed the signal trampoline code onto the user stack. Nowadays, pages of the user stack are protected so as to disallow code execution. Thus, on contemporary Linux systems, depending on the architecture, the signal trampoline code lives either in the *vdso*(7) or in the C library. In the latter case, the C library's *sigaction*(2) wrapper function informs the kernel of the location of the trampoline code by placing its address in the *sa_restorer* field of the *sigaction* structure, and sets the **SA_RESTORER** flag in the *sa_flags* field.

The saved process context information is placed in a *ucontext_t* structure (see <*sys/ucontext.h*>). That structure is visible within the signal handler as the third argument of a handler established via *sigaction*(2) with the **SA_SIGINFO** flag.

On some other UNIX systems, the operation of the signal trampoline differs a little. In particular, on some systems, upon transitioning back to user mode, the kernel passes control to the trampoline (rather than the signal handler), and the trampoline code calls the signal handler (and then calls **sigreturn**() once the handler returns).

C library/kernel differences

The original Linux system call was named **sigreturn**(). However, with the addition of real-time signals in Linux 2.2, a new system call, **rt_sigreturn**() was added to support an enlarged *sigset_t* type. The GNU C library hides these details from us, transparently employing **rt_sigreturn**() when the kernel provides it.

NAME

sigsuspend, rt_sigsuspend − wait for a signal

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <signal.h>

int sigsuspend(const sigset_t **mask*);

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

sigsuspend():
_POSIX_C_SOURCE

DESCRIPTION

sigsuspend() temporarily replaces the signal mask of the calling thread with the mask given by *mask* and then suspends the thread until delivery of a signal whose action is to invoke a signal handler or to terminate a process.

If the signal terminates the process, then **sigsuspend**() does not return. If the signal is caught, then **sigsuspend**() returns after the signal handler returns, and the signal mask is restored to the state before the call to **sigsuspend**().

It is not possible to block **SIGKILL** or **SIGSTOP**; specifying these signals in *mask*, has no effect on the thread's signal mask.

RETURN VALUE

sigsuspend() always returns −1, with *errno* set to indicate the error (normally, **EINTR**).

ERRORS

EFAULT
mask points to memory which is not a valid part of the process address space.

EINTR
The call was interrupted by a signal; *signal*(7).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

C library/kernel differences

The original Linux system call was named **sigsuspend**(). However, with the addition of real-time signals in Linux 2.2, the fixed-size, 32-bit *sigset_t* type supported by that system call was no longer fit for purpose. Consequently, a new system call, **rt_sigsuspend**(), was added to support an enlarged *sigset_t* type. The new system call takes a second argument, *size_t sigsetsize*, which specifies the size in bytes of the signal set in *mask*. This argument is currently required to have the value *sizeof(sigset_t)* (or the error **EINVAL** results). The glibc **sigsuspend**() wrapper function hides these details from us, transparently calling **rt_sigsuspend**() when the kernel provides it.

NOTES

Normally, **sigsuspend**() is used in conjunction with *sigprocmask*(2) in order to prevent delivery of a signal during the execution of a critical code section. The caller first blocks the signals with *sigprocmask*(2). When the critical code has completed, the caller then waits for the signals by calling **sigsuspend**() with the signal mask that was returned by *sigprocmask*(2) (in the *oldset* argument).

See *sigsetops*(3) for details on manipulating signal sets.

SEE ALSO

kill(2), *pause*(2), *sigaction*(2), *signal*(2), *sigprocmask*(2), *sigwaitinfo*(2), *sigsetops*(3), *sigwait*(3), *signal*(7)

NAME

sigwaitinfo, sigtimedwait, rt_sigtimedwait − synchronously wait for queued signals

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <signal.h>

int sigwaitinfo(const sigset_t *restrict set,
                siginfo_t *_Nullable restrict info);
int sigtimedwait(const sigset_t *restrict set,
                 siginfo_t *_Nullable restrict info,
                 const struct timespec *restrict timeout);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

sigwaitinfo(), **sigtimedwait**():
_POSIX_C_SOURCE >= 199309L

DESCRIPTION

sigwaitinfo() suspends execution of the calling thread until one of the signals in *set* is pending (If one of the signals in *set* is already pending for the calling thread, **sigwaitinfo**() will return immediately.)

sigwaitinfo() removes the signal from the set of pending signals and returns the signal number as its function result. If the *info* argument is not NULL, then the buffer that it points to is used to return a structure of type *siginfo_t* (see *sigaction*(2)) containing information about the signal.

If multiple signals in *set* are pending for the caller, the signal that is retrieved by **sigwaitinfo**() is determined according to the usual ordering rules; see *signal*(7) for further details.

sigtimedwait() operates in exactly the same way as **sigwaitinfo**() except that it has an additional argument, *timeout*, which specifies the interval for which the thread is suspended waiting for a signal. (This interval will be rounded up to the system clock granularity, and kernel scheduling delays mean that the interval may overrun by a small amount.) This argument is a *timespec*(3) structure.

If both fields of this structure are specified as 0, a poll is performed: **sigtimedwait**() returns immediately, either with information about a signal that was pending for the caller, or with an error if none of the signals in *set* was pending.

RETURN VALUE

On success, both **sigwaitinfo**() and **sigtimedwait**() return a signal number (i.e., a value greater than zero). On failure both calls return −1, with *errno* set to indicate the error.

ERRORS

EAGAIN
No signal in *set* became pending within the *timeout* period specified to **sigtimedwait**().

EINTR
The wait was interrupted by a signal handler; see *signal*(7). (This handler was for a signal other than one of those in *set*.)

EINVAL
timeout was invalid.

VERSIONS

C library/kernel differences

On Linux, **sigwaitinfo**() is a library function implemented on top of **sigtimedwait**().

The glibc wrapper functions for **sigwaitinfo**() and **sigtimedwait**() silently ignore attempts to wait for the two real-time signals that are used internally by the NPTL threading implementation. See *nptl*(7) for details.

The original Linux system call was named **sigtimedwait**(). However, with the addition of real-time signals in Linux 2.2, the fixed-size, 32-bit *sigset_t* type supported by that system call was no longer fit for purpose. Consequently, a new system call, **rt_sigtimedwait**(), was added to support an enlarged *sigset_t* type. The new system call takes a fourth argument, *size_t sigsetsize*, which specifies the size in bytes of the signal set in *set*. This argument is currently required to have the value *sizeof(sigset_t)* (or the error **EINVAL** results). The glibc **sigtimedwait**() wrapper function hides these details from us,

transparently calling **rt_sigtimedwait**() when the kernel provides it.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

NOTES

In normal usage, the calling program blocks the signals in *set* via a prior call to *sigprocmask*(2) (so that the default disposition for these signals does not occur if they become pending between successive calls to **sigwaitinfo**() or *sigtimedwait*()) and does not establish handlers for these signals. In a multithreaded program, the signal should be blocked in all threads, in order to prevent the signal being treated according to its default disposition in a thread other than the one calling **sigwaitinfo**() or *sigtimedwait*())

The set of signals that is pending for a given thread is the union of the set of signals that is pending specifically for that thread and the set of signals that is pending for the process as a whole (see *signal*(7)).

Attempts to wait for **SIGKILL** and **SIGSTOP** are silently ignored.

If multiple threads of a process are blocked waiting for the same signal(s) in **sigwaitinfo**() or **sigtimedwait**(), then exactly one of the threads will actually receive the signal if it becomes pending for the process as a whole; which of the threads receives the signal is indeterminate.

sigwaitinfo() or **sigtimedwait**(), can't be used to receive signals that are synchronously generated, such as the **SIGSEGV** signal that results from accessing an invalid memory address or the **SIGFPE** signal that results from an arithmetic error. Such signals can be caught only via signal handler.

POSIX leaves the meaning of a NULL value for the *timeout* argument of **sigtimedwait**() unspecified, permitting the possibility that this has the same meaning as a call to **sigwaitinfo**(), and indeed this is what is done on Linux.

SEE ALSO

kill(2), *sigaction*(2), *signal*(2), *signalfd*(2), *sigpending*(2), *sigprocmask*(2), *sigqueue*(3), *sigsetops*(3), *sigwait*(3), *timespec*(3), *signal*(7), *time*(7)

NAME

socket − create an endpoint for communication

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/socket.h>

int socket(int *domain***, int** *type***, int** *protocol***);**

DESCRIPTION

socket() creates an endpoint for communication and returns a file descriptor that refers to that endpoint. The file descriptor returned by a successful call will be the lowest-numbered file descriptor not currently open for the process.

The *domain* argument specifies a communication domain; this selects the protocol family which will be used for communication. These families are defined in <*sys/socket.h*>. The formats currently understood by the Linux kernel include:

Name	Purpose	Man page
AF_UNIX	Local communication	*unix*(7)
AF_LOCAL	Synonym for **AF_UNIX**	
AF_INET	IPv4 Internet protocols	*ip*(7)
AF_AX25	Amateur radio AX.25 protocol	*ax25*(4)
AF_IPX	IPX − Novell protocols	
AF_APPLETALK	AppleTalk	*ddp*(7)
AF_X25	ITU-T X.25 / ISO/IEC 8208 protocol	*x25*(7)
AF_INET6	IPv6 Internet protocols	*ipv6*(7)
AF_DECnet	DECet protocol sockets	
AF_KEY	Key management protocol, originally developed for usage with IPsec	
AF_NETLINK	Kernel user interface device	*netlink*(7)
AF_PACKET	Low-level packet interface	*packet*(7)
AF_RDS	Reliable Datagram Sockets (RDS) protocol	*rds*(7) *rds-rdma*(7)
AF_PPPOX	Generic PPP transport layer, for setting up L2 tunnels (L2TP and PPPoE)	
AF_LLC	Logical link control (IEEE 802.2 LLC) protocol	
AF_IB	InfiniBand native addressing	
AF_MPLS	Multiprotocol Label Switching	
AF_CAN	Controller Area Network automotive bus protocol	
AF_TIPC	TIPC, "cluster domain sockets" protocol	
AF_BLUETOOTH	Bluetooth low-level socket protocol	
AF_ALG	Interface to kernel crypto API	
AF_VSOCK	VSOCK (originally "VMWare VSockets") protocol for hypervisor-guest communication	*vsock*(7)
AF_KCM	KCM (kernel connection multiplexer) interface	
AF_XDP	XDP (express data path) interface	

Further details of the above address families, as well as information on several other address families, can be found in *address_families*(7).

The socket has the indicated *type*, which specifies the communication semantics. Currently defined types are:

SOCK_STREAM
: Provides sequenced, reliable, two-way, connection-based byte streams. An out-of-band data transmission mechanism may be supported.

SOCK_DGRAM
: Supports datagrams (connectionless, unreliable messages of a fixed maximum length).

SOCK_SEQPACKET
: Provides a sequenced, reliable, two-way connection-based data transmission path for datagrams of fixed maximum length; a consumer is required to read an entire

packet with each input system call.

SOCK_RAW Provides raw network protocol access.

SOCK_RDM Provides a reliable datagram layer that does not guarantee ordering.

SOCK_PACKET Obsolete and should not be used in new programs; see *packet*(7).

Some socket types may not be implemented by all protocol families.

Since Linux 2.6.27, the *type* argument serves a second purpose: in addition to specifying a socket type, it may include the bitwise OR of any of the following values, to modify the behavior of **socket**():

SOCK_NONBLOCK
Set the **O_NONBLOCK** file status flag on the open file description (see *open*(2)) referred to by the new file descriptor. Using this flag saves extra calls to *fcntl*(2) to achieve the same result.

SOCK_CLOEXEC
Set the close-on-exec (**FD_CLOEXEC**) flag on the new file descriptor. See the description of the **O_CLOEXEC** flag in *open*(2) for reasons why this may be useful.

The *protocol* specifies a particular protocol to be used with the socket. Normally only a single protocol exists to support a particular socket type within a given protocol family, in which case *protocol* can be specified as 0. However, it is possible that many protocols may exist, in which case a particular protocol must be specified in this manner. The protocol number to use is specific to the "communication domain" in which communication is to take place; see *protocols*(5). See *getprotoent*(3) on how to map protocol name strings to protocol numbers.

Sockets of type **SOCK_STREAM** are full-duplex byte streams. They do not preserve record boundaries. A stream socket must be in a *connected* state before any data may be sent or received on it. A connection to another socket is created with a *connect*(2) call. Once connected, data may be transferred using *read*(2) and *write*(2) calls or some variant of the *send*(2) and *recv*(2) calls. When a session has been completed a *close*(2) may be performed. Out-of-band data may also be transmitted as described in *send*(2) and received as described in *recv*(2).

The communications protocols which implement a **SOCK_STREAM** ensure that data is not lost or duplicated. If a piece of data for which the peer protocol has buffer space cannot be successfully transmitted within a reasonable length of time, then the connection is considered to be dead. When **SO_KEEPALIVE** is enabled on the socket the protocol checks in a protocol-specific manner if the other end is still alive. A **SIGPIPE** signal is raised if a process sends or receives on a broken stream; this causes naive processes, which do not handle the signal, to exit. **SOCK_SEQPACKET** sockets employ the same system calls as **SOCK_STREAM** sockets. The only difference is that *read*(2) calls will return only the amount of data requested, and any data remaining in the arriving packet will be discarded. Also all message boundaries in incoming datagrams are preserved.

SOCK_DGRAM and **SOCK_RAW** sockets allow sending of datagrams to correspondents named in *sendto*(2) calls. Datagrams are generally received with *recvfrom*(2), which returns the next datagram along with the address of its sender.

SOCK_PACKET is an obsolete socket type to receive raw packets directly from the device driver. Use *packet*(7) instead.

An *fcntl*(2) **F_SETOWN** operation can be used to specify a process or process group to receive a **SIGURG** signal when the out-of-band data arrives or **SIGPIPE** signal when a **SOCK_STREAM** connection breaks unexpectedly. This operation may also be used to set the process or process group that receives the I/O and asynchronous notification of I/O events via **SIGIO**. Using **F_SETOWN** is equivalent to an *ioctl*(2) call with the **FIOSETOWN** or **SIOCSPGRP** argument.

When the network signals an error condition to the protocol module (e.g., using an ICMP message for IP) the pending error flag is set for the socket. The next operation on this socket will return the error code of the pending error. For some protocols it is possible to enable a per-socket error queue to retrieve detailed information about the error; see **IP_RECVERR** in *ip*(7).

The operation of sockets is controlled by socket level *options*. These options are defined in <*sys/socket.h*>. The functions *setsockopt*(2) and *getsockopt*(2) are used to set and get options.

RETURN VALUE

On success, a file descriptor for the new socket is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
Permission to create a socket of the specified type and/or protocol is denied.

EAFNOSUPPORT
The implementation does not support the specified address family.

EINVAL
Unknown protocol, or protocol family not available.

EINVAL
Invalid flags in *type*.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENOBUFS or **ENOMEM**
Insufficient memory is available. The socket cannot be created until sufficient resources are freed.

EPROTONOSUPPORT
The protocol type or the specified protocol is not supported within this domain.

Other errors may be generated by the underlying protocol modules.

STANDARDS

POSIX.1-2008.

SOCK_NONBLOCK and **SOCK_CLOEXEC** are Linux-specific.

HISTORY

POSIX.1-2001, 4.4BSD.

socket() appeared in 4.2BSD. It is generally portable to/from non-BSD systems supporting clones of the BSD socket layer (including System V variants).

The manifest constants used under 4.x BSD for protocol families are **PF_UNIX**, **PF_INET**, and so on, while **AF_UNIX**, **AF_INET**, and so on are used for address families. However, already the BSD man page promises: "The protocol family generally is the same as the address family", and subsequent standards use AF_* everywhere.

EXAMPLES

An example of the use of **socket**() is shown in *getaddrinfo*(3).

#include <linux/net.h>      /* Definition of SYS_* constants */
#include <sys/syscall.h>    /* Definition of SYS_socketcall */
#include <unistd.h>

int syscall(SYS_socketcall, int call, unsigned long *args);
```

Note: glibc provides no wrapper for **socketcall**(), necessitating the use of *syscall*(2).

DESCRIPTION

socketcall() is a common kernel entry point for the socket system calls. *call* determines which socket function to invoke. *args* points to a block containing the actual arguments, which are passed through to the appropriate call.

User programs should call the appropriate functions by their usual names. Only standard library implementors and kernel hackers need to know about **socketcall**().

SYS_RECVMMSG	*recvmmsg*(2)
SYS_SENDMMSG	*sendmmsg*(2)

VERSIONS

On some architectures—for example, x86-64 and ARM—there is no **socketcall**() system call; instead *socket*(2), *accept*(2), *bind*(2), and so on really are implemented as separate system calls.

STANDARDS

Linux.

On x86-32, **socketcall**() was historically the only entry point for the sockets API. However, starting in Linux 4.3, direct system calls are provided on x86-32 for the sockets API. This facilitates the creation of *seccomp*(2) filters that filter sockets system calls (for new user-space binaries that are compiled to use the new entry points) and also provides a (very) small performance improvement.

NAME

socketpair − create a pair of connected sockets

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/socket.h>

int socketpair(int *domain***, int** *type***, int** *protocol***, int** *sv***[2]);**

DESCRIPTION

The **socketpair**() call creates an unnamed pair of connected sockets in the specified *domain*, of the specified *type*, and using the optionally specified *protocol*. For further details of these arguments, see *socket*(2).

The file descriptors used in referencing the new sockets are returned in *sv[0]* and *sv[1]*. The two sockets are indistinguishable.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, *errno* is set to indicate the error, and *sv* is left unchanged

On Linux (and other systems), **socketpair**() does not modify *sv* on failure. A requirement standardizing this behavior was added in POSIX.1-2008 TC2.

ERRORS

EAFNOSUPPORT
The specified address family is not supported on this machine.

EFAULT
The address *sv* does not specify a valid part of the process address space.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENFILE
The system-wide limit on the total number of open files has been reached.

EOPNOTSUPP
The specified protocol does not support creation of socket pairs.

EPROTONOSUPPORT
The specified protocol is not supported on this machine.

VERSIONS

On Linux, the only supported domains for this call are **AF_UNIX** (or synonymously, **AF_LOCAL**) and **AF_TIPC** (since Linux 4.12).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001, 4.4BSD.

socketpair() first appeared in 4.2BSD. It is generally portable to/from non-BSD systems supporting clones of the BSD socket layer (including System V variants).

Since Linux 2.6.27, **socketpair**() supports the **SOCK_NONBLOCK** and **SOCK_CLOEXEC** flags in the *type* argument, as described in *socket*(2).

SEE ALSO

pipe(2), *read*(2), *socket*(2), *write*(2), *socket*(7), *unix*(7)

NAME

splice − splice data to/from a pipe

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#define _FILE_OFFSET_BITS 64
#include <fcntl.h>

ssize_t splice(int  fd_in, off_t *_Nullable off_in,
               int  fd_out, off_t *_Nullable off_out,
               size_t len, unsigned int  flags);
```

DESCRIPTION

splice() moves data between two file descriptors without copying between kernel address space and user address space. It transfers up to *len* bytes of data from the file descriptor *fd_in* to the file descriptor *fd_out*, where one of the file descriptors must refer to a pipe.

The following semantics apply for *fd_in* and *off_in*:

- If *fd_in* refers to a pipe, then *off_in* must be NULL.
- If *fd_in* does not refer to a pipe and *off_in* is NULL, then bytes are read from *fd_in* starting from the file offset, and the file offset is adjusted appropriately.
- If *fd_in* does not refer to a pipe and *off_in* is not NULL, then *off_in* must point to a buffer which specifies the starting offset from which bytes will be read from *fd_in*; in this case, the file offset of *fd_in* is not changed.

Analogous statements apply for *fd_out* and *off_out*.

The *flags* argument is a bit mask that is composed by ORing together zero or more of the following values:

SPLICE_F_MOVE
: Attempt to move pages instead of copying. This is only a hint to the kernel: pages may still be copied if the kernel cannot move the pages from the pipe, or if the pipe buffers don't refer to full pages. The initial implementation of this flag was buggy: therefore starting in Linux 2.6.21 it is a no-op (but is still permitted in a **splice**() call); in the future, a correct implementation may be restored.

SPLICE_F_NONBLOCK
: Do not block on I/O. This makes the splice pipe operations nonblocking, but **splice**() may nevertheless block because the file descriptors that are spliced to/from may block (unless they have the **O_NONBLOCK** flag set).

SPLICE_F_MORE
: More data will be coming in a subsequent splice. This is a helpful hint when the *fd_out* refers to a socket (see also the description of **MSG_MORE** in *send*(2), and the description of **TCP_CORK** in *tcp*(7)).

SPLICE_F_GIFT
: Unused for **splice**(); see *vmsplice*(2).

RETURN VALUE

Upon successful completion, **splice**() returns the number of bytes spliced to or from the pipe.

A return value of 0 means end of input. If *fd_in* refers to a pipe, then this means that there was no data to transfer, and it would not make sense to block because there are no writers connected to the write end of the pipe.

On error, **splice**() returns −1 and *errno* is set to indicate the error.

ERRORS

EAGAIN
: **SPLICE_F_NONBLOCK** was specified in *flags* or one of the file descriptors had been marked as nonblocking (**O_NONBLOCK**), and the operation would block.

EBADF
One or both file descriptors are not valid, or do not have proper read-write mode.

EINVAL
The target filesystem doesn't support splicing.

EINVAL
The target file is opened in append mode.

EINVAL
Neither of the file descriptors refers to a pipe.

EINVAL
An offset was given for nonseekable device (e.g., a pipe).

EINVAL
fd_in and *fd_out* refer to the same pipe.

ENOMEM
Out of memory.

ESPIPE
Either *off_in* or *off_out* was not NULL, but the corresponding file descriptor refers to a pipe.

STANDARDS
Linux.

HISTORY
Linux 2.6.17, glibc 2.5.

In Linux 2.6.30 and earlier, exactly one of *fd_in* and *fd_out* was required to be a pipe. Since Linux 2.6.31, both arguments may refer to pipes.

NOTES
The three system calls **splice**(), *vmsplice*(2), and *tee*(2), provide user-space programs with full control over an arbitrary kernel buffer, implemented within the kernel using the same type of buffer that is used for a pipe. In overview, these system calls perform the following tasks:

splice() moves data from the buffer to an arbitrary file descriptor, or vice versa, or from one buffer to another.

tee(2) "copies" the data from one buffer to another.

vmsplice(2)
"copies" data from user space into the buffer.

Though we talk of copying, actual copies are generally avoided. The kernel does this by implementing a pipe buffer as a set of reference-counted pointers to pages of kernel memory. The kernel creates "copies" of pages in a buffer by creating new pointers (for the output buffer) referring to the pages, and increasing the reference counts for the pages: only pointers are copied, not the pages of the buffer.

_FILE_OFFSET_BITS should be defined to be 64 in code that uses non-null *off_in* or *off_out* or that takes the address of **splice**, if the code is intended to be portable to traditional 32-bit x86 and ARM platforms where **off_t**'s width defaults to 32 bits.

EXAMPLES
See *tee*(2).

copy_file_range(2), *sendfile*(2), *tee*(2), *vmsplice*(2), *pipe*(7)

NAME

spu_create − create a new spu context

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/spu.h>        /* Definition of SPU_* constants */
#include <sys/syscall.h>    /* Definition of SYS_* constants */
#include <unistd.h>

int syscall(SYS_spu_create, const char *pathname, unsigned int flags,
        mode_t mode, int neighbor_fd);
```

Note: glibc provides no wrapper for **spu_create**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **spu_create**() system call is used on PowerPC machines that implement the Cell Broadband Engine Architecture in order to access Synergistic Processor Units (SPUs). It creates a new logical context for an SPU in *pathname* and returns a file descriptor associated with it. *pathname* must refer to a nonexistent directory in the mount point of the SPU filesystem (**spufs**). If **spu_create**() is successful, a directory is created at *pathname* and it is populated with the files described in *spufs*(7).

When a context is created, the returned file descriptor can only be passed to *spu_run*(2), used as the *dirfd* argument to the ***at** family of system calls (e.g., *openat*(2)), or closed; other operations are not defined. A logical SPU context is destroyed (along with all files created within the context's *pathname* directory) once the last reference to the context has gone; this usually occurs when the file descriptor returned by **spu_create**() is closed.

The *mode* argument (minus any bits set in the process's *umask*(2)) specifies the permissions used for creating the new directory in **spufs**. See *stat*(2) for a full list of the possible *mode* values.

The *neighbor_fd* is used only when the **SPU_CREATE_AFFINITY_SPU** flag is specified; see below.

The *flags* argument can be zero or any bitwise OR-ed combination of the following constants:

SPU_CREATE_EVENTS_ENABLED
: Rather than using signals for reporting DMA errors, use the *event* argument to *spu_run*(2).

SPU_CREATE_GANG
: Create an SPU gang instead of a context. (A gang is a group of SPU contexts that are functionally related to each other and which share common scheduling parameters—priority and policy. In the future, gang scheduling may be implemented causing the group to be switched in and out as a single unit.)

  A new directory will be created at the location specified by the *pathname* argument. This gang may be used to hold other SPU contexts, by providing a pathname that is within the gang directory to further calls to **spu_create**().

SPU_CREATE_NOSCHED
: Create a context that is not affected by the SPU scheduler. Once the context is run, it will not be scheduled out until it is destroyed by the creating process.

  Because the context cannot be removed from the SPU, some functionality is disabled for **SPU_CREATE_NOSCHED** contexts. Only a subset of the files will be available in this context directory in **spufs**. Additionally, **SPU_CREATE_NOSCHED** contexts cannot dump a core file when crashing.

  Creating **SPU_CREATE_NOSCHED** contexts requires the **CAP_SYS_NICE** capability.

SPU_CREATE_ISOLATE
: Create an isolated SPU context. Isolated contexts are protected from some PPE (PowerPC Processing Element) operations, such as access to the SPU local store and the NPC register.

  Creating **SPU_CREATE_ISOLATE** contexts also requires the **SPU_CREATE_NOSCHED** flag.

SPU_CREATE_AFFINITY_SPU (since Linux 2.6.23)
Create a context with affinity to another SPU context. This affinity information is used within the SPU scheduling algorithm. Using this flag requires that a file descriptor referring to the other SPU context be passed in the *neighbor_fd* argument.

SPU_CREATE_AFFINITY_MEM (since Linux 2.6.23)
Create a context with affinity to system memory. This affinity information is used within the SPU scheduling algorithm.

RETURN VALUE

On success, **spu_create**() returns a new file descriptor. On failure, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
The current user does not have write access to the *spufs*(7) mount point.

EEXIST
An SPU context already exists at the given pathname.

EFAULT
pathname is not a valid string pointer in the calling process's address space.

EINVAL
pathname is not a directory in the *spufs*(7) mount point, or invalid flags have been provided.

ELOOP
Too many symbolic links were found while resolving *pathname*.

EMFILE
The per-process limit on the number of open file descriptors has been reached.

ENAMETOOLONG
pathname is too long.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENODEV
An isolated context was requested, but the hardware does not support SPU isolation.

ENOENT
Part of *pathname* could not be resolved.

ENOMEM
The kernel could not allocate all resources required.

ENOSPC
There are not enough SPU resources available to create a new context or the user-specific limit for the number of SPU contexts has been reached.

ENOSYS
The functionality is not provided by the current system, because either the hardware does not provide SPUs or the spufs module is not loaded.

ENOTDIR
A part of *pathname* is not a directory.

EPERM
The **SPU_CREATE_NOSCHED** flag has been given, but the user does not have the **CAP_SYS_NICE** capability.

FILES

pathname must point to a location beneath the mount point of **spufs**. By convention, it gets mounted in */spu*.

STANDARDS

Linux on PowerPC.

HISTORY

Linux 2.6.16.

Prior to the addition of the **SPU_CREATE_AFFINITY_SPU** flag in Linux 2.6.23, the **spu_create**() system call took only three arguments (i.e., there was no *neighbor_fd* argument).

NOTES

spu_create() is meant to be used from libraries that implement a more abstract interface to SPUs, not to be used from regular applications. See for the recommended libraries.

EXAMPLES

See *spu_run*(2) for an example of the use of **spu_create**()

SEE ALSO

close(2), *spu_run*(2), *capabilities*(7), *spufs*(7)

NAME

spu_run − execute an SPU context

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/spu.h> /* Definition of **SPU_*** constants */
#include <sys/syscall.h> /* Definition of **SYS_*** constants */
#include <unistd.h>

int syscall(SYS_spu_run, int *fd***, uint32_t *****npc***, uint32_t *****event***);**

Note: glibc provides no wrapper for **spu_run**(), necessitating the use of *syscall*(2).

DESCRIPTION

The **spu_run**() system call is used on PowerPC machines that implement the Cell Broadband Engine Architecture in order to access Synergistic Processor Units (SPUs). The *fd* argument is a file descriptor returned by *spu_create*(2) that refers to a specific SPU context. When the context gets scheduled to a physical SPU, it starts execution at the instruction pointer passed in *npc*.

Execution of SPU code happens synchronously, meaning that **spu_run**() blocks while the SPU is still running. If there is a need to execute SPU code in parallel with other code on either the main CPU or other SPUs, a new thread of execution must be created first (e.g., using *pthread_create*(3)).

When **spu_run**() returns, the current value of the SPU program counter is written to *npc*, so successive calls to **spu_run**() can use the same *npc* pointer.

The *event* argument provides a buffer for an extended status code. If the SPU context was created with the **SPU_CREATE_EVENTS_ENABLED** flag, then this buffer is populated by the Linux kernel before **spu_run**() returns.

The status code may be one (or more) of the following constants:

SPE_EVENT_DMA_ALIGNMENT
A DMA alignment error occurred.

SPE_EVENT_INVALID_DMA
An invalid MFC DMA command was attempted.

SPE_EVENT_SPE_DATA_STORAGE
A DMA storage error occurred.

SPE_EVENT_SPE_ERROR
An illegal instruction was executed.

NULL is a valid value for the *event* argument. In this case, the events will not be reported to the calling process.

RETURN VALUE

On success, **spu_run**() returns the value of the *spu_status* register. On failure, it returns −1 and sets *errno* is set to indicate the error.

The *spu_status* register value is a bit mask of status codes and optionally a 14-bit code returned from the **stop-and-signal** instruction on the SPU. The bit masks for the status codes are:

0x02 SPU was stopped by a **stop-and-signal** instruction.

0x04 SPU was stopped by a **halt** instruction.

0x08 SPU is waiting for a channel.

0x10 SPU is in single-step mode.

0x20 SPU has tried to execute an invalid instruction.

0x40 SPU has tried to access an invalid channel.

0x3fff0000
The bits masked with this value contain the code returned from a **stop-and-signal** instruction. These bits are valid only if the 0x02 bit is set.

If **spu_run**() has not returned an error, one or more bits among the lower eight ones are always set.

ERRORS

EBADF
fd is not a valid file descriptor.

EFAULT
npc is not a valid pointer, or *event* is non-NULL and an invalid pointer.

EINTR
A signal occurred while **spu_run**() was in progress; see *signal*(7). The *npc* value has been updated to the new program counter value if necessary.

EINVAL
fd is not a valid file descriptor returned from *spu_create*(2).

ENOMEM
There was not enough memory available to handle a page fault resulting from a Memory Flow Controller (MFC) direct memory access.

ENOSYS
The functionality is not provided by the current system, because either the hardware does not provide SPUs or the spufs module is not loaded.

STANDARDS

Linux on PowerPC.

HISTORY

Linux 2.6.16.

NOTES

spu_run() is meant to be used from libraries that implement a more abstract interface to SPUs, not to be used from regular applications. See for the recommended libraries.

EXAMPLES

The following is an example of running a simple, one-instruction SPU program with the **spu_run**() system call.

```
#include <err.h>
#include <fcntl.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/types.h>
#include <unistd.h>

int main(void)
{
    int       context, fd, spu_status;
    uint32_t  instruction, npc;

    context = syscall(SYS_spu_create, "/spu/example-context", 0, 0755);
    if (context == -1)
        err(EXIT_FAILURE, "spu_create");

    /*
     * Write a 'stop 0x1234' instruction to the SPU's
     * local store memory.
     */
    instruction = 0x00001234;

    fd = open("/spu/example-context/mem", O_RDWR);
    if (fd == -1)
        err(EXIT_FAILURE, "open");
    write(fd, &instruction, sizeof(instruction));

    /*
```

```
             * set npc to the starting instruction address of the
             * SPU program. Since we wrote the instruction at the
             * start of the mem file, the entry point will be 0x0.
             */
            npc = 0;

            spu_status = syscall(SYS_spu_run, context, &npc, NULL);
            if (spu_status == -1)
                err(EXIT_FAILURE, "open");

            /*
             * We should see a status code of 0x12340002:
             *   0x00000002 (spu was stopped due to stop-and-signal)
             * | 0x12340000 (the stop-and-signal code)
             */
            printf("SPU Status: %#08x\n", spu_status);

            exit(EXIT_SUCCESS);
        }
```

NAME

stat, fstat, lstat, fstatat − get file status

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <sys/stat.h>

int stat(const char *restrict pathname,
         struct stat *restrict statbuf);
int fstat(int fd, struct stat *statbuf);
int lstat(const char *restrict pathname,
         struct stat *restrict statbuf);

#include <fcntl.h>           /* Definition of AT_* constants */
#include <sys/stat.h>

int fstatat(int dirfd, const char *restrict pathname,
         struct stat *restrict statbuf, int flags);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

lstat():

```
/* Since glibc 2.20 */ _DEFAULT_SOURCE
   || _XOPEN_SOURCE >= 500
   || /* Since glibc 2.10: */ _POSIX_C_SOURCE >= 200112L
   || /* glibc 2.19 and earlier */ _BSD_SOURCE
```

fstatat():

```
Since glibc 2.10:
   _POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
   _ATFILE_SOURCE
```

DESCRIPTION

These functions return information about a file, in the buffer pointed to by *statbuf*. No permissions are required on the file itself, but—in the case of **stat**(), **fstatat**(), and **lstat**()—execute (search) permission is required on all of the directories in *pathname* that lead to the file.

stat() and **fstatat**() retrieve information about the file pointed to by *pathname*; the differences for **fstatat**() are described below.

lstat() is identical to **stat**(), except that if *pathname* is a symbolic link, then it returns information about the link itself, not the file that the link refers to.

fstat() is identical to **stat**(), except that the file about which information is to be retrieved is specified by the file descriptor *fd*.

The stat structure

All of these system calls return a *stat* structure (see *stat*(3type)).

Note: for performance and simplicity reasons, different fields in the *stat* structure may contain state information from different moments during the execution of the system call. For example, if *st_mode* or *st_uid* is changed by another process by calling *chmod*(2) or *chown*(2), **stat**() might return the old *st_mode* together with the new *st_uid*, or the old *st_uid* together with the new *st_mode*.

fstatat()

The **fstatat**() system call is a more general interface for accessing file information which can still provide exactly the behavior of each of **stat**(), **lstat**(), and **fstat**().

If the pathname given in *pathname* is relative, then it is interpreted relative to the directory referred to by the file descriptor *dirfd* (rather than relative to the current working directory of the calling process, as is done by **stat**() and **lstat**() for a relative pathname).

If *pathname* is relative and *dirfd* is the special value **AT_FDCWD**, then *pathname* is interpreted relative to the current working directory of the calling process (like **stat**() and *lstat*())

If *pathname* is absolute, then *dirfd* is ignored.

flags can either be 0, or include one or more of the following flags ORed:

AT_EMPTY_PATH (since Linux 2.6.39)
If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the *open*(2) **O_PATH** flag). In this case, *dirfd* can refer to any type of file, not just a directory, and the behavior of **fstatat**() is similar to that of **fstat**(). If *dirfd* is **AT_FDCWD**, the call operates on the current working directory. This flag is Linux-specific; define **_GNU_SOURCE** to obtain its definition.

AT_NO_AUTOMOUNT (since Linux 2.6.38)
Don't automount the terminal ("basename") component of *pathname*. Since Linux 3.1 this flag is ignored. Since Linux 4.11 this flag is implied.

AT_SYMLINK_NOFOLLOW
If *pathname* is a symbolic link, do not dereference it: instead return information about the link itself, like **lstat**(). (By default, **fstatat**() dereferences symbolic links, like *stat*().)

See *openat*(2) for an explanation of the need for **fstatat**().

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
Search permission is denied for one of the directories in the path prefix of *pathname*. (See also *path_resolution*(7).)

EBADF
fd is not a valid open file descriptor.

EBADF
(**fstatat**()) *pathname* is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT
Bad address.

EINVAL
(**fstatat**()) Invalid flag specified in *flags*.

ELOOP
Too many symbolic links encountered while traversing the path.

ENAMETOOLONG
pathname is too long.

ENOENT
A component of *pathname* does not exist or is a dangling symbolic link.

ENOENT
pathname is an empty string and **AT_EMPTY_PATH** was not specified in *flags*.

ENOMEM
Out of memory (i.e., kernel memory).

ENOTDIR
A component of the path prefix of *pathname* is not a directory.

ENOTDIR
(**fstatat**()) *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

EOVERFLOW
pathname or *fd* refers to a file whose size, inode number, or number of blocks cannot be represented in, respectively, the types *off_t*, *ino_t*, or *blkcnt_t*. This error can occur when, for example, an application compiled on a 32-bit platform without *−D_FILE_OFFSET_BITS=64* calls **stat**() on a file whose size exceeds *(1<<31)−1* bytes.

STANDARDS

POSIX.1-2008.

HISTORY

stat()
fstat()
lstat() SVr4, 4.3BSD, POSIX.1-2001.

fstatat()
POSIX.1-2008. Linux 2.6.16, glibc 2.4.

According to POSIX.1-2001, **lstat**() on a symbolic link need return valid information only in the *st_size* field and the file type of the *st_mode* field of the *stat* structure. POSIX.1-2008 tightens the specification, requiring **lstat**() to return valid information in all fields except the mode bits in *st_mode*.

Use of the *st_blocks* and *st_blksize* fields may be less portable. (They were introduced in BSD. The interpretation differs between systems, and possibly on a single system when NFS mounts are involved.)

C library/kernel differences

Over time, increases in the size of the *stat* structure have led to three successive versions of **stat**(): *sys_stat*() (slot *__NR_oldstat*), *sys_newstat*() (slot *__NR_stat*), and *sys_stat64()* (slot *__NR_stat64*) on 32-bit platforms such as i386. The first two versions were already present in Linux 1.0 (albeit with different names); the last was added in Linux 2.4. Similar remarks apply for **fstat**() and **lstat**().

The kernel-internal versions of the *stat* structure dealt with by the different versions are, respectively:

__old_kernel_stat
The original structure, with rather narrow fields, and no padding.

stat Larger *st_ino* field and padding added to various parts of the structure to allow for future expansion.

stat64 Even larger *st_ino* field, larger *st_uid* and *st_gid* fields to accommodate the Linux-2.4 expansion of UIDs and GIDs to 32 bits, and various other enlarged fields and further padding in the structure. (Various padding bytes were eventually consumed in Linux 2.6, with the advent of 32-bit device IDs and nanosecond components for the timestamp fields.)

The glibc **stat**() wrapper function hides these details from applications, invoking the most recent version of the system call provided by the kernel, and repacking the returned information if required for old binaries.

On modern 64-bit systems, life is simpler: there is a single **stat**() system call and the kernel deals with a *stat* structure that contains fields of a sufficient size.

The underlying system call employed by the glibc **fstatat**() wrapper function is actually called **fstatat64**() or, on some architectures, **newfstatat**().

EXAMPLES

The following program calls **lstat**() and displays selected fields in the returned *stat* structure.

```
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/stat.h>
#include <sys/sysmacros.h>
#include <time.h>

int
main(int argc, char *argv[])
{
    struct stat sb;

    if (argc != 2) {
        fprintf(stderr, "Usage: %s <pathname>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    if (lstat(argv[1], &sb) == -1) {
```

```
            perror("lstat");
            exit(EXIT_FAILURE);
        }

        printf("ID of containing device:  [%x,%x]\n",
               major(sb.st_dev),
               minor(sb.st_dev));

        printf("File type:                ");

        switch (sb.st_mode & S_IFMT) {
        case S_IFBLK:  printf("block device\n");            break;
        case S_IFCHR:  printf("character device\n");        break;
        case S_IFDIR:  printf("directory\n");               break;
        case S_IFIFO:  printf("FIFO/pipe\n");               break;
        case S_IFLNK:  printf("symlink\n");                 break;
        case S_IFREG:  printf("regular file\n");            break;
        case S_IFSOCK: printf("socket\n");                  break;
        default:       printf("unknown?\n");                break;
        }

        printf("I-node number:            %ju\n", (uintmax_t) sb.st_ino);

        printf("Mode:                     %jo (octal)\n",
               (uintmax_t) sb.st_mode);

        printf("Link count:               %ju\n", (uintmax_t) sb.st_nlink);
        printf("Ownership:                UID=%ju   GID=%ju\n",
               (uintmax_t) sb.st_uid, (uintmax_t) sb.st_gid);

        printf("Preferred I/O block size: %jd bytes\n",
               (intmax_t) sb.st_blksize);
        printf("File size:                %jd bytes\n",
               (intmax_t) sb.st_size);
        printf("Blocks allocated:         %jd\n",
               (intmax_t) sb.st_blocks);

        printf("Last status change:       %s", ctime(&sb.st_ctime));
        printf("Last file access:         %s", ctime(&sb.st_atime));
        printf("Last file modification:   %s", ctime(&sb.st_mtime));

        exit(EXIT_SUCCESS);
    }
```

NAME

statfs, fstatfs − get filesystem statistics

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <sys/vfs.h> /* or <sys/statfs.h> */

int statfs(const char * *path*, **struct statfs *** *buf* **);**
int fstatfs(int *fd*, **struct statfs *** *buf* **);**

Unless you need the *f_type* field, you should use the standard *statvfs*(3) interface instead.

DESCRIPTION

The **statfs**() system call returns information about a mounted filesystem. *path* is the pathname of any file within the mounted filesystem. *buf* is a pointer to a *statfs* structure defined approximately as follows:

```
struct statfs {
    __fsword_t f_type;    /* Type of filesystem (see below) */
    __fsword_t f_bsize;   /* Optimal transfer block size */
    fsblkcnt_t f_blocks;  /* Total data blocks in filesystem */
    fsblkcnt_t f_bfree;   /* Free blocks in filesystem */
    fsblkcnt_t f_bavail;  /* Free blocks available to
                             unprivileged user */
    fsfilcnt_t f_files;   /* Total inodes in filesystem */
    fsfilcnt_t f_ffree;   /* Free inodes in filesystem */
    fsid_t     f_fsid;    /* Filesystem ID */
    __fsword_t f_namelen; /* Maximum length of filenames */
    __fsword_t f_frsize;  /* Fragment size (since Linux 2.6) */
    __fsword_t f_flags;   /* Mount flags of filesystem
                             (since Linux 2.6.36) */
    __fsword_t f_spare[xxx];
                     /* Padding bytes reserved for future use */
};
```

The following filesystem types may appear in *f_type*:

```
ADFS_SUPER_MAGIC      0xadf5
AFFS_SUPER_MAGIC      0xadff
AFS_SUPER_MAGIC       0x5346414f

```

Most of these MAGIC constants are defined in */usr/include/linux/magic.h*, and some are hardcoded in kernel sources.

The *f_flags* field is a bit mask indicating mount options for the filesystem. It contains zero or more of the following bits:

ST_MANDLOCK
Mandatory locking is permitted on the filesystem (see *fcntl*(2)).

ST_NOATIME
Do not update access times; see *mount*(2).

ST_NODEV
Disallow access to device special files on this filesystem.

ST_NODIRATIME
Do not update directory access times; see *mount*(2).

ST_NOEXEC
Execution of programs is disallowed on this filesystem.

ST_NOSUID
The set-user-ID and set-group-ID bits are ignored by *exec*(3) for executable files on this filesystem

ST_RDONLY
This filesystem is mounted read-only.

ST_RELATIME
Update atime relative to mtime/ctime; see *mount*(2).

ST_SYNCHRONOUS
Writes are synched to the filesystem immediately (see the description of **O_SYNC** in *open*(2)).

ST_NOSYMFOLLOW (since Linux 5.10)
Symbolic links are not followed when resolving paths; see *mount*(2).

Nobody knows what *f_fsid* is supposed to contain (but see below).

Fields that are undefined for a particular filesystem are set to 0.

fstatfs() returns the same information about an open file referenced by descriptor *fd*.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
(**statfs**()) Search permission is denied for a component of the path prefix of *path*. (See also *path_resolution*(7).)

EBADF
(**fstatfs**()) *fd* is not a valid open file descriptor.

EFAULT
buf or *path* points to an invalid address.

EINTR
The call was interrupted by a signal; see *signal*(7).

EIO An I/O error occurred while reading from the filesystem.

ELOOP
(**statfs**()) Too many symbolic links were encountered in translating *path*.

ENAMETOOLONG
(**statfs**()) *path* is too long.

ENOENT
(**statfs**()) The file referred to by *path* does not exist.

ENOMEM
Insufficient kernel memory was available.

ENOSYS
The filesystem does not support this call.

ENOTDIR
(**statfs**()) A component of the path prefix of *path* is not a directory.

EOVERFLOW
Some values were too large to be represented in the returned struct.

VERSIONS

The f_fsid field

Solaris, Irix, and POSIX have a system call *statvfs*(2) that returns a *struct statvfs* (defined in <*sys/statvfs.h*>) containing an *unsigned long f_fsid*. Linux, SunOS, HP-UX, 4.4BSD have a system call **statfs**() that returns a *struct statfs* (defined in <*sys/vfs.h*>) containing a *fsid_t f_fsid*, where *fsid_t* is defined as *struct { int val[2]; }*. The same holds for FreeBSD, except that it uses the include file <*sys/mount.h*>.

The general idea is that *f_fsid* contains some random stuff such that the pair (*f_fsid*,*ino*) uniquely determines a file. Some operating systems use (a variation on) the device number, or the device number combined with the filesystem type. Several operating systems restrict giving out the *f_fsid* field to the superuser only (and zero it for unprivileged users), because this field is used in the filehandle of the filesystem when NFS-exported, and giving it out is a security concern.

Under some operating systems, the *fsid* can be used as the second argument to the *sysfs*(2) system call.

STANDARDS

Linux.

HISTORY

The Linux **statfs**() was inspired by the 4.4BSD one (but they do not use the same structure).

The original Linux **statfs**() and **fstatfs**() system calls were not designed with extremely large file sizes in mind. Subsequently, Linux 2.6 added new **statfs64**() and **fstatfs64**() system calls that employ a new structure, *statfs64*. The new structure contains the same fields as the original *statfs* structure, but the sizes of various fields are increased, to accommodate large file sizes. The glibc **statfs**() and **fstatfs**() wrapper functions transparently deal with the kernel differences.

LSB has deprecated the library calls **statfs**() and **fstatfs**() and tells us to use *statvfs*(3) and *fstatvfs*(3) instead.

NOTES

The *__fsword_t* type used for various fields in the *statfs* structure definition is a glibc internal type, not intended for public use. This leaves the programmer in a bit of a conundrum when trying to copy or compare these fields to local variables in a program. Using *unsigned int* for such variables suffices on most systems.

Some systems have only <*sys/vfs.h*>, other systems also have <*sys/statfs.h*>, where the former includes the latter. So it seems including the former is the best choice.

BUGS

From Linux 2.6.38 up to and including Linux 3.1, **fstatfs**() failed with the error **ENOSYS** for file descriptors created by *pipe*(2).

NAME

statx − get file status (extended)

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <fcntl.h>          /* Definition of AT_* constants */
#include <sys/stat.h>

int statx(int dirfd, const char *restrict pathname, int flags,
          unsigned int mask, struct statx *restrict statxbuf);
```

DESCRIPTION

This function returns information about a file, storing it in the buffer pointed to by *statxbuf*. The returned buffer is a structure of the following type:

```
struct statx {
    __u32 stx_mask;        /* Mask of bits indicating
                              filled fields */
    __u32 stx_blksize;     /* Block size for filesystem I/O */
    __u64 stx_attributes;  /* Extra file attribute indicators */
    __u32 stx_nlink;       /* Number of hard links */
    __u32 stx_uid;         /* User ID of owner */
    __u32 stx_gid;         /* Group ID of owner */
    __u16 stx_mode;        /* File type and mode */
    __u64 stx_ino;         /* Inode number */
    __u64 stx_size;        /* Total size in bytes */
    __u64 stx_blocks;      /* Number of 512B blocks allocated */
    __u64 stx_attributes_mask;
                           /* Mask to show what's supported
                              in stx_attributes */

    /* The following fields are file timestamps */
    struct statx_timestamp stx_atime;  /* Last access */
    struct statx_timestamp stx_btime;  /* Creation */
    struct statx_timestamp stx_ctime;  /* Last status change */
    struct statx_timestamp stx_mtime;  /* Last modification */

    /* If this file represents a device, then the next two
       fields contain the ID of the device */
    __u32 stx_rdev_major;  /* Major ID */
    __u32 stx_rdev_minor;  /* Minor ID */

    /* The next two fields contain the ID of the device
       containing the filesystem where the file resides */
    __u32 stx_dev_major;   /* Major ID */
    __u32 stx_dev_minor;   /* Minor ID */

    __u64 stx_mnt_id;      /* Mount ID */

    /* Direct I/O alignment restrictions */
    __u32 stx_dio_mem_align;
    __u32 stx_dio_offset_align;
};
```

The file timestamps are structures of the following type:

```
struct statx_timestamp {
    __s64 tv_sec;    /* Seconds since the Epoch (UNIX time) */
    __u32 tv_nsec;   /* Nanoseconds since tv_sec */
};
```

(Note that reserved space and padding is omitted.)

Invoking statx():

To access a file's status, no permissions are required on the file itself, but in the case of **statx**() with a pathname, execute (search) permission is required on all of the directories in *pathname* that lead to the file.

statx() uses *pathname*, *dirfd*, and *flags* to identify the target file in one of the following ways:

An absolute pathname

If *pathname* begins with a slash, then it is an absolute pathname that identifies the target file. In this case, *dirfd* is ignored.

A relative pathname

If *pathname* is a string that begins with a character other than a slash and *dirfd* is **AT_FDCWD**, then *pathname* is a relative pathname that is interpreted relative to the process's current working directory.

A directory-relative pathname

If *pathname* is a string that begins with a character other than a slash and *dirfd* is a file descriptor that refers to a directory, then *pathname* is a relative pathname that is interpreted relative to the directory referred to by *dirfd*. (See *openat*(2) for an explanation of why this is useful.)

By file descriptor

If *pathname* is an empty string and the **AT_EMPTY_PATH** flag is specified in *flags* (see below), then the target file is the one referred to by the file descriptor *dirfd*.

flags can be used to influence a pathname-based lookup. A value for *flags* is constructed by ORing together zero or more of the following constants:

AT_EMPTY_PATH

If *pathname* is an empty string, operate on the file referred to by *dirfd* (which may have been obtained using the *open*(2) **O_PATH** flag). In this case, *dirfd* can refer to any type of file, not just a directory.

If *dirfd* is **AT_FDCWD**, the call operates on the current working directory.

AT_NO_AUTOMOUNT

Don't automount the terminal ("basename") component of *pathname* if it is a directory that is an automount point. This allows the caller to gather attributes of an automount point (rather than the location it would mount). This flag has no effect if the mount point has already been mounted over.

The **AT_NO_AUTOMOUNT** flag can be used in tools that scan directories to prevent mass-automounting of a directory of automount points.

All of *stat*(2), *lstat*(2), and *fstatat*(2) act as though **AT_NO_AUTOMOUNT** was set.

AT_SYMLINK_NOFOLLOW

If *pathname* is a symbolic link, do not dereference it: instead return information about the link itself, like *lstat*(2).

flags can also be used to control what sort of synchronization the kernel will do when querying a file on a remote filesystem. This is done by ORing in one of the following values:

AT_STATX_SYNC_AS_STAT

Do whatever *stat*(2) does. This is the default and is very much filesystem-specific.

AT_STATX_FORCE_SYNC

Force the attributes to be synchronized with the server. This may require that a network filesystem perform a data writeback to get the timestamps correct.

AT_STATX_DONT_SYNC

Don't synchronize anything, but rather just take whatever the system has cached if possible. This may mean that the information returned is approximate, but, on a network filesystem, it may not involve a round trip to the server - even if no lease is held.

The *mask* argument to **statx**() is used to tell the kernel which fields the caller is interested in. *mask* is

an ORed combination of the following constants:

STATX_TYPE	Want stx_mode & S_IFMT
STATX_MODE	Want stx_mode & ~S_IFMT
STATX_NLINK	Want stx_nlink
STATX_UID	Want stx_uid
STATX_GID	Want stx_gid
STATX_ATIME	Want stx_atime
STATX_MTIME	Want stx_mtime
STATX_CTIME	Want stx_ctime
STATX_INO	Want stx_ino
STATX_SIZE	Want stx_size
STATX_BLOCKS	Want stx_blocks
STATX_BASIC_STATS	[All of the above]
STATX_BTIME	Want stx_btime
STATX_ALL	The same as STATX_BASIC_STATS | STATX_BTIME. It is deprecated and should not be used.
STATX_MNT_ID	Want stx_mnt_id (since Linux 5.8)
STATX_DIOALIGN	Want stx_dio_mem_align and stx_dio_offset_align (since Linux 6.1; support varies by filesystem)

Note that, in general, the kernel does *not* reject values in *mask* other than the above. (For an exception, see **EINVAL** in errors.) Instead, it simply informs the caller which values are supported by this kernel and filesystem via the *statx.stx_mask* field. Therefore, *do not* simply set *mask* to **UINT_MAX** (all bits set), as one or more bits may, in the future, be used to specify an extension to the buffer.

The returned information

The status information for the target file is returned in the *statx* structure pointed to by *statxbuf*. Included in this is *stx_mask* which indicates what other information has been returned. *stx_mask* has the same format as the *mask* argument and bits are set in it to indicate which fields have been filled in.

It should be noted that the kernel may return fields that weren't requested and may fail to return fields that were requested, depending on what the backing filesystem supports. (Fields that are given values despite being unrequested can just be ignored.) In either case, *stx_mask* will not be equal *mask*.

If a filesystem does not support a field or if it has an unrepresentable value (for instance, a file with an exotic type), then the mask bit corresponding to that field will be cleared in *stx_mask* even if the user asked for it and a dummy value will be filled in for compatibility purposes if one is available (e.g., a dummy UID and GID may be specified to mount under some circumstances).

A filesystem may also fill in fields that the caller didn't ask for if it has values for them available and the information is available at no extra cost. If this happens, the corresponding bits will be set in *stx_mask*.

Note: for performance and simplicity reasons, different fields in the *statx* structure may contain state information from different moments during the execution of the system call. For example, if *stx_mode* or *stx_uid* is changed by another process by calling *chmod*(2) or *chown*(2), **stat**() might return the old *stx_mode* together with the new *stx_uid*, or the old *stx_uid* together with the new *stx_mode*.

Apart from *stx_mask* (which is described above), the fields in the *statx* structure are:

stx_blksize
: The "preferred" block size for efficient filesystem I/O. (Writing to a file in smaller chunks may cause an inefficient read-modify-rewrite.)

stx_attributes
: Further status information about the file (see below for more information).

stx_nlink
: The number of hard links on a file.

stx_uid This field contains the user ID of the owner of the file.

stx_gid This field contains the ID of the group owner of the file.

stx_mode
: The file type and mode. See *inode*(7) for details.

stx_ino The inode number of the file.

stx_size
: The size of the file (if it is a regular file or a symbolic link) in bytes. The size of a symbolic link is the length of the pathname it contains, without a terminating null byte.

stx_blocks
: The number of blocks allocated to the file on the medium, in 512-byte units. (This may be smaller than *stx_size*/512 when the file has holes.)

stx_attributes_mask
: A mask indicating which bits in *stx_attributes* are supported by the VFS and the filesystem.

stx_atime
: The file's last access timestamp.

stx_btime
: The file's creation timestamp.

stx_ctime
: The file's last status change timestamp.

stx_mtime
: The file's last modification timestamp.

stx_dev_major and *stx_dev_minor*
: The device on which this file (inode) resides.

stx_rdev_major and *stx_rdev_minor*
: The device that this file (inode) represents if the file is of block or character device type.

stx_mnt_id
: The mount ID of the mount containing the file. This is the same number reported by *name_to_handle_at*(2) and corresponds to the number in the first field in one of the records in */proc/self/mountinfo*.

stx_dio_mem_align
: The alignment (in bytes) required for user memory buffers for direct I/O (**O_DIRECT**) on this file, or 0 if direct I/O is not supported on this file.

  STATX_DIOALIGN (*stx_dio_mem_align* and *stx_dio_offset_align*) is supported on block devices since Linux 6.1. The support on regular files varies by filesystem; it is supported by ext4, f2fs, and xfs since Linux 6.1.

stx_dio_offset_align
: The alignment (in bytes) required for file offsets and I/O segment lengths for direct I/O (**O_DIRECT**) on this file, or 0 if direct I/O is not supported on this file. This will only be nonzero if *stx_dio_mem_align* is nonzero, and vice versa.

For further information on the above fields, see *inode*(7).

File attributes

The *stx_attributes* field contains a set of ORed flags that indicate additional attributes of the file. Note that any attribute that is not indicated as supported by *stx_attributes_mask* has no usable value here. The bits in *stx_attributes_mask* correspond bit-by-bit to *stx_attributes*.

The flags are as follows:

STATX_ATTR_COMPRESSED
: The file is compressed by the filesystem and may take extra resources to access.

STATX_ATTR_IMMUTABLE
: The file cannot be modified: it cannot be deleted or renamed, no hard links can be created to this file and no data can be written to it. See *chattr*(1)

STATX_ATTR_APPEND
: The file can only be opened in append mode for writing. Random access writing is not permitted. See *chattr*(1)

STATX_ATTR_NODUMP
File is not a candidate for backup when a backup program such as *dump*(8) is run. See *chattr*(1)

STATX_ATTR_ENCRYPTED
A key is required for the file to be encrypted by the filesystem.

STATX_ATTR_VERITY (since Linux 5.5)
The file has fs-verity enabled. It cannot be written to, and all reads from it will be verified against a cryptographic hash that covers the entire file (e.g., via a Merkle tree).

STATX_ATTR_DAX (since Linux 5.8)
The file is in the DAX (cpu direct access) state. DAX state attempts to minimize software cache effects for both I/O and memory mappings of this file. It requires a file system which has been configured to support DAX.

DAX generally assumes all accesses are via CPU load / store instructions which can minimize overhead for small accesses, but may adversely affect CPU utilization for large transfers.

File I/O is done directly to/from user-space buffers and memory mapped I/O may be performed with direct memory mappings that bypass the kernel page cache.

While the DAX property tends to result in data being transferred synchronously, it does not give the same guarantees as the **O_SYNC** flag (see *open*(2)), where data and the necessary metadata are transferred together.

A DAX file may support being mapped with the **MAP_SYNC** flag, which enables a program to use CPU cache flush instructions to persist CPU store operations without an explicit *fsync*(2). See *mmap*(2) for more information.

STATX_ATTR_MOUNT_ROOT (since Linux 5.8)
The file is the root of a mount.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EACCES
Search permission is denied for one of the directories in the path prefix of *pathname*. (See also *path_resolution*(7).)

EBADF
pathname is relative but *dirfd* is neither **AT_FDCWD** nor a valid file descriptor.

EFAULT
pathname or *statxbuf* is NULL or points to a location outside the process's accessible address space.

EINVAL
Invalid flag specified in *flags*.

EINVAL
Reserved flag specified in *mask*. (Currently, there is one such flag, designated by the constant **STATX__RESERVED**, with the value 0x80000000U.)

ELOOP
Too many symbolic links encountered while traversing the pathname.

ENAMETOOLONG
pathname is too long.

ENOENT
A component of *pathname* does not exist, or *pathname* is an empty string and **AT_EMPTY_PATH** was not specified in *flags*.

ENOMEM
Out of memory (i.e., kernel memory).

ENOTDIR
A component of the path prefix of *pathname* is not a directory or *pathname* is relative and *dirfd* is a file descriptor referring to a file other than a directory.

STANDARDS
Linux.

HISTORY
Linux 4.11, glibc 2.28.

NAME

stime − set time

SYNOPSIS

#include <time.h>

[[deprecated]] int stime(const time_t *_t_);

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

stime():
Since glibc 2.19:
_DEFAULT_SOURCE
glibc 2.19 and earlier:
_SVID_SOURCE

DESCRIPTION

NOTE: This function is deprecated; use *clock_settime*(2) instead.

stime() sets the system's idea of the time and date. The time, pointed to by *t*, is measured in seconds since the Epoch, 1970-01-01 00:00:00 +0000 (UTC). **stime**() may be executed only by the superuser.

RETURN VALUE

On success, zero is returned. On error, −1 is returned, and *errno* is set to indicate the error.

ERRORS

EFAULT
Error in getting information from user space.

EPERM
The calling process has insufficient privilege. Under Linux, the **CAP_SYS_TIME** privilege is required.

STANDARDS

None.

HISTORY

SVr4.

Starting with glibc 2.31, this function is no longer available to newly linked applications and is no longer declared in <*time.h*>.
