NAME

unlockpt − unlock a pseudoterminal master/slave pair

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#define _XOPEN_SOURCE
#include <stdlib.h>

int unlockpt(int fd);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

unlockpt():
Since glibc 2.24:
_XOPEN_SOURCE >= 500
glibc 2.23 and earlier:
_XOPEN_SOURCE

DESCRIPTION

The **unlockpt**() function unlocks the slave pseudoterminal device corresponding to the master pseudoterminal referred to by the file descriptor *fd*.

unlockpt() should be called before opening the slave side of a pseudoterminal.

RETURN VALUE

When successful, **unlockpt**() returns 0. Otherwise, it returns −1 and sets *errno* to indicate the error.

ERRORS

EBADF
The *fd* argument is not a file descriptor open for writing.

EINVAL
The *fd* argument is not associated with a master pseudoterminal.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
unlockpt()	Thread safety	MT-Safe

STANDARDS

POSIX.1-2008.

HISTORY

glibc 2.1. POSIX.1-2001.

SEE ALSO

grantpt(3), *posix_openpt*(3), *ptsname*(3), *pts*(4), *pty*(7)

NAME

updwtmp, logwtmp − append an entry to the wtmp file

LIBRARY

System utilities library (*libutil*, *−lutil*)

SYNOPSIS

#include <utmp.h>

void updwtmp(const char ****wtmp_file*, const struct utmp ****ut***);**
void logwtmp(const char ****line*, const char ****name***, const char ****host***);**

DESCRIPTION

updwtmp() appends the utmp structure *ut* to the wtmp file.

logwtmp() constructs a utmp structure using *line*, *name*, *host*, current time, and current process ID. Then it calls **updwtmp**() to append the structure to the wtmp file.

FILES

/var/log/wtmp
database of past user logins

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
updwtmp(), **logwtmp**()	Thread safety	MT-Unsafe sig:ALRM timer

VERSIONS

For consistency with the other "utmpx" functions (see *getutxent*(3)), glibc provides (since glibc 2.1):

```
#define _GNU_SOURCE          /* See feature_test_macros(7) */
#include <utmpx.h>
void updwtmpx (const char *wtmpx_file, const struct utmpx *utx);
```

This function performs the same task as **updwtmp**(), but differs in that it takes a *utmpx* structure as its last argument.

STANDARDS

None.

HISTORY

Solaris, NetBSD.

SEE ALSO

getutxent(3), *wtmp*(5)

NAME

uselocale − set/get the locale for the calling thread

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <locale.h>

locale_t uselocale(locale_t *newloc***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

uselocale():
Since glibc 2.10:
_XOPEN_SOURCE >= 700
Before glibc 2.10:
_GNU_SOURCE

DESCRIPTION

The **uselocale**() function sets the current locale for the calling thread, and returns the thread's previously current locale. After a successful call to **uselocale**(), any calls by this thread to functions that depend on the locale will operate as though the locale has been set to *newloc*.

The *newloc* argument can have one of the following values:

A handle returned by a call to **newlocale**(3) or **duplocale**(3)
: The calling thread's current locale is set to the specified locale.

The special locale object handle **LC_GLOBAL_LOCALE**
: The calling thread's current locale is set to the global locale determined by *setlocale*(3).

(locale_t) 0
: The calling thread's current locale is left unchanged (and the current locale is returned as the function result).

RETURN VALUE

On success, **uselocale**() returns the locale handle that was set by the previous call to **uselocale**() in this thread, or **LC_GLOBAL_LOCALE** if there was no such previous call. On error, it returns *(locale_t) 0*, and sets *errno* to indicate the error.

ERRORS

EINVAL
: *newloc* does not refer to a valid locale object.

STANDARDS

POSIX.1-2008.

HISTORY

glibc 2.3. POSIX.1-2008.

NOTES

Unlike *setlocale*(3), **uselocale**() does not allow selective replacement of individual locale categories. To employ a locale that differs in only a few categories from the current locale, use calls to *duplocale*(3) and *newlocale*(3) to obtain a locale object equivalent to the current locale and modify the desired categories in that object.

EXAMPLES

See *newlocale*(3) and *duplocale*(3).

SEE ALSO

locale(1), *duplocale*(3), *freelocale*(3), *newlocale*(3), *setlocale*(3), *locale*(5), *locale*(7)

NAME

usleep − suspend execution for microsecond intervals

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <unistd.h>

int usleep(useconds_t usec);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

usleep():
  Since glibc 2.12:
    (_XOPEN_SOURCE >= 500) && ! (_POSIX_C_SOURCE >= 200809L)
      || /* glibc >= 2.19: */ _DEFAULT_SOURCE
      || /* glibc <= 2.19: */ _BSD_SOURCE
  Before glibc 2.12:
    _BSD_SOURCE || _XOPEN_SOURCE >= 500

DESCRIPTION

The **usleep**() function suspends execution of the calling thread for (at least) *usec* microseconds. The sleep may be lengthened slightly by any system activity or by the time spent processing the call or by the granularity of system timers.

RETURN VALUE

The **usleep**() function returns 0 on success. On error, −1 is returned, with *errno* set to indicate the error.

ERRORS

EINTR
: Interrupted by a signal; see *signal*(7).

EINVAL
: *usec* is greater than or equal to 1000000. (On systems where that is considered an error.)

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
usleep()	Thread safety	MT-Safe

STANDARDS

None.

HISTORY

4.3BSD, POSIX.1-2001. POSIX.1-2001 declares it obsolete, suggesting *nanosleep*(2) instead. Removed in POSIX.1-2008.

On the original BSD implementation, and before glibc 2.2.2, the return type of this function is *void*. The POSIX version returns *int*, and this is also the prototype used since glibc 2.2.2.

Only the **EINVAL** error return is documented by SUSv2 and POSIX.1-2001.

CAVEATS

The interaction of this function with the **SIGALRM** signal, and with other timer functions such as *alarm*(2), *sleep*(3), *nanosleep*(2), *setitimer*(2), *timer_create*(2), *timer_delete*(2), *timer_getoverrun*(2), *timer_gettime*(2), *timer_settime*(2), *ualarm*(3) is unspecified.

NAME

wcpcpy − copy a wide-character string, returning a pointer to its end

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

wchar_t *wcpcpy(wchar_t *restrict *dest***, const wchar_t *restrict** *src***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

wcpcpy():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_GNU_SOURCE

DESCRIPTION

The **wcpcpy**() function is the wide-character equivalent of the *stpcpy*(3) function. It copies the wide-character string pointed to by *src*, including the terminating null wide character (L'\0'), to the array pointed to by *dest*.

The strings may not overlap.

The programmer must ensure that there is room for at least *wcslen(src)+1* wide characters at *dest*.

RETURN VALUE

wcpcpy() returns a pointer to the end of the wide-character string *dest*, that is, a pointer to the terminating null wide character.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wcpcpy()	Thread safety	MT-Safe

STANDARDS

POSIX.1-2008.

SEE ALSO

strcpy(3), *wcscpy*(3)

NAME

wcpncpy − copy a fixed-size string of wide characters, returning a pointer to its end

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wchar.h>

wchar_t *wcpncpy(wchar_t dest[restrict .n],
                 const wchar_t src[restrict .n],
                 size_t n);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

wcpncpy():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_GNU_SOURCE

DESCRIPTION

The **wcpncpy**() function is the wide-character equivalent of the *stpncpy*(3) function. It copies at most *n* wide characters from the wide-character string pointed to by *src*, including the terminating null wide (L'\0'), to the array pointed to by *dest*. Exactly *n* wide characters are written at *dest*. If the length *wcslen(src)* is smaller than *n*, the remaining wide characters in the array pointed to by *dest* are filled with L'\0' characters. If the length *wcslen(src)* is greater than or equal to *n*, the string pointed to by *dest* will not be L'\0' terminated.

The strings may not overlap.

The programmer must ensure that there is room for at least *n* wide characters at *dest*.

RETURN VALUE

wcpncpy() returns a pointer to the last wide character written, that is, *dest*+*n*−1.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wcpncpy()	Thread safety	MT-Safe

STANDARDS

POSIX.1-2008.

SEE ALSO

stpncpy(3), *wcsncpy*(3)

NAME

wcrtomb − convert a wide character to a multibyte sequence

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

size_t wcrtomb(char *restrict *s***, wchar_t** *wc***, mbstate_t *restrict** *ps***);**

DESCRIPTION

The main case for this function is when *s* is not NULL and *wc* is not a null wide character (L'\0'). In this case, the **wcrtomb**() function converts the wide character *wc* to its multibyte representation and stores it at the beginning of the character array pointed to by *s*. It updates the shift state **ps*, and returns the length of said multibyte representation, that is, the number of bytes written at *s*.

A different case is when *s* is not NULL, but *wc* is a null wide character (L'\0'). In this case, the **wcrtomb**() function stores at the character array pointed to by *s* the shift sequence needed to bring **ps* back to the initial state, followed by a '\0' byte. It updates the shift state **ps* (i.e., brings it into the initial state), and returns the length of the shift sequence plus one, that is, the number of bytes written at *s*.

A third case is when *s* is NULL. In this case, *wc* is ignored, and the function effectively returns

```
wcrtomb(buf, L'\0', ps)
```

where *buf* is an internal anonymous buffer.

In all of the above cases, if *ps* is NULL, a static anonymous state known only to the **wcrtomb**() function is used instead.

RETURN VALUE

The **wcrtomb**() function returns the number of bytes that have been or would have been written to the byte array at *s*. If *wc* can not be represented as a multibyte sequence (according to the current locale), *(size_t) −1* is returned, and *errno* set to **EILSEQ**.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wcrtomb()	Thread safety	MT-Unsafe race:wcrtomb/!ps

STANDARDS

C11, POSIX.1-2008.

HISTORY

POSIX.1-2001, C99.

NOTES

The behavior of **wcrtomb**() depends on the **LC_CTYPE** category of the current locale.

Passing NULL as *ps* is not multithread safe.

NAME

wcscasecmp − compare two wide-character strings, ignoring case

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wchar.h>

int wcscasecmp(const wchar_t *s1, const wchar_t *s2);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

wcscasecmp():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_GNU_SOURCE

DESCRIPTION

The **wcscasecmp**() function is the wide-character equivalent of the *strcasecmp*(3) function. It compares the wide-character string pointed to by *s1* and the wide-character string pointed to by *s2*, ignoring case differences (**towupper**(3), *towlower*(3)).

RETURN VALUE

The **wcscasecmp**() function returns zero if the wide-character strings at *s1* and *s2* are equal except for case distinctions. It returns a positive integer if *s1* is greater than *s2*, ignoring case. It returns a negative integer if *s1* is smaller than *s2*, ignoring case.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

NAME

wcscspn − search a wide-character string for any of a set of wide characters

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

size_t wcscspn(const wchar_t **wcs*, const wchar_t **reject*);

DESCRIPTION

The **wcscspn**() function is the wide-character equivalent of the *strcspn*(3) function. It determines the length of the longest initial segment of *wcs* which consists entirely of wide-characters not listed in *reject*. In other words, it searches for the first occurrence in the wide-character string *wcs* of any of the characters in the wide-character string *reject*.

RETURN VALUE

The **wcscspn**() function returns the number of wide characters in the longest initial segment of *wcs* which consists entirely of wide-characters not listed in *reject*. In other words, it returns the position of the first occurrence in the wide-character string *wcs* of any of the characters in the wide-character string *reject*, or *wcslen(wcs)* if there is none.

NAME

wcsdup − duplicate a wide-character string

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

wchar_t *wcsdup(const wchar_t *s);

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

wcsdup():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_GNU_SOURCE

DESCRIPTION

The **wcsdup**() function is the wide-character equivalent of the *strdup*(3) function. It allocates and returns a new wide-character string whose initial contents is a duplicate of the wide-character string pointed to by *s*.

Memory for the new wide-character string is obtained with *malloc*(3), and should be freed with *free*(3).

RETURN VALUE

On success, **wcsdup**() returns a pointer to the new wide-character string. On error, it returns NULL, with *errno* set to indicate the error.

ERRORS

ENOMEM
Insufficient memory available to allocate duplicate string.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

NAME

wcsncmp − compare two fixed-size wide-character strings

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

int wcsncmp(const wchar_t *s1***[.***n***], const wchar_t** *s2***[.***n***], size_t** *n***);**

DESCRIPTION

The **wcsncmp**() function is the wide-character equivalent of the *strncmp*(3) function. It compares the wide-character string pointed to by *s1* and the wide-character string pointed to by *s2*, but at most *n* wide characters from each string. In each string, the comparison extends only up to the first occurrence of a null wide character (L'\0'), if any.

RETURN VALUE

The **wcsncmp**() function returns zero if the wide-character strings at *s1* and *s2*, truncated to at most length *n*, are equal. It returns an integer greater than zero if at the first differing position *i* (*i* < *n*), the corresponding wide-character *s1[i]* is greater than *s2[i]*. It returns an integer less than zero if at the first differing position *i* (*i* < *n*), the corresponding wide-character *s1[i]* is less than *s2[i]*.

ATTRIBUTES

NAME

wcsncpy − copy a fixed-size string of wide characters

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wchar.h>

wchar_t *wcsncpy(wchar_t dest[restrict .n],
                 const wchar_t src[restrict .n],
                 size_t n);
```

DESCRIPTION

The **wcsncpy**() function is the wide-character equivalent of the *strncpy*(3) function. It copies at most *n* wide characters from the wide-character string pointed to by *src*, including the terminating null wide character (L'\0'), to the array pointed to by *dest*. Exactly *n* wide characters are written at *dest*. If the length *wcslen(src)* is smaller than *n*, the remaining wide characters in the array pointed to by *dest* are filled with null wide characters. If the length *wcslen(src)* is greater than or equal to *n*, the string pointed to by *dest* will not be terminated by a null wide character.

The strings may not overlap.

The programmer must ensure that there is room for at least *n* wide characters at *dest*.

RETURN VALUE

wcsncpy() returns *dest*.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

NAME

wcsnlen − determine the length of a fixed-size wide-character string

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

size_t wcsnlen(const wchar_t *s***[.***maxlen***], size_t** *maxlen***);**

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

wcsnlen():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_GNU_SOURCE

DESCRIPTION

The **wcsnlen**() function is the wide-character equivalent of the *strnlen*(3) function. It returns the number of wide-characters in the string pointed to by *s*, not including the terminating null wide character (L'\0'), but at most *maxlen* wide characters (note: this parameter is not a byte count). In doing this, **wcsnlen**() looks at only the first *maxlen* wide characters at *s* and never beyond *s[maxlen−1]*.

RETURN VALUE

The **wcsnlen**() function returns *wcslen(s)*, if that is less than *maxlen*, or *maxlen* if there is no null wide character among the first *maxlen* wide characters pointed to by *s*.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

NAME

wcsnrtombs − convert a wide-character string to a multibyte string

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wchar.h>

size_t wcsnrtombs(char dest[restrict .len], const wchar_t **restrict src,
                  size_t nwc, size_t len, mbstate_t *restrict ps);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

wcsnrtombs():
Since glibc 2.10:
_POSIX_C_SOURCE >= 200809L
Before glibc 2.10:
_GNU_SOURCE

DESCRIPTION

The **wcsnrtombs**() function is like the *wcsrtombs*(3) function, except that the number of wide characters to be converted, starting at **src*, is limited to *nwc*.

If *dest* is not NULL, the **wcsnrtombs**() function converts at most *nwc* wide characters from the wide-character string **src* to a multibyte string starting at *dest*. At most *len* bytes are written to *dest*. The shift state **ps* is updated. The conversion is effectively performed by repeatedly calling *wcrtomb(dest, *src, ps)*, as long as this call succeeds, and then incrementing *dest* by the number of bytes written and **src* by one. The conversion can stop for three reasons:

- A wide character has been encountered that can not be represented as a multibyte sequence (according to the current locale). In this case, **src* is left pointing to the invalid wide character, *(size_t) −1* is returned, and *errno* is set to **EILSEQ**.
- *nwc* wide characters have been converted without encountering a null wide character (L'\0'), or the length limit forces a stop. In this case, **src* is left pointing to the next wide character to be converted, and the number of bytes written to *dest* is returned.
- The wide-character string has been completely converted, including the terminating null wide character (which has the side effect of bringing back **ps* to the initial state). In this case, **src* is set to NULL, and the number of bytes written to *dest*, excluding the terminating null byte ('\0'), is returned.

If *dest* is NULL, *len* is ignored, and the conversion proceeds as above, except that the converted bytes are not written out to memory, and that no destination length limit exists.

In both of the above cases, if *ps* is NULL, a static anonymous state known only to the **wcsnrtombs**() function is used instead.

The programmer must ensure that there is room for at least *len* bytes at *dest*.

RETURN VALUE

The **wcsnrtombs**() function returns the number of bytes that make up the converted part of multibyte sequence, not including the terminating null byte. If a wide character was encountered which could not be converted, *(size_t) −1* is returned, and *errno* set to **EILSEQ**.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wcsnrtombs()	Thread safety	MT-Unsafe race:wcsnrtombs/!ps

STANDARDS

POSIX.1-2008.

NOTES

The behavior of **wcsnrtombs**() depends on the **LC_CTYPE** category of the current locale.

Passing NULL as *ps* is not multithread safe.

NAME

wcspbrk − search a wide-character string for any of a set of wide characters

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

wchar_t *wcspbrk(const wchar_t *_wcs_, const wchar_t *_accept_);

DESCRIPTION

The **wcspbrk**() function is the wide-character equivalent of the *strpbrk*(3) function. It searches for the first occurrence in the wide-character string pointed to by *wcs* of any of the characters in the wide-character string pointed to by *accept*.

RETURN VALUE

The **wcspbrk**() function returns a pointer to the first occurrence in *wcs* of any of the characters listed in *accept*. If *wcs* contains none of these characters, NULL is returned.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

wcsrtombs − convert a wide-character string to a multibyte string

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wchar.h>

size_t wcsrtombs(char dest[restrict .len], const wchar_t **restrict src,
                 size_t len, mbstate_t *restrict ps);
```

DESCRIPTION

If *dest* is not NULL, the **wcsrtombs**() function converts the wide-character string **src* to a multibyte string starting at *dest*. At most *len* bytes are written to *dest*. The shift state **ps* is updated. The conversion is effectively performed by repeatedly calling *wcrtomb(dest, *src, ps)*, as long as this call succeeds, and then incrementing *dest* by the number of bytes written and **src* by one. The conversion can stop for three reasons:

- A wide character has been encountered that can not be represented as a multibyte sequence (according to the current locale). In this case, **src* is left pointing to the invalid wide character, *(size_t) −1* is returned, and *errno* is set to **EILSEQ**.
- The length limit forces a stop. In this case, **src* is left pointing to the next wide character to be converted, and the number of bytes written to *dest* is returned.
- The wide-character string has been completely converted, including the terminating null wide character (L'\0'), which has the side effect of bringing back **ps* to the initial state. In this case, **src* is set to NULL, and the number of bytes written to *dest*, excluding the terminating null byte ('\0'), is returned.

If *dest* is NULL, *len* is ignored, and the conversion proceeds as above, except that the converted bytes are not written out to memory, and that no length limit exists.

In both of the above cases, if *ps* is NULL, a static anonymous state known only to the **wcsrtombs**() function is used instead.

The programmer must ensure that there is room for at least *len* bytes at *dest*.

RETURN VALUE

The **wcsrtombs**() function returns the number of bytes that make up the converted part of multibyte sequence, not including the terminating null byte. If a wide character was encountered which could not be converted, *(size_t) −1* is returned, and *errno* set to **EILSEQ**.

NAME

wcsspn − get length of a prefix wide-character substring

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

size_t wcsspn(const wchar_t **wcs*, const wchar_t **accept*);

DESCRIPTION

The **wcsspn**() function is the wide-character equivalent of the *strspn*(3) function. It determines the length of the longest initial segment of *wcs* which consists entirely of wide-characters listed in *accept*. In other words, it searches for the first occurrence in the wide-character string *wcs* of a wide-character not contained in the wide-character string *accept*.

RETURN VALUE

The **wcsspn**() function returns the number of wide characters in the longest initial segment of *wcs* which consists entirely of wide-characters listed in *accept*. In other words, it returns the position of the first occurrence in the wide-character string *wcs* of a wide-character not contained in the wide-character string *accept*, or *wcslen(wcs)* if there is none.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

NAME

wcsstr − locate a substring in a wide-character string

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

wchar_t *wcsstr(const wchar_t ****haystack*, const wchar_t ****needle***);**

DESCRIPTION

The **wcsstr**() function is the wide-character equivalent of the *strstr*(3) function. It searches for the first occurrence of the wide-character string *needle* (without its terminating null wide character (L'\0')) as a substring in the wide-character string *haystack*.

RETURN VALUE

The **wcsstr**() function returns a pointer to the first occurrence of *needle* in *haystack*. It returns NULL if *needle* does not occur as a substring in *haystack*.

Note the special case: If *needle* is the empty wide-character string, the return value is always *haystack* itself.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

NAME

wcstok − split wide-character string into tokens

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wchar.h>

wchar_t *wcstok(wchar_t *restrict wcs, const wchar_t *restrict delim,
                wchar_t **restrict ptr);
```

DESCRIPTION

The **wcstok**() function is the wide-character equivalent of the *strtok*(3) function, with an added argument to make it multithread-safe. It can be used to split a wide-character string *wcs* into tokens, where a token is defined as a substring not containing any wide-characters from *delim*.

The search starts at *wcs*, if *wcs* is not NULL, or at **ptr*, if *wcs* is NULL. First, any delimiter wide-characters are skipped, that is, the pointer is advanced beyond any wide-characters which occur in *delim*. If the end of the wide-character string is now reached, **wcstok**() returns NULL, to indicate that no tokens were found, and stores an appropriate value in **ptr*, so that subsequent calls to **wcstok**() will continue to return NULL. Otherwise, the **wcstok**() function recognizes the beginning of a token and returns a pointer to it, but before doing that, it zero-terminates the token by replacing the next wide-character which occurs in *delim* with a null wide character (L'\0'), and it updates **ptr* so that subsequent calls will continue searching after the end of recognized token.

RETURN VALUE

The **wcstok**() function returns a pointer to the next token, or NULL if no further token was found.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wcstok()	Thread safety	MT-Safe

STANDARDS

C11, POSIX.1-2008.

HISTORY

POSIX.1-2001, C99.

NOTES

The original *wcs* wide-character string is destructively modified during the operation.

EXAMPLES

The following code loops over the tokens contained in a wide-character string.

```
wchar_t *wcs = ...;
wchar_t *token;
wchar_t *state;
for (token = wcstok(wcs, L" \t\n", &state);
    token != NULL;
    token = wcstok(NULL, L" \t\n", &state)) {
    ...
}
```

SEE ALSO

strtok(3), *wcschr*(3)

NAME

wcstombs − convert a wide-character string to a multibyte string

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <stdlib.h>

size_t wcstombs(char dest[restrict .n], const wchar_t *restrict src,
                size_t n);
```

DESCRIPTION

If *dest* is not NULL, the **wcstombs**() function converts the wide-character string *src* to a multibyte string starting at *dest*. At most *n* bytes are written to *dest*. The sequence of characters placed in *dest* begins in the initial shift state. The conversion can stop for three reasons:

- A wide character has been encountered that can not be represented as a multibyte sequence (according to the current locale). In this case, *(size_t) −1* is returned.
- The length limit forces a stop. In this case, the number of bytes written to *dest* is returned, but the shift state at this point is lost.
- The wide-character string has been completely converted, including the terminating null wide character (L'\0'). In this case, the conversion ends in the initial shift state. The number of bytes written to *dest*, excluding the terminating null byte ('\0'), is returned.

The programmer must ensure that there is room for at least *n* bytes at *dest*.

If *dest* is NULL, *n* is ignored, and the conversion proceeds as above, except that the converted bytes are not written out to memory, and no length limit exists.

In order to avoid the case 2 above, the programmer should make sure *n* is greater than or equal to *wcstombs(NULL,src,0)+1*.

RETURN VALUE

The **wcstombs**() function returns the number of bytes that make up the converted part of a multibyte sequence, not including the terminating null byte. If a wide character was encountered which could not be converted, *(size_t) −1* is returned.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wcstombs()	Thread safety	MT-Safe

VERSIONS

The function *wcsrtombs*(3) provides a better interface to the same functionality.

STANDARDS

C11, POSIX.1-2008.

HISTORY

POSIX.1-2001, C99.

NOTES

The behavior of **wcstombs**() depends on the **LC_CTYPE** category of the current locale.

NAME

wctob − try to represent a wide character as a single byte

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

int wctob(wint_t *c***);**

DESCRIPTION

The **wctob**() function tests whether the multibyte representation of the wide character *c*, starting in the initial state, consists of a single byte. If so, it is returned as an *unsigned char*.

Never use this function. It cannot help you in writing internationalized programs. Internationalized programs must never distinguish single-byte and multibyte characters.

RETURN VALUE

The **wctob**() function returns the single-byte representation of *c*, if it exists, or **EOF** otherwise.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wctob()	Thread safety	MT-Safe

STANDARDS

C11, POSIX.1-2008.

HISTORY

POSIX.1-2001, C99.

NOTES

The behavior of **wctob**() depends on the **LC_CTYPE** category of the current locale.

This function should never be used. Internationalized programs must never distinguish single-byte and multibyte characters. Use either *wctomb*(3) or the thread-safe *wcrtomb*(3) instead.

SEE ALSO

btowc(3), *wcrtomb*(3), *wctomb*(3)

NAME

wctomb − convert a wide character to a multibyte sequence

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <stdlib.h>

int wctomb(char ****s*, wchar_t** *wc***);**

DESCRIPTION

If *s* is not NULL, the **wctomb**() function converts the wide character *wc* to its multibyte representation and stores it at the beginning of the character array pointed to by *s*. It updates the shift state, which is stored in a static anonymous variable known only to the **wctomb**() function, and returns the length of said multibyte representation, that is, the number of bytes written at *s*.

The programmer must ensure that there is room for at least **MB_CUR_MAX** bytes at *s*.

If *s* is NULL, the **wctomb**() function resets the shift state, known only to this function, to the initial state, and returns nonzero if the encoding has nontrivial shift state, or zero if the encoding is stateless.

RETURN VALUE

If *s* is not NULL, the **wctomb**() function returns the number of bytes that have been written to the byte array at *s*. If *wc* can not be represented as a multibyte sequence (according to the current locale), −1 is returned.

If *s* is NULL, the **wctomb**() function returns nonzero if the encoding has nontrivial shift state, or zero if the encoding is stateless.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wctomb()	Thread safety	MT-Unsafe race

VERSIONS

The function *wcrtomb*(3) provides a better interface to the same functionality.

NAME

wctrans − wide-character translation mapping

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wctype.h>

wctrans_t wctrans(const char *_name_);

DESCRIPTION

The *wctrans_t* type represents a mapping which can map a wide character to another wide character. Its nature is implementation-dependent, but the special value *(wctrans_t) 0* denotes an invalid mapping. Nonzero *wctrans_t* values can be passed to the *towctrans*(3) function to actually perform the wide-character mapping.

The **wctrans**() function returns a mapping, given by its name. The set of valid names depends on the **LC_CTYPE** category of the current locale, but the following names are valid in all locales.

"tolower" − realizes the **tolower**(3) mapping
"toupper" − realizes the **toupper**(3) mapping

RETURN VALUE

The **wctrans**() function returns a mapping descriptor if the *name* is valid. Otherwise, it returns *(wctrans_t) 0*.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value

NAME

wctype − wide-character classification

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wctype.h>

wctype_t wctype(const char *****name***);**

DESCRIPTION

The *wctype_t* type represents a property which a wide character may or may not have. In other words, it represents a class of wide characters. This type's nature is implementation-dependent, but the special value *(wctype_t) 0* denotes an invalid property. Nonzero *wctype_t* values can be passed to the *iswctype*(3) function to actually test whether a given wide character has the property.

The **wctype**() function returns a property, given by its name. The set of valid names depends on the **LC_CTYPE** category of the current locale, but the following names are valid in all locales.

"alnum" − realizes the **isalnum**(3) classification function
"alpha" − realizes the **isalpha**(3) classification function
"blank" − realizes the **isblank**(3) classification function
"cntrl" − realizes the **iscntrl**(3) classification function
"digit" − realizes the **isdigit**(3) classification function
"graph" − realizes the **isgraph**(3) classification function
"lower" − realizes the **islower**(3) classification function
"print" − realizes the **isprint**(3) classification function
"punct" − realizes the **ispunct**(3) classification function
"space" − realizes the **isspace**(3) classification function
"upper" − realizes the **isupper**(3) classification function
"xdigit" − realizes the **isxdigit**(3) classification function

RETURN VALUE

The **wctype**() function returns a property descriptor if the *name* is valid. Otherwise, it returns *(wctype_t) 0*.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value

NAME

wmemcmp − compare two arrays of wide-characters

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <wchar.h>

int wmemcmp(const wchar_t *s1***[.***n***], const wchar_t** *s2***[.***n***], size_t** *n***);**

DESCRIPTION

The **wmemcmp**() function is the wide-character equivalent of the *memcmp*(3) function. It compares the *n* wide-characters starting at *s1* and the *n* wide-characters starting at *s2*.

RETURN VALUE

The **wmemcmp**() function returns zero if the wide-character arrays of size *n* at *s1* and *s2* are equal. It returns an integer greater than zero if at the first differing position *i* ($i < n$), the corresponding wide-character *s1[i]* is greater than *s2[i]*. It returns an integer less than zero if at the first differing position *i* ($i < n$), the corresponding wide-character *s1[i]* is less than *s2[i]*.

NAME

wmemcpy − copy an array of wide-characters

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wchar.h>

wchar_t *wmemcpy(wchar_t dest[restrict .n],
                 const wchar_t src[restrict .n],
                 size_t n);
```

DESCRIPTION

The **wmemcpy**() function is the wide-character equivalent of the *memcpy*(3) function. It copies *n* wide characters from the array starting at *src* to the array starting at *dest*.

The arrays may not overlap; use *wmemmove*(3) to copy between overlapping arrays.

The programmer must ensure that there is room for at least *n* wide characters at *dest*.

RETURN VALUE

wmemcpy() returns *dest*.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

NAME

wordexp, wordfree − perform word expansion like a posix-shell

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <wordexp.h>

int wordexp(const char *restrict s, wordexp_t *restrict p, int flags);
void wordfree(wordexp_t *p);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

wordexp(), **wordfree**():
_XOPEN_SOURCE

DESCRIPTION

The function **wordexp**() performs a shell-like expansion of the string *s* and returns the result in the structure pointed to by *p*. The data type *wordexp_t* is a structure that at least has the fields *we_wordc*, *we_wordv*, and *we_offs*. The field *we_wordc* is a *size_t* that gives the number of words in the expansion of *s*. The field *we_wordv* is a *char* ** that points to the array of words found. The field *we_offs* of type *size_t* is sometimes (depending on *flags*, see below) used to indicate the number of initial elements in the *we_wordv* array that should be filled with NULLs.

The function **wordfree**() frees the allocated memory again. More precisely, it does not free its argument, but it frees the array *we_wordv* and the strings that points to.

The string argument

Since the expansion is the same as the expansion by the shell (see *sh*(1)) of the parameters to a command, the string *s* must not contain characters that would be illegal in shell command parameters. In particular, there must not be any unescaped newline or |, &, ;, <, >, (,), {, } characters outside a command substitution or parameter substitution context.

If the argument *s* contains a word that starts with an unquoted comment character #, then it is unspecified whether that word and all following words are ignored, or the # is treated as a non-comment character.

The expansion

The expansion done consists of the following stages: tilde expansion (replacing ~user by user's home directory), variable substitution (replacing $FOO by the value of the environment variable FOO), command substitution (replacing $(command) or `command` by the output of command), arithmetic expansion, field splitting, wildcard expansion, quote removal.

The result of expansion of special parameters ($@, $*, $#, $?, $−, $$, $!, $0) is unspecified.

Field splitting is done using the environment variable $IFS. If it is not set, the field separators are space, tab, and newline.

The output array

The array *we_wordv* contains the words found, followed by a NULL.

The flags argument

The *flag* argument is a bitwise inclusive OR of the following values:

WRDE_APPEND
Append the words found to the array resulting from a previous call.

WRDE_DOOFFS
Insert *we_offs* initial NULLs in the array *we_wordv*. (These are not counted in the returned *we_wordc*.)

WRDE_NOCMD
Don't do command substitution.

WRDE_REUSE
The argument *p* resulted from a previous call to **wordexp**(), and **wordfree**() was not called. Reuse the allocated storage.

WRDE_SHOWERR
Normally during command substitution *stderr* is redirected to */dev/null*. This flag specifies that *stderr* is not to be redirected.

WRDE_UNDEF
Consider it an error if an undefined shell variable is expanded.

RETURN VALUE

On success, **wordexp**() returns 0. On failure, **wordexp**() returns one of the following nonzero values:

WRDE_BADCHAR
Illegal occurrence of newline or one of |, &, ;, <, >, (,), {, }.

WRDE_BADVAL
An undefined shell variable was referenced, and the **WRDE_UNDEF** flag told us to consider this an error.

WRDE_CMDSUB
Command substitution requested, but the **WRDE_NOCMD** flag told us to consider this an error.

WRDE_NOSPACE
Out of memory.

WRDE_SYNTAX
Shell syntax error, such as unbalanced parentheses or unmatched quotes.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
wordexp()	Thread safety	MT-Unsafe race:utent const:env env sig:ALRM timer locale
wordfree()	Thread safety	MT-Safe

In the above table, *utent* in *race:utent* signifies that if any of the functions *setutent*(3), *getutent*(3), or *endutent*(3) are used in parallel in different threads of a program, then data races could occur. **wordexp**() calls those functions, so we use race:utent to remind users.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001. glibc 2.1.

EXAMPLES

The output of the following example program is approximately that of "ls [a-c]*.c".

```
#include <stdio.h>
#include <stdlib.h>
#include <wordexp.h>

int
main(void)
{
    wordexp_t p;
    char **w;

    wordexp("[a-c]*.c", &p, 0);
    w = p.we_wordv;
    for (size_t i = 0; i < p.we_wordc; i++)
        printf("%s\n", w[i]);
    wordfree(&p);
    exit(EXIT_SUCCESS);
}
```

NAME

wprintf, fwprintf, swprintf, vwprintf, vfwprintf, vswprintf − formatted wide-character output conversion

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

```
#include <stdio.h>
#include <wchar.h>

int wprintf(const wchar_t *restrict format, ...);
int fwprintf(FILE *restrict stream,
        const wchar_t *restrict format, ...);
int swprintf(wchar_t wcs[restrict .maxlen], size_t maxlen,
        const wchar_t *restrict format, ...);

int vwprintf(const wchar_t *restrict format, va_list args);
int vfwprintf(FILE *restrict stream,
        const wchar_t *restrict format, va_list args);
int vswprintf(wchar_t wcs[restrict .maxlen], size_t maxlen,
        const wchar_t *restrict format, va_list args);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

All functions shown above:
_XOPEN_SOURCE >= 500 || _ISOC99_SOURCE
|| _POSIX_C_SOURCE >= 200112L

DESCRIPTION

The **wprintf**() family of functions is the wide-character equivalent of the *printf*(3) family of functions. It performs formatted output of wide characters.

The **wprintf**() and **vwprintf**() functions perform wide-character output to *stdout*. *stdout* must not be byte oriented; see *fwide*(3) for more information.

The **fwprintf**() and **vfwprintf**() functions perform wide-character output to *stream*. *stream* must not be byte oriented; see *fwide*(3) for more information.

The **swprintf**() and **vswprintf**() functions perform wide-character output to an array of wide characters. The programmer must ensure that there is room for at least *maxlen* wide characters at *wcs*.

These functions are like the *printf*(3), *vprintf*(3), *fprintf*(3), *vfprintf*(3), *sprintf*(3), *vsprintf*(3) functions except for the following differences:

- The *format* string is a wide-character string.
- The output consists of wide characters, not bytes.
- **swprintf**() and **vswprintf**() take a *maxlen* argument, *sprintf*(3) and *vsprintf*(3) do not. (**snprintf**(3) and *vsnprintf*(3) take a *maxlen* argument, but these functions do not return −1 upon buffer overflow on Linux.)

The treatment of the conversion characters **c** and **s** is different:

c If no **l** modifier is present, the *int* argument is converted to a wide character by a call to the *btowc*(3) function, and the resulting wide character is written. If an **l** modifier is present, the *wint_t* (wide character) argument is written.

s If no **l** modifier is present: the *const char* * argument is expected to be a pointer to an array of character type (pointer to a string) containing a multibyte character sequence beginning in the initial shift state. Characters from the array are converted to wide characters (each by a call to the *mbrtowc*(3) function with a conversion state starting in the initial state before the first byte). The resulting wide characters are written up to (but not including) the terminating null wide character (L'\0'). If a precision is specified, no more wide characters than the number specified are written. Note that the precision determines the number of *wide characters* written, not the number of *bytes* or *screen positions*. The array must contain a terminating null byte ('\0'), unless a precision is given and it is so small that the number of converted wide characters reaches it before the end of the array is reached. If an **l** modifier is present: the

*const wchar_t ** argument is expected to be a pointer to an array of wide characters. Wide characters from the array are written up to (but not including) a terminating null wide character. If a precision is specified, no more than the number specified are written. The array must contain a terminating null wide character, unless a precision is given and it is smaller than or equal to the number of wide characters in the array.

RETURN VALUE

The functions return the number of wide characters written, excluding the terminating null wide character in case of the functions **swprintf**() and **vswprintf**(). They return −1 when an error occurs.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

STANDARDS

C11, POSIX.1-2008.

HISTORY

POSIX.1-2001, C99.

NOTES

The behavior of **wprintf**() et al. depends on the **LC_CTYPE** category of the current locale.

If the *format* string contains non-ASCII wide characters, the program will work correctly only if the **LC_CTYPE** category of the current locale at run time is the same as the **LC_CTYPE** category of the current locale at compile time. This is because the *wchar_t* representation is platform- and locale-dependent. (The glibc represents wide characters using their Unicode (ISO/IEC 10646) code point, but other platforms don't do this. Also, the use of C99 universal character names of the form \unnnn does not solve this problem.) Therefore, in internationalized programs, the *format* string should consist of ASCII wide characters only, or should be constructed at run time in an internationalized way (e.g., using *gettext*(3) or *iconv*(3), followed by *mbstowcs*(3)).

NAME

xencrypt, xdecrypt, passwd2des − RFS password encryption

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS

#include <rpc/des_crypt.h>

void passwd2des(char **passwd***, char ***_key_**);**

int xencrypt(char ***_secret_, char ***_passwd_**);**
int xdecrypt(char ***_secret_, char ***_passwd_**);**

DESCRIPTION

WARNING: Do not use these functions in new code. They do not achieve any type of acceptable cryptographic security guarantees.

The function **passwd2des**() takes a character string *passwd* of arbitrary length and fills a character array *key* of length 8. The array *key* is suitable for use as DES key. It has odd parity set in bit 0 of each byte. Both other functions described here use this function to turn their argument *passwd* into a DES key.

The **xencrypt**() function takes the ASCII character string *secret* given in hex, which must have a length that is a multiple of 16, encrypts it using the DES key derived from *passwd* by **passwd2des**(), and outputs the result again in *secret* as a hex string of the same length.

The **xdecrypt**() function performs the converse operation.

RETURN VALUE

The functions **xencrypt**() and **xdecrypt**() return 1 on success and 0 on error.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
passwd2des(), **xencrypt**(), **xdecrypt**()	Thread safety	MT-Safe

VERSIONS

These functions are available since glibc 2.1.

BUGS

The prototypes are missing from the abovementioned include file.

NAME

xdr − library routines for external data representation

LIBRARY

Standard C library (*libc*, *−lc*)

SYNOPSIS AND DESCRIPTION

These routines allow C programmers to describe arbitrary data structures in a machine-independent fashion. Data for remote procedure calls are transmitted using these routines.

The prototypes below are declared in <*rpc/xdr.h*> and make use of the following types:

```
typedef int bool_t;

typedef bool_t (*xdrproc_t)(XDR *, void *,...);
```

For the declaration of the *XDR* type, see <*rpc/xdr.h*>.

bool_t xdr_array(XDR ****xdrs*, char *****arrp***, unsigned int ****sizep***,**
unsigned int *maxsize***, unsigned int** *elsize***,**
xdrproc_t *elproc***);**

A filter primitive that translates between variable-length arrays and their corresponding external representations. The argument *arrp* is the address of the pointer to the array, while *sizep* is the address of the element count of the array; this element count cannot exceed *maxsize*. The argument *elsize* is the *sizeof* each of the array's elements, and *elproc* is an XDR filter that translates between the array elements' C form, and their external representation. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_bool(XDR ****xdrs*, bool_t ****bp***);**

A filter primitive that translates between booleans (C integers) and their external representations. When encoding data, this filter produces values of either one or zero. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_bytes(XDR ****xdrs*, char *****sp***, unsigned int ****sizep***,**
unsigned int *maxsize***);**

A filter primitive that translates between counted byte strings and their external representations. The argument *sp* is the address of the string pointer. The length of the string is located at address *sizep*; strings cannot be longer than *maxsize*. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_char(XDR ****xdrs*, char ****cp***);**

A filter primitive that translates between C characters and their external representations. This routine returns one if it succeeds, zero otherwise. Note: encoded characters are not packed, and occupy 4 bytes each. For arrays of characters, it is worthwhile to consider **xdr_bytes**(), **xdr_opaque**(), or **xdr_string**().

void xdr_destroy(XDR ****xdrs*);**

A macro that invokes the destroy routine associated with the XDR stream, *xdrs*. Destruction usually involves freeing private data structures associated with the stream. Using *xdrs* after invoking **xdr_destroy**() is undefined.

bool_t xdr_double(XDR ****xdrs*, double ****dp***);**

A filter primitive that translates between C *double* precision numbers and their external representations. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_enum(XDR ****xdrs*, enum_t ****ep***);**

A filter primitive that translates between C *enum*s (actually integers) and their external representations. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_float(XDR ****xdrs*, float *** *fp***);**

A filter primitive that translates between C *float*s and their external representations. This routine returns one if it succeeds, zero otherwise.

void xdr_free(xdrproc_t *proc***, char ****objp***);**

Generic freeing routine. The first argument is the XDR routine for the object being freed. The second argument is a pointer to the object itself. Note: the pointer passed to this routine is *not* freed, but what it points to *is* freed (recursively).

unsigned int xdr_getpos(XDR *****xdrs*);**

A macro that invokes the get-position routine associated with the XDR stream, *xdrs*. The routine returns an unsigned integer, which indicates the position of the XDR byte stream. A desirable feature of XDR streams is that simple arithmetic works with this number, although the XDR stream instances need not guarantee this.

long *xdr_inline(XDR *****xdrs*, int** *len***);**

A macro that invokes the inline routine associated with the XDR stream, *xdrs*. The routine returns a pointer to a contiguous piece of the stream's buffer; *len* is the byte length of the desired buffer. Note: pointer is cast to *long **.

Warning: **xdr_inline**() may return NULL (0) if it cannot allocate a contiguous piece of a buffer. Therefore the behavior may vary among stream instances; it exists for the sake of efficiency.

bool_t xdr_int(XDR *****xdrs*, int *****ip***);**

A filter primitive that translates between C integers and their external representations. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_long(XDR *****xdrs*, long *****lp***);**

A filter primitive that translates between C *long* integers and their external representations. This routine returns one if it succeeds, zero otherwise.

void xdrmem_create(XDR *****xdrs*, char *****addr***, unsigned int** *size***,**
enum xdr_op *op***);**

This routine initializes the XDR stream object pointed to by *xdrs*. The stream's data is written to, or read from, a chunk of memory at location *addr* whose length is no more than *size* bytes long. The *op* determines the direction of the XDR stream (either **XDR_ENCODE**, **XDR_DECODE**, or **XDR_FREE**).

bool_t xdr_opaque(XDR *****xdrs*, char *****cp***, unsigned int** *cnt***);**

A filter primitive that translates between fixed size opaque data and its external representation. The argument *cp* is the address of the opaque object, and *cnt* is its size in bytes. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_pointer(XDR *****xdrs*, char ******objpp***,**
unsigned int *objsize***, xdrproc_t** *xdrobj***);**

Like **xdr_reference**() except that it serializes null pointers, whereas **xdr_reference**() does not. Thus, **xdr_pointer**() can represent recursive data structures, such as binary trees or linked lists.

void xdrrec_create(XDR *****xdrs*, unsigned int** *sendsize***,**
unsigned int *recvsize***, char *****handle***,**
int (***readit***)(char *, char *, int),**
int (***writeit***)(char *, char *, int));**

This routine initializes the XDR stream object pointed to by *xdrs*. The stream's data is written to a buffer of size *sendsize*; a value of zero indicates the system should use a suitable default. The stream's data is read from a buffer of size *recvsize*; it too can be set to a suitable default by passing a zero value. When a stream's output buffer is full, *writeit* is called. Similarly, when a stream's input buffer is empty, *readit* is called. The behavior of these two routines is similar to the system calls *read*(2) and *write*(2), except that *handle* is passed to the former routines as the first argument. Note: the XDR stream's *op* field must be set by the caller.

Warning: to read from an XDR stream created by this API, you'll need to call **xdrrec_skiprecord**() first before calling any other XDR APIs. This inserts additional bytes in the stream to provide record boundary information. Also, XDR streams created with different **xdr*_create** APIs are not compatible for the same reason.

bool_t xdrrec_endofrecord(XDR ****xdrs*, int** *sendnow***);**

This routine can be invoked only on streams created by **xdrrec_create**(). The data in the output buffer is marked as a completed record, and the output buffer is optionally written out if *sendnow* is nonzero. This routine returns one if it succeeds, zero otherwise.

bool_t xdrrec_eof(XDR ****xdrs*);**

This routine can be invoked only on streams created by **xdrrec_create**(). After consuming the rest of the current record in the stream, this routine returns one if the stream has no more input, zero otherwise.

bool_t xdrrec_skiprecord(XDR ****xdrs*);**

This routine can be invoked only on streams created by **xdrrec_create**(). It tells the XDR implementation that the rest of the current record in the stream's input buffer should be discarded. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_reference(XDR ****xdrs*, char *****pp***, unsigned int** *size***,**
xdrproc_t *proc***);**

A primitive that provides pointer chasing within structures. The argument *pp* is the address of the pointer; *size* is the *sizeof* the structure that **pp* points to; and *proc* is an XDR procedure that filters the structure between its C form and its external representation. This routine returns one if it succeeds, zero otherwise.

Warning: this routine does not understand null pointers. Use **xdr_pointer**() instead.

xdr_setpos(XDR ****xdrs*, unsigned int** *pos***);**

A macro that invokes the set position routine associated with the XDR stream *xdrs*. The argument *pos* is a position value obtained from **xdr_getpos**(). This routine returns one if the XDR stream could be repositioned, and zero otherwise.

Warning: it is difficult to reposition some types of XDR streams, so this routine may fail with one type of stream and succeed with another.

bool_t xdr_short(XDR ****xdrs*, short ****sp***);**

A filter primitive that translates between C *short* integers and their external representations. This routine returns one if it succeeds, zero otherwise.

void xdrstdio_create(XDR ****xdrs*, FILE ****file***, enum xdr_op** *op***);**

This routine initializes the XDR stream object pointed to by *xdrs*. The XDR stream data is written to, or read from, the *stdio* stream *file*. The argument *op* determines the direction of the XDR stream (either **XDR_ENCODE**, **XDR_DECODE**, or **XDR_FREE**).

Warning: the destroy routine associated with such XDR streams calls *fflush*(3) on the *file* stream, but never *fclose*(3).

bool_t xdr_string(XDR ****xdrs*, char *****sp***, unsigned int** *maxsize***);**

A filter primitive that translates between C strings and their corresponding external representations. Strings cannot be longer than *maxsize*. Note: *sp* is the address of the string's pointer. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_u_char(XDR ****xdrs*, unsigned char ****ucp***);**

A filter primitive that translates between *unsigned* C characters and their external representations. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_u_int(XDR ****xdrs*, unsigned int ****up***);**

A filter primitive that translates between C *unsigned* integers and their external representations. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_u_long(XDR ****xdrs*, unsigned long ****ulp***);**

A filter primitive that translates between C *unsigned long* integers and their external representations. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_u_short(XDR ****xdrs*, unsigned short ****usp***);**

A filter primitive that translates between C *unsigned short* integers and their external representations. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_union(XDR ****xdrs*, enum_t ****dscmp***, char ****unp***,**
const struct xdr_discrim ****choices*,**
xdrproc_t *defaultarm***); /* may equal NULL */**

A filter primitive that translates between a discriminated C *union* and its corresponding external representation. It first translates the discriminant of the union located at *dscmp*. This discriminant is always an *enum_t*. Next the union located at *unp* is translated. The argument *choices* is a pointer to an array of **xdr_discrim**() structures. Each structure contains an ordered pair of [*value*,*proc*]. If the union's discriminant is equal to the associated *value*, then the *proc* is called to translate the union. The end of the **xdr_discrim**() structure array is denoted by a routine of value NULL. If the discriminant is not found in the *choices* array, then the *defaultarm* procedure is called (if it is not NULL). Returns one if it succeeds, zero otherwise.

bool_t xdr_vector(XDR ****xdrs*, char ****arrp***, unsigned int** *size***,**
unsigned int *elsize***, xdrproc_t** *elproc***);**

A filter primitive that translates between fixed-length arrays and their corresponding external representations. The argument *arrp* is the address of the pointer to the array, while *size* is the element count of the array. The argument *elsize* is the *sizeof* each of the array's elements, and *elproc* is an XDR filter that translates between the array elements' C form, and their external representation. This routine returns one if it succeeds, zero otherwise.

bool_t xdr_void(void);

This routine always returns one. It may be passed to RPC routines that require a function argument, where nothing is to be done.

bool_t xdr_wrapstring(XDR ****xdrs*, char *****sp***);**

A primitive that calls **xdr_string(xdrs, sp,MAXUN.UNSIGNED);** where **MAXUN.UNSIGNED** is the maximum value of an unsigned integer. **xdr_wrapstring**() is handy because the RPC package passes a maximum of two XDR routines as arguments, and **xdr_string**(), one of the most frequently used primitives, requires three. Returns one if it succeeds, zero otherwise.

NAME

y0, y0f, y0l, y1, y1f, y1l, yn, ynf, ynl − Bessel functions of the second kind

LIBRARY

Math library (*libm*, −*lm*)

SYNOPSIS

```
#include <math.h>

double y0(double x);
double y1(double x);
double yn(int n, double x);

float y0f(float x);
float y1f(float x);
float ynf(int n, float x);

long double y0l(long double x);
long double y1l(long double x);
long double ynl(int n, long double x);
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

y0(), **y1**(), **yn**():
_XOPEN_SOURCE
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _SVID_SOURCE || _BSD_SOURCE

y0f(), **y0l**(), **y1f**(), **y1l**(), **ynf**(), **ynl**():
_XOPEN_SOURCE >= 600
|| (_ISOC99_SOURCE && _XOPEN_SOURCE)
|| /* Since glibc 2.19: */ _DEFAULT_SOURCE
|| /* glibc <= 2.19: */ _SVID_SOURCE || _BSD_SOURCE

DESCRIPTION

The **y0**() and **y1**() functions return Bessel functions of *x* of the second kind of orders 0 and 1, respectively. The **yn**() function returns the Bessel function of *x* of the second kind of order *n*.

The value of *x* must be positive.

The **y0f**(), **y1f**(), and **ynf**() functions are versions that take and return *float* values. The **y0l**(), **y1l**(), and **ynl**() functions are versions that take and return *long double* values.

RETURN VALUE

On success, these functions return the appropriate Bessel value of the second kind for *x*.

If *x* is a NaN, a NaN is returned.

If *x* is negative, a domain error occurs, and the functions return −**HUGE_VAL**, −**HUGE_VALF**, or −**HUGE_VALL**, respectively. (POSIX.1-2001 also allows a NaN return for this case.)

If *x* is 0.0, a pole error occurs, and the functions return −**HUGE_VAL**, −**HUGE_VALF**, or −**HUGE_VALL**, respectively.

If the result underflows, a range error occurs, and the functions return 0.0

If the result overflows, a range error occurs, and the functions return −**HUGE_VAL**, −**HUGE_VALF**, or −**HUGE_VALL**, respectively. (POSIX.1-2001 also allows a 0.0 return for this case.)

ERRORS

See *math_error*(7) for information on how to determine whether an error has occurred when calling these functions.

The following errors can occur:

Domain error: *x* is negative
: *errno* is set to **EDOM**. An invalid floating-point exception (**FE_INVALID**) is raised.

Pole error: *x* is 0.0
: *errno* is set to **ERANGE** and an **FE_DIVBYZERO** exception is raised (but see BUGS).

Range error: result underflow
: *errno* is set to **ERANGE**. No **FE_UNDERFLOW** exception is returned by *fetestexcept*(3) for this case.

Range error: result overflow
: *errno* is set to **ERANGE** (but see BUGS). An overflow floating-point exception (**FE_OVERFLOW**) is raised.

ATTRIBUTES

For an explanation of the terms used in this section, see *attributes*(7).

Interface	Attribute	Value
y0(), **y0f**(), **y0l**()	Thread safety	MT-Safe
y1(), **y1f**(), **y1l**()	Thread safety	MT-Safe
yn(), **ynf**(), **ynl**()	Thread safety	MT-Safe

STANDARDS

y0()
y1()
yn() POSIX.1-2008.

Others: BSD.

HISTORY

y0()
y1()
yn() SVr4, 4.3BSD, POSIX.1-2001.

Others: BSD.

BUGS

Before glibc 2.19, these functions misdiagnosed pole errors: *errno* was set to **EDOM**, instead of **ERANGE** and no **FE_DIVBYZERO** exception was raised.

Before glibc 2.17, did not set *errno* for "range error: result underflow".

In glibc 2.3.2 and earlier, these functions do not raise an invalid floating-point exception (**FE_INVALID**) when a domain error occurs.

j0(3)

NAME

EOF − end of file or error indicator

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <stdio.h>

#define EOF  /* ... */
```

DESCRIPTION

EOF represents the end of an input file, or an error indication. It is a negative value, of type *int*.

EOF is not a character (it can't be represented by *unsigned char*). It is instead a sentinel value outside of the valid range for valid characters.

CONFORMING TO

C99 and later; POSIX.1-2001 and later.

CAVEATS

Programs can't pass this value to an output function to "write" the end of a file. That would likely result in undefined behavior. Instead, closing the writing stream or file descriptor that refers to such file is the way to signal the end of that file.

SEE ALSO

feof(3), *fgetc*(3)

NAME

EXIT_SUCCESS, EXIT_FAILURE − termination status constants

LIBRARY

Standard C library (*libc*)

SYNOPSIS

#include <stdlib.h>

#define EXIT_SUCCESS 0
#define EXIT_FAILURE /* nonzero */

DESCRIPTION

EXIT_SUCCESS and **EXIT_FAILURE** represent a successful and unsuccessful exit status respectively, and can be used as arguments to the *exit*(3) function.

CONFORMING TO

C99 and later; POSIX.1-2001 and later.

EXAMPLES

```
#include <stdio.h>
#include <stdlib.h>

int
main(int argc, char *argv[])
{
    FILE *fp;

    if (argc != 2) {
        fprintf(stderr, "Usage: %s <file>\n", argv[0]);
        exit(EXIT_FAILURE);
    }

    fp = fopen(argv[1], "r");
    if (fp == NULL) {
        perror(argv[1]);
        exit(EXIT_FAILURE);
    }

    /* Other code omitted */

    fclose(fp);
    exit(EXIT_SUCCESS);
}
```

SEE ALSO

exit(3), *sysexits.h*(3head)

NAME

NULL − null pointer constant

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <stddef.h>

#define NULL  ((void *) 0)
```

DESCRIPTION

NULL represents a null pointer constant, that is, a pointer that does not point to anything.

CONFORMING TO

C99 and later; POSIX.1-2001 and later.

NOTES

The following headers also provide **NULL**: <*locale.h*>, <*stdio.h*>, <*stdlib.h*>, <*string.h*>, <*time.h*>, <*unistd.h*>, and <*wchar.h*>.

CAVEATS

It is undefined behavior to dereference a null pointer, and that usually causes a segmentation fault in practice.

It is also undefined behavior to perform pointer arithmetic on it.

NULL − *NULL* is undefined behavior, according to ISO C, but is defined to be 0 in C++.

To avoid confusing human readers of the code, do not compare pointer variables to **0**, and do not assign **0** to them. Instead, always use **NULL**.

NULL shouldn't be confused with **NUL**, which is an *ascii*(7) character, represented in C as '**\0**'.

BUGS

When it is necessary to set a pointer variable to a null pointer, it is not enough to use *memset*(3) to zero the pointer (this is usually done when zeroing a struct that contains pointers), since ISO C and POSIX don't guarantee that a bit pattern of all 0s represent a null pointer. See the EXAMPLES section in *getaddrinfo*(3) for an example program that does this correctly.

#define PA_FLAG_PTR          /* ... */
```

DESCRIPTION

These functions serve to extend and/or modify the behavior of the *printf*(3) family of functions.

register_printf_specifier()

This function registers a custom conversion specifier for the *printf*(3) family of functions.

spec The character which will be used as a conversion specifier in the format string.

func Callback function that will be executed by the *printf*(3) family of functions to format the input arguments into the output *stream*.

stream Output stream where the formatted output should be printed. This stream transparently represents the output, even in the case of functions that write to a string.

info Structure that holds context information, including the modifiers specified in the format string. This holds the same contents as in *arginfo*.

args Array of pointers to the arguments to the *printf*(3)-like function.

arginfo Callback function that will be executed by the *printf*(3) family of functions to know how many arguments should be parsed for the custom specifier and also their types.

info Structure that holds context information, including the modifiers specified in the format string. This holds the same contents as in *func*.

n Number of arguments remaining to be parsed.

argtypes
This array should be set to define the type of each of the arguments that will be parsed. Each element in the array represents one of the arguments to be parsed, in the same order that they are passed to the *printf*(3)-like function. Each element should be set to a base type (**PA_***) from the enum above, or a custom one, and optionally ORed with an appropriate length modifier (**PA_FLAG_***).

The type is determined by using one of the following constants:

PA_INT
int.

PA_CHAR
int, cast to *char*.

PA_WCHAR
wchar_t.

PA_STRING
const char *, a '\0'-terminated string.

PA_WSTRING
const wchar_t *, a wide character L'\0'-terminated string.

PA_POINTER
void *.

PA_FLOAT
float.

PA_DOUBLE
double.

PA_LAST
TODO.

size For user-defined types, the size of the type (in bytes) should also be specified through this array. Otherwise, leave it unused.

arginfo is called before *func*, and prepares some information needed to call *func*.

register_printf_modifier()
TODO

register_printf_type()
TODO

RETURN VALUE

register_printf_specifier(), **register_printf_modifier**(), and **register_printf_type**() return zero on success, or −1 on error.

Callbacks

The callback of type *printf_function* should return the number of characters written, or −1 on error.

The callback of type *printf_arginfo_size_function* should return the number of arguments to be parsed by this specifier. It also passes information about the type of those arguments to the caller through *argtypes*. On error, it should return −1.

ERRORS

EINVAL

The specifier was not a valid character.

STANDARDS

GNU.

HISTORY

register_printf_function(3) is an older function similar to **register_printf_specifier**(), and is now deprecated. That function can't handle user-defined types.

register_printf_specifier() supersedes **register_printf_function**(3).

EXAMPLES

The following example program registers the 'b' and 'B' specifiers to print integers in binary format, mirroring rules for other unsigned conversion specifiers like 'x' and 'u'. This can be used to print in binary prior to C23.

```
/* This code is in the public domain */

#include <err.h>
#include <limits.h>
#include <stddef.h>
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <string.h>
#include <sys/param.h>

#include <printf.h>

#define GROUP_SEP  '\''

NAME

sysexits.h − exit codes for programs

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sysexits.h>
#define EX_OK          0   /* successful termination */

    #define EX__BASE      64   /* base value for error messages */

    #define EX_USAGE      64   /* command line usage error */
#define EX_DATAERR     65  /* data format error */
#define EX_NOINPUT     66  /* cannot open input */
#define EX_NOUSER      67  /* addressee unknown */
#define EX_NOHOST      68  /* host name unknown */
#define EX_UNAVAILABLE 69  /* service unavailable */
#define EX_SOFTWARE    70  /* internal software error */
#define EX_OSERR       71  /* system error (e.g., can't fork) */
#define EX_OSFILE      72  /* critical OS file missing */
#define EX_CANTCREAT   73  /* can't create (user) output file */
#define EX_IOERR       74  /* input/output error */
#define EX_TEMPFAIL    75  /* temp failure; user is invited to retry */
#define EX_PROTOCOL    76  /* remote error in protocol */
#define EX_NOPERM      77  /* permission denied */
#define EX_CONFIG      78  /* configuration error */

    #define EX__MAX       ...   /* maximum listed value */
```

DESCRIPTION

A few programs exit with the following error codes.

The successful exit is always indicated by a status of **0**, or **EX_OK** (equivalent to **EXIT_SUCCESS** from <*stdlib.h*>). Error numbers begin at **EX__BASE** to reduce the possibility of clashing with other exit statuses that random programs may already return. The meaning of the code is approximately as follows:

EX_USAGE
: The command was used incorrectly, e.g., with the wrong number of arguments, a bad flag, bad syntax in a parameter, or whatever.

EX_DATAERR
: The input data was incorrect in some way. This should only be used for user's data and not system files.

EX_NOINPUT
: An input file (not a system file) did not exist or was not readable. This could also include errors like "No message" to a mailer (if it cared to catch it).

EX_NOUSER
: The user specified did not exist. This might be used for mail addresses or remote logins.

EX_NOHOST
: The host specified did not exist. This is used in mail addresses or network requests.

EX_UNAVAILABLE
: A service is unavailable. This can occur if a support program or file does not exist. This can also be used as a catch-all message when something you wanted to do doesn't work, but you don't know why.

EX_SOFTWARE
: An internal software error has been detected. This should be limited to non-operating system related errors if possible.

EX_OSERR
: An operating system error has been detected. This is intended to be used for such things as "cannot fork", "cannot create pipe", or the like. It includes things like *getuid*(2) returning a

user that does not exist in the *passwd*(5) file.

EX_OSFILE
Some system file (e.g., */etc/passwd*, */etc/utmp*, etc.) does not exist, cannot be opened, or has some sort of error (e.g., syntax error).

EX_CANTCREAT
A (user specified) output file cannot be created.

EX_IOERR
An error occurred while doing I/O on some file.

EX_TEMPFAIL
Temporary failure, indicating something that is not really an error. For example that a mailer could not create a connection, and the request should be reattempted later.

EX_PROTOCOL
The remote system returned something that was "not possible" during a protocol exchange.

EX_OSFILE
You did not have sufficient permission to perform the operation. This is not intended for file system problems, which should use **EX_NOINPUT** or **EX_CANTCREAT**, but rather for higher level permissions.

EX_CONFIG
Something was found in an unconfigured or misconfigured state.

The numerical values corresponding to the symbolical ones are given in parenthesis for easy reference.

STANDARDS
BSD.

HISTORY
The <*sysexits.h*> file appeared in 4.0BSD for use by the deliverymail utility, later renamed to *sendmail*(8)

CAVEATS
The choice of an appropriate exit value is often ambiguous.

NAME

cc_t, speed_t, tcflag_t − terminal special characters, baud rates, modes

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <termios.h>

typedef /* ... */ cc_t;
typedef /* ... */ speed_t;
typedef /* ... */ tcflag_t;
```

DESCRIPTION

cc_t is used for terminal special characters, *speed_t* for baud rates, and *tcflag_t* for modes.

All are unsigned integer types.

NAME

clock_t − system time

LIBRARY

Standard C library (*libc*)

SYNOPSIS

#include <time.h>

typedef /* ... */ **clock_t;**

DESCRIPTION

Used for system time in clock ticks or **CLOCKS_PER_SEC** (defined in <*time.h*>). According to POSIX, it is an integer type or a real-floating type.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C89, POSIX.1-2001.

NOTES

The following headers also provide this type: <*sys/types.h*> and <*sys/times.h*>.

SEE ALSO

NAME

dev_t − device ID

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/types.h>

typedef /* ... */ dev_t;
```

DESCRIPTION

Used for device IDs. It is an integer type. For further details of this type, see *makedev*(3).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

NOTES

The following header also provides this type: <*sys/stat.h*>.

SEE ALSO

mknod(2), *stat*(3type)

NAME

div_t, ldiv_t, lldiv_t, imaxdiv_t − quotient and remainder of an integer division

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <stdlib.h>

typedef struct {
    int quot; /* Quotient */
    int rem;  /* Remainder */
} div_t;

typedef struct {
    long quot; /* Quotient */
    long rem;  /* Remainder */
} ldiv_t;

typedef struct {
    long long quot; /* Quotient */
    long long rem;  /* Remainder */
} lldiv_t;

#include <inttypes.h>

typedef struct {
    intmax_t quot; /* Quotient */
    intmax_t rem;  /* Remainder */
} imaxdiv_t;
```

DESCRIPTION

[[*l*]*l*]*div_t* is the type of the value returned by the **[[l]l]***div*(3) function.

imaxdiv_t is the type of the value returned by the *imaxdiv*(3) function.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C99, POSIX.1-2001.

SEE ALSO

div(3), *imaxdiv*(3), *ldiv*(3), *lldiv*(3)

NAME

float_t, double_t − most efficient floating types

LIBRARY

Math library (*libm*)

SYNOPSIS

#include <math.h>

typedef /* ... */ **float_t;**
typedef /* ... */ **double_t;**

DESCRIPTION

The implementation's most efficient floating types at least as wide as *float* and *double* respectively. Their type depends on the value of the macro **FLT_EVAL_METHOD** (defined in <*float.h*>):

FLT_EVAL_METHOD	*float_t*	*double_t*
0	*float*	*double*
1	*double*	*double*
2	*long double*	*long double*

For other values of **FLT_EVAL_METHOD**, the types of *float_t* and *double_t* are implementation-defined.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C99, POSIX.1-2001.

SEE ALSO

float.h(0p), *math.h*(0p)

NAME

epoll_event, epoll_data, epoll_data_t − epoll event

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/epoll.h>

struct epoll_event {
    uint32_t      events;  /* Epoll events */
    epoll_data_t  data;    /* User data variable */
};

union epoll_data {
    void     *ptr;
    int       fd;
    uint32_t  u32;
    uint64_t  u64;
};

typedef union epoll_data  epoll_data_t;
```

DESCRIPTION

The *epoll_event* structure specifies data that the kernel should save and return when the corresponding file descriptor becomes ready.

VERSIONS

C library/kernel differences

The Linux kernel headers also provide this type, with a slightly different definition:

```
#include <linux/eventpoll.h>

struct epoll_event {
    __poll_t  events;
    __u64     data;
};
```

STANDARDS

Linux.

SEE ALSO

epoll_wait(2), *epoll_ctl*(2)

NAME

fenv_t, fexcept_t − floating-point environment

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <fenv.h>

typedef /* ... */ fenv_t;
typedef /* ... */ fexcept_t;
```

DESCRIPTION

fenv_t represents the entire floating-point environment, including control modes and status flags.

fexcept_t represents the floating-point status flags collectively.

For further details see *fenv*(3).

STANDARDS

C11, POSIX.1-2008.

HISTORY

C99, POSIX.1-2001.

SEE ALSO

fenv(3)

NAME

FILE − input/output stream

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <stdio.h>

typedef /* ... */ FILE;
```

DESCRIPTION

An object type used for streams.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C89, POSIX.1-2001.

NOTES

The following header also provides this type: <*wchar.h*>.

SEE ALSO

NAME

pid_t, uid_t, gid_t, id_t − process/user/group identifier

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/types.h>

typedef /* ... */ pid_t;
typedef /* ... */ uid_t;
typedef /* ... */ gid_t;
typedef /* ... */ id_t;
```

DESCRIPTION

pid_t is a type used for storing process IDs, process group IDs, and session IDs. It is a signed integer type.

uid_t is a type used to hold user IDs. It is an integer type.

gid_t is a type used to hold group IDs. It is an integer type.

id_t is a type used to hold a general identifier. It is an integer type that can be used to contain a *pid_t*, *uid_t*, or *gid_t*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

NOTES

The following headers also provide *pid_t*: <*fcntl.h*>, <*sched.h*>, <*signal.h*>, <*spawn.h*>, <*sys/msg.h*>, <*sys/sem.h*>, <*sys/shm.h*>, <*sys/wait.h*>, <*termios.h*>, <*time.h*>, <*unistd.h*>, and <*utmpx.h*>.

The following headers also provide *uid_t*: <*pwd.h*>, <*signal.h*>, <*stropts.h*>, <*sys/ipc.h*>, <*sys/stat.h*>, and <*unistd.h*>.

The following headers also provide *gid_t*: <*grp.h*>, <*pwd.h*>, <*signal.h*>, <*stropts.h*>, <*sys/ipc.h*>, <*sys/stat.h*>, and <*unistd.h*>.

The following header also provides *id_t*: <*sys/resource.h*>.

NAME

intmax_t, uintmax_t − greatest-width basic integer types

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <stdint.h>

typedef /* ... */ intmax_t;
typedef /* ... */ uintmax_t;

#define INTMAX_WIDTH  /* ... */
#define UINTMAX_WIDTH INTMAX_WIDTH

#define INTMAX_MAX    /*  2**(INTMAX_WIDTH - 1) - 1  */
#define INTMAX_MIN    /*  - 2**(INTMAX_WIDTH - 1)    */
#define UINTMAX_MAX   /*  2**UINTMAX_WIDTH - 1       */

#define INTMAX_C(c)   c ## /* ... */
#define UINTMAX_C(c)  c ## /* ... */
```

DESCRIPTION

intmax_t is a signed integer type capable of representing any value of any basic signed integer type supported by the implementation. It is capable of storing values in the range [**INTMAX_MIN**, **INTMAX_MAX**].

uintmax_t is an unsigned integer type capable of representing any value of any basic unsigned integer type supported by the implementation. It is capable of storing values in the range [**0**, **UINTMAX_MAX**].

The macros [**U**]**INTMAX_WIDTH** expand to the width in bits of these types.

The macros [**U**]**INTMAX_MAX** expand to the maximum value that these types can hold.

The macro **INTMAX_MIN** expands to the minimum value that *intmax_t* can hold.

The macros [**U**]**INTMAX_C**() expand their argument to an integer constant of type [*u*]*intmax_t*.

The length modifier for [*u*]*intmax_t* for the *printf*(3) and the *scanf*(3) families of functions is **j**; resulting commonly in **%jd**, **%ji**, **%ju**, or **%jx** for printing [*u*]*intmax_t* values.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C99, POSIX.1-2001.

NOTES

The following header also provides these types: <*inttypes.h*>.

BUGS

These types may not be as large as extended integer types, such as *__int128*

SEE ALSO

int64_t(3type), *intptr_t*(3type), *printf*(3), *strtoimax*(3)

#define UINT64_C(c)  c ## /* ... */
```

DESCRIPTION

*int*N*_t* are signed integer types of a fixed width of exactly N bits, *N* being the value specified in its type name. They are be capable of storing values in the range [**INT***N***_MIN**, **INT***N***_MAX**], substituting *N* by the appropriate number.

*uint*N*_t* are unsigned integer types of a fixed width of exactly N bits, N being the value specified in its type name. They are capable of storing values in the range [**0**, **UINT***N***_MAX**], substituting *N* by the appropriate number.

According to POSIX, [*u*]*int8_t*, [*u*]*int16_t*, and [*u*]*int32_t* are required; [*u*]*int64_t* are only required in implementations that provide integer types with width 64; and all other types of this form are optional.

The macros [**U**]**INT***N***_WIDTH** expand to the width in bits of these types (*N*).

The macros [**U**]**INT***N***_MAX** expand to the maximum value that these types can hold.

The macros **INT***N***_MIN** expand to the minimum value that these types can hold.

The macros [**U**]**INT***N***_C**() expand their argument to an integer constant of type [*u*]*int*N*_t*.

The length modifiers for the [*u*]*int*N*_t* types for the *printf*(3) family of functions are expanded by macros of the forms **PRId***N*, **PRIi***N*, **PRIu***N*, and **PRIx***N* (defined in <*inttypes.h*>); resulting for example in **%"PRId64"** or **%"PRIi64"** for printing *int64_t* values. The length modifiers for the [*u*]*int*N*_t* types for the *scanf*(3) family of functions are expanded by macros of the forms **SCNd***N*, **SCNi***N*, **SCNu***N*, and **SCNx***N*, (defined in <*inttypes.h*>); resulting for example in **%"SCNu8"** or **%"SCNx8"** for scanning *uint8_t* values.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C99, POSIX.1-2001.

The [**U**]**INT***N***_WIDTH** macros were added in C23.

NOTES

The following header also provides these types: <*inttypes.h*>. <*arpa/inet.h*> also provides *uint16_t* and *uint32_t*.

NAME

intptr_t, uintptr_t − integer types wide enough to hold pointers

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <stdint.h>

typedef /* ... */ intptr_t;
typedef /* ... */ uintptr_t;

#define INTPTR_WIDTH  /* ... */
#define UINTPTR_WIDTH INTPTR_WIDTH

#define INTPTR_MAX    /*  2**(INTPTR_WIDTH - 1) - 1  */
#define INTPTR_MIN    /*  - 2**(INTPTR_WIDTH - 1)    */
#define UINTPTR_MAX   /*  2**UINTPTR_WIDTH - 1       */
```

DESCRIPTION

intptr_t is a signed integer type such that any valid (*void **) value can be converted to this type and then converted back. It is capable of storing values in the range [**INTPTR_MIN**, **INTPTR_MAX**].

uintptr_t is an unsigned integer type such that any valid (*void **) value can be converted to this type and then converted back. It is capable of storing values in the range [**0**, **INTPTR_MAX**].

The macros [**U**]**INTPTR_WIDTH** expand to the width in bits of these types.

The macros [**U**]**INTPTR_MAX** expand to the maximum value that these types can hold.

The macro **INTPTR_MIN** expands to the minimum value that *intptr_t* can hold.

The length modifiers for the [*u*]*intptr_t* types for the *printf*(3) family of functions are expanded by the macros **PRIdPTR**, **PRIiPTR**, and **PRIuPTR** (defined in <*inttypes.h*>); resulting commonly in **%"PRIdPTR"** or **%"PRIiPTR"** for printing *intptr_t* values. The length modifiers for the *[*u*]*intptr_t types for the *scanf*(3) family of functions are expanded by the macros **SCNdPTR**, **SCNiPTR**, and **SCNuPTR** (defined in <*inttypes.h*>); resulting commonly in **%"SCNuPTR"** for scanning *uintptr_t* values.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C99, POSIX.1-2001.

NAME

iovec − Vector I/O data structure

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/uio.h>

struct iovec {
    void   *iov_base;  /* Starting address */
    size_t  iov_len;   /* Size of the memory pointed to by iov_base. */
};
```

DESCRIPTION

Describes a region of memory, beginning at *iov_base* address and with the size of *iov_len* bytes. System calls use arrays of this structure, where each element of the array represents a memory region, and the whole array represents a vector of memory regions. The maximum number of *iovec* structures in that array is limited by **IOV_MAX** (defined in <*limits.h*>, or accessible via the call *sysconf(_SC_IOV_MAX)*).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

process_madvise(2), *readv*(2)

NAME

itimerspec − interval for a timer with nanosecond precision

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <time.h>

struct itimerspec {
    struct timespec  it_interval;  /* Interval for periodic timer */
    struct timespec  it_value;     /* Initial expiration */
};
```

DESCRIPTION

Describes the initial expiration of a timer, and its interval, in seconds and nanoseconds.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

SEE ALSO

timerfd_create(2), *timer_settime*(2), *timespec*(3type)

NAME

lconv − numeric formatting information

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <locale.h>

struct lconv {                  /* Values in the "C" locale: */
    char *decimal_point;        /* "." */
    char *thousands_sep;        /* "" */
    char *grouping;             /* "" */
    char *mon_decimal_point;    /* "" */
    char *mon_thousands_sep;    /* "" */
    char *mon_grouping;         /* "" */
    char *positive_sign;        /* "" */
    char *negative_sign;        /* "" */
    char *currency_symbol;      /* "" */
    char  frac_digits;          /* CHAR_MAX */
    char  p_cs_precedes;        /* CHAR_MAX */
    char  n_cs_precedes;        /* CHAR_MAX */
    char  p_sep_by_space;       /* CHAR_MAX */
    char  n_sep_by_space;       /* CHAR_MAX */
    char  p_sign_posn;          /* CHAR_MAX */
    char  n_sign_posn;          /* CHAR_MAX */
    char *int_curr_symbol;      /* "" */
    char  int_frac_digits;      /* CHAR_MAX */
    char  int_p_cs_precedes;    /* CHAR_MAX */
    char  int_n_cs_precedes;    /* CHAR_MAX */
    char  int_p_sep_by_space;   /* CHAR_MAX */
    char  int_n_sep_by_space;   /* CHAR_MAX */
    char  int_p_sign_posn;      /* CHAR_MAX */
    char  int_n_sign_posn;      /* CHAR_MAX */
};
```

DESCRIPTION

Contains members related to the formatting of numeric values. In the "C" locale, its members have the values shown in the comments above.

STANDARDS

C11, POSIX.1-2008.

HISTORY

POSIX.1-2001.

NAME

mode_t − file attributes

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/types.h>

typedef /* ... */ mode_t;
```

DESCRIPTION

Used for some file attributes (e.g., file mode). It is an integer type.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

NOTES

The following headers also provide this type: <*fcntl.h*>, <*ndbm.h*>, <*spawn.h*>, <*sys/ipc.h*>, <*sys/mman.h*>, and <*sys/stat.h*>.

SEE ALSO

chmod(2), *mkdir*(2), *open*(2), *umask*(2), *stat*(3type)

NAME

off_t, off64_t, loff_t − file sizes

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/types.h>

typedef /* ... */ off_t;

#define _LARGEFILE64_SOURCE
#include <sys/types.h>

typedef /* ... */ off64_t;

#define _GNU_SOURCE
#include <sys/types.h>

typedef /* ... */ loff_t;
```

DESCRIPTION

off_t is used for describing file sizes. It is a signed integer type.

off64_t is a 64-bit version of the type, used in glibc.

loff_t is a 64-bit version of the type, introduced by the Linux kernel.

STANDARDS

off_t POSIX.1-2008.

off64_t GNU and some BSDs.

loff_t Linux.

VERSIONS

off_t POSIX.1-2001.

<*aio.h*> and <*stdio.h*> define *off_t* since POSIX.1-2008.

NOTES

On some architectures, the width of *off_t* can be controlled with the feature test macro **_FILE_OFFSET_BITS**.

The following headers also provide *off_t*: <*aio.h*>, <*fcntl.h*>, <*stdio.h*>, <*sys/mman.h*>, <*sys/stat.h*>, and <*unistd.h*>.

NAME

ptrdiff_t − count of elements or array index

LIBRARY

Standard C library (*libc*)

SYNOPSIS

#include <stddef.h>

typedef /* ... */ **ptrdiff_t;**

DESCRIPTION

Used for a count of elements, or an array index. It is the result of subtracting two pointers. It is a signed integer type capable of storing values in the range [**PTRDIFF_MIN**, **PTRDIFF_MAX**].

The length modifier for *ptrdiff_t* for the *printf*(3) and the *scanf*(3) families of functions is **t**, resulting commonly in **%td** or **%ti** for printing *ptrdiff_t* values.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C89, POSIX.1-2001.

SEE ALSO

size_t(3type)

NAME

sigevent, sigval − structure for notification from asynchronous routines

SYNOPSIS

```
#include <signal.h>

struct sigevent {
    int             sigev_notify;  /* Notification type */
    int             sigev_signo;   /* Signal number */
    union sigval    sigev_value;   /* Data passed with notification */

    void          (*sigev_notify_function)(union sigval);
                                   /* Notification function
                                      (SIGEV_THREAD) */
    pthread_attr_t *sigev_notify_attributes;
                                   /* Notification attributes */

    /* Linux only: */
    pid_t           sigev_notify_thread_id;
                                   /* ID of thread to signal
                                      (SIGEV_THREAD_ID) */
};

union sigval {                     /* Data passed with notification */
    int             sival_int;     /* Integer value */
    void           *sival_ptr;     /* Pointer value */
};
```

DESCRIPTION

sigevent

The *sigevent* structure is used by various APIs to describe the way a process is to be notified about an event (e.g., completion of an asynchronous request, expiration of a timer, or the arrival of a message).

The definition shown in the SYNOPSIS is approximate: some of the fields in the *sigevent* structure may be defined as part of a union. Programs should employ only those fields relevant to the value specified in *sigev_notify*.

The *sigev_notify* field specifies how notification is to be performed. This field can have one of the following values:

SIGEV_NONE
A "null" notification: don't do anything when the event occurs.

SIGEV_SIGNAL
Notify the process by sending the signal specified in *sigev_signo*.

If the signal is caught with a signal handler that was registered using the *sigaction*(2) **SA_SIGINFO** flag, then the following fields are set in the *siginfo_t* structure that is passed as the second argument of the handler:

si_code This field is set to a value that depends on the API delivering the notification.

si_signo This field is set to the signal number (i.e., the same value as in *sigev_signo*).

si_value This field is set to the value specified in *sigev_value*.

Depending on the API, other fields may also be set in the *siginfo_t* structure.

The same information is also available if the signal is accepted using *sigwaitinfo*(2).

SIGEV_THREAD
Notify the process by invoking *sigev_notify_function* "as if" it were the start function of a new thread. (Among the implementation possibilities here are that each timer notification could result in the creation of a new thread, or that a single thread is created to receive all notifications.) The function is invoked with *sigev_value* as its sole argument. If *sigev_notify_attributes* is not NULL, it should point to a *pthread_attr_t* structure that defines attributes for the

new thread (see *pthread_attr_init*(3)).

SIGEV_THREAD_ID (Linux-specific)
Currently used only by POSIX timers; see *timer_create*(2).

sigval
Data passed with a signal.

STANDARDS
POSIX.1-2008.

HISTORY
POSIX.1-2001.

<*aio.h*> and <*time.h*> define *sigevent* since POSIX.1-2008.

NOTES
The following headers also provide *sigevent*: <*aio.h*>, <*mqueue.h*>, and <*time.h*>.

SEE ALSO

NAME

size_t, ssize_t − count of bytes

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <stddef.h>

typedef /* ... */ size_t;

#include <sys/types.h>

typedef /* ... */ ssize_t;
```

DESCRIPTION

size_t Used for a count of bytes. It is the result of the *sizeof*() operator. It is an unsigned integer type capable of storing values in the range [**0**, **SIZE_MAX**].

ssize_t Used for a count of bytes or an error indication. It is a signed integer type capable of storing values at least in the range [**−1**, **SSIZE_MAX**].

Use with printf(3) and scanf(3)

size_t The length modifier for *size_t* for the *printf*(3) and the *scanf*(3) families of functions is **z**, resulting commonly in **%zu** or **%zx** for printing *size_t* values.

ssize_t glibc and most other implementations provide a length modifier for *ssize_t* for the *printf*(3) and the *scanf*(3) families of functions, which is **z**; resulting commonly in **%zd** or **%zi** for printing *ssize_t* values. Although **z** works for *ssize_t* on most implementations, portable POSIX programs should avoid using it—for example, by converting the value to *intmax_t* and using its length modifier (**j**).

STANDARDS

size_t C11, POSIX.1-2008.

ssize_t POSIX.1-2008.

HISTORY

NAME

sockaddr, sockaddr_storage, sockaddr_in, sockaddr_in6, sockaddr_un, socklen_t, in_addr, in6_addr, in_addr_t, in_port_t, − socket address

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/socket.h>

struct sockaddr {
    sa_family_t     sa_family;      /* Address family */
    char            sa_data[];      /* Socket address */
};

struct sockaddr_storage {
    sa_family_t     ss_family;      /* Address family */
};

typedef /* ... */ socklen_t;
typedef /* ... */ sa_family_t;
```

Internet domain sockets

```
#include <netinet/in.h>

struct sockaddr_in {
    sa_family_t     sin_family;     /* AF_INET */
    in_port_t       sin_port;       /* Port number */
    struct in_addr  sin_addr;       /* IPv4 address */
};

struct sockaddr_in6 {
    sa_family_t     sin6_family;    /* AF_INET6 */
    in_port_t       sin6_port;      /* Port number */
    uint32_t        sin6_flowinfo;  /* IPv6 flow info */
    struct in6_addr sin6_addr;      /* IPv6 address */
    uint32_t        sin6_scope_id;  /* Set of interfaces for a scope */
};

struct in_addr {
    in_addr_t s_addr;
};

struct in6_addr {
    uint8_t   s6_addr[16];
};

typedef uint32_t in_addr_t;
typedef uint16_t in_port_t;
```

UNIX domain sockets

```
#include <sys/un.h>

struct sockaddr_un {
    sa_family_t     sun_family;     /* Address family */
    char            sun_path[];     /* Socket pathname */
};
```

DESCRIPTION

sockaddr
: Describes a socket address.

sockaddr_storage
: A structure at least as large as any other *sockaddr_** address structures. It's aligned so that a pointer to it can be cast as a pointer to other *sockaddr_** structures and used to access its fields.

socklen_t
: Describes the length of a socket address. This is an integer type of at least 32 bits.

sa_family_t
: Describes a socket's protocol family. This is an unsigned integer type.

Internet domain sockets

sockaddr_in
: Describes an IPv4 Internet domain socket address. The *sin_port* and *sin_addr* members are stored in network byte order.

sockaddr_in6
: Describes an IPv6 Internet domain socket address. The *sin6_addr.s6_addr* array is used to contain a 128-bit IPv6 address, stored in network byte order.

UNIX domain sockets

sockaddr_un
: Describes a UNIX domain socket address.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

socklen_t was invented by POSIX. See also *accept*(2).

These structures were invented before modern ISO C strict-aliasing rules. If aliasing rules are applied strictly, these structures would be extremely difficult to use without invoking Undefined Behavior. POSIX Issue 8 will fix this by requiring that implementations make sure that these structures can be safely used as they were designed.

NOTES

socklen_t is also defined in <*netdb.h*>.

sa_family_t is also defined in <*netinet/in.h*> and <*sys/un.h*>.

NAME

stat − file status

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <sys/stat.h>

struct stat {
    dev_t      st_dev;      /* ID of device containing file */
    ino_t      st_ino;      /* Inode number */
    mode_t     st_mode;     /* File type and mode */
    nlink_t    st_nlink;    /* Number of hard links */
    uid_t      st_uid;      /* User ID of owner */
    gid_t      st_gid;      /* Group ID of owner */
    dev_t      st_rdev;     /* Device ID (if special file) */
    off_t      st_size;     /* Total size, in bytes */
    blksize_t  st_blksize;  /* Block size for filesystem I/O */
    blkcnt_t   st_blocks;   /* Number of 512 B blocks allocated */

    /* Since POSIX.1-2008, this structure supports nanosecond
       precision for the following timestamp fields.
       For the details before POSIX.1-2008, see VERSIONS. */

    struct timespec  st_atim;  /* Time of last access */
    struct timespec  st_mtim;  /* Time of last modification */
    struct timespec  st_ctim;  /* Time of last status change */

#define st_atime  st_atim.tv_sec  /* Backward compatibility */
#define st_mtime  st_mtim.tv_sec
#define st_ctime  st_ctim.tv_sec
};
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

st_atim, *st_mtim*, *st_ctim*:
Since glibc 2.12:
_POSIX_C_SOURCE >= 200809L || _XOPEN_SOURCE >= 700
glibc 2.19 and earlier:
_BSD_SOURCE || _SVID_SOURCE

DESCRIPTION

Describes information about a file.

The fields are as follows:

st_dev This field describes the device on which this file resides. (The *major*(3) and *minor*(3) macros may be useful to decompose the device ID in this field.)

st_ino This field contains the file's inode number.

st_mode
This field contains the file type and mode. See *inode*(7) for further information.

st_nlink
This field contains the number of hard links to the file.

st_uid This field contains the user ID of the owner of the file.

st_gid This field contains the ID of the group owner of the file.

st_rdev This field describes the device that this file (inode) represents.

st_size This field gives the size of the file (if it is a regular file or a symbolic link) in bytes. The size of a symbolic link is the length of the pathname it contains, without a terminating null byte.

st_blksize
: This field gives the "preferred" block size for efficient filesystem I/O.

st_blocks
: This field indicates the number of blocks allocated to the file, in 512-byte units. (This may be smaller than *st_size*/512 when the file has holes.)

st_atime
: This is the time of the last access of file data.

st_mtime
: This is the time of last modification of file data.

st_ctime
: This is the file's last status change timestamp (time of last change to the inode).

For further information on the above fields, see *inode*(7).

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

Old kernels and old standards did not support nanosecond timestamp fields. Instead, there were three timestamp fields—*st_atime*, *st_mtime*, and *st_ctime*—typed as *time_t* that recorded timestamps with one-second precision.

Since Linux 2.5.48, the *stat* structure supports nanosecond resolution for the three file timestamp fields. The nanosecond components of each timestamp are available via names of the form *st_atim.tv_nsec*, if suitable test macros are defined. Nanosecond timestamps were standardized in POSIX.1-2008, and, starting with glibc 2.12, glibc exposes the nanosecond component names if **_POSIX_C_SOURCE** is defined with the value 200809L or greater, or **_XOPEN_SOURCE** is defined with the value 700 or greater. Up to and including glibc 2.19, the definitions of the nanoseconds components are also defined if **_BSD_SOURCE** or **_SVID_SOURCE** is defined. If none of the aforementioned macros are defined, then the nanosecond values are exposed with names of the form *st_atimensec*.

NOTES

The following header also provides this type: <*ftw.h*>.

stat(2), *inode*(7)

NAME

time_t, suseconds_t, useconds_t − integer time

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <time.h>

typedef /* ... */  time_t;

#include <sys/types.h>

typedef /* ... */  suseconds_t;
typedef /* ... */  useconds_t;
```

DESCRIPTION

time_t Used for time in seconds. According to POSIX, it is an integer type.

suseconds_t
: Used for time in microseconds. It is a signed integer type capable of storing values at least in the range [**−1**, **1000000**].

useconds_t
: Used for time in microseconds. It is an unsigned integer type capable of storing values at least in the range [**0**, **1000000**].

STANDARDS

time_t C11, POSIX.1-2008.

suseconds_t
useconds_t
: POSIX.1-2008.

HISTORY

time_t C89, POSIX.1-2001.

suseconds_t
useconds_t
: POSIX.1-2001.

<*sched.h*> defines *time_t* since POSIX.1-2008.

POSIX.1-2001 defined *useconds_t* in <*unistd.h*> too.

NOTES

On some architectures, the width of *time_t* can be controlled with the feature test macro **_TIME_BITS**. See *feature_test_macros*(7).

The following headers also provide *time_t*: <*sched.h*>, <*sys/msg.h*>, <*sys/select.h*>, <*sys/sem.h*>, <*sys/shm.h*>, <*sys/stat.h*>, <*sys/time.h*>, <*sys/types.h*>, and <*utime.h*>.

The following headers also provide *suseconds_t*: <*sys/select.h*> and <*sys/time.h*>.

NAME

timespec − time in seconds and nanoseconds

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <time.h>

struct timespec {
    time_t     tv_sec;   /* Seconds */
    /* ... */  tv_nsec;  /* Nanoseconds [0, 999'999'999] */
};
```

DESCRIPTION

Describes times in seconds and nanoseconds.

tv_nsec is of an implementation-defined signed type capable of holding the specified range. Under glibc, this is usually *long*, and *long long* on X32. It can be safely down-cast to any concrete 32-bit integer type for processing.

VERSIONS

Prior to C23, *tv_nsec* was *long*.

STANDARDS

C11, POSIX.1-2008.

HISTORY

POSIX.1-2001.

NOTES

tm − broken-down time

LIBRARY

Standard C library (*libc*)

SYNOPSIS

```
#include <time.h>

struct tm {
    int         tm_sec;    /* Seconds          [0, 60] */
    int         tm_min;    /* Minutes          [0, 59] */
    int         tm_hour;   /* Hour             [0, 23] */
    int         tm_mday;   /* Day of the month [1, 31] */
    int         tm_mon;    /* Month            [0, 11]  (January = 0) */
    int         tm_year;   /* Year minus 1900 */
    int         tm_wday;   /* Day of the week  [0, 6]   (Sunday = 0) */
    int         tm_yday;   /* Day of the year  [0, 365] (Jan/01 = 0) */
    int         tm_isdst;  /* Daylight savings flag */

    long        tm_gmtoff; /* Seconds East of UTC */
    const char *tm_zone;   /* Timezone abbreviation */
};
```

Feature Test Macro Requirements for glibc (see *feature_test_macros*(7)):

tm_gmtoff , *tm_zone*:
Since glibc 2.20:
_DEFAULT_SOURCE
glibc 2.20 and earlier:
_BSD_SOURCE

DESCRIPTION

Describes time, broken down into distinct components.

tm_isdst describes whether daylight saving time is in effect at the time described. The value is positive if daylight saving time is in effect, zero if it is not, and negative if the information is not available.

tm_gmtoff is the difference, in seconds, of the timezone represented by this broken-down time and UTC (this is the additive inverse of *timezone*(3)).

tm_zone is the equivalent of *tzname*(3) for the timezone represented by this broken-down time.

VERSIONS

In C90, *tm_sec* could represent values in the range [**0**, **61**], which could represent a double leap second. UTC doesn't permit double leap seconds, so it was limited to **60** in C99.

timezone(3), as a variable, is an XSI extension: some systems provide the V7-compatible *timezone*(3) function. The *tm_gmtoff* field provides an alternative (with the opposite sign) for those systems.

tm_zone points to static storage and may be overridden on subsequent calls to *localtime*(3) and similar functions (however, this never happens under glibc).

STANDARDS

C11, POSIX.1-2008.

HISTORY

C89, POSIX.1-2001.

tm_gmtoff and *tm_zone* originate from 4.3BSD-Tahoe (where *tm_zone* is a *char* *).

NOTES

tm_sec can represent a leap second with the value **60**.

NAME

va_list − variable argument list

LIBRARY

Standard C library (*libc*)

SYNOPSIS

#include <stdarg.h>

typedef /* ... */ **va_list;**

DESCRIPTION

Used by functions with a varying number of arguments of varying types. The function must declare an object of type *va_list* which is used by the macros *va_start*(3), *va_arg*(3), *va_copy*(3), and *va_end*(3) to traverse the list of arguments.

STANDARDS

C11, POSIX.1-2008.

HISTORY

C89, POSIX.1-2001.

NOTES

The following headers also provide *va_list*: <*stdio.h*> and <*wchar.h*>.

SEE ALSO

va_start(3), *va_arg*(3), *va_copy*(3), *va_end*(3)

NAME

void − abstract type

SYNOPSIS

void *

DESCRIPTION

A pointer to any object type may be converted to a pointer to *void* and back. POSIX further requires that any pointer, including pointers to functions, may be converted to a pointer to *void* and back.

Conversions from and to any other pointer type are done implicitly, not requiring casts at all. Note that this feature prevents any kind of type checking: the programmer should be careful not to convert a *void* * value to a type incompatible to that of the underlying data, because that would result in undefined behavior.

This type is useful in function parameters and return value to allow passing values of any type. The function will typically use some mechanism to know the real type of the data being passed via a pointer to *void*.

A value of this type can't be dereferenced, as it would give a value of type *void*, which is not possible. Likewise, pointer arithmetic is not possible with this type. However, in GNU C, pointer arithmetic is allowed as an extension to the standard; this is done by treating the size of a *void* or of a function as 1. A consequence of this is that *sizeof* is also allowed on *void* and on function types, and returns 1.

Use with printf(3) and scanf(3)

The conversion specifier for *void* * for the *printf*(3) and the *scanf*(3) families of functions is **p**.

VERSIONS

The POSIX requirement about compatibility between *void* * and function pointers was added in POSIX.1-2008 Technical Corrigendum 1 (2013).

STANDARDS

C11, POSIX.1-2008.

HISTORY

C89, POSIX.1-2001.

NAME

cciss − HP Smart Array block driver

SYNOPSIS

modprobe cciss [cciss_allow_hpsa=1]

DESCRIPTION

Note: This obsolete driver was removed in Linux 4.14, as it is superseded by the *hpsa*(4) driver in newer kernels.

cciss is a block driver for older HP Smart Array RAID controllers.

Options

cciss_allow_hpsa=1: This option prevents the **cciss** driver from attempting to drive any controllers that the *hpsa*(4) driver is capable of controlling, which is to say, the **cciss** driver is restricted by this option to the following controllers:

Smart Array 5300
Smart Array 5i
Smart Array 532
Smart Array 5312
Smart Array 641
Smart Array 642
Smart Array 6400
Smart Array 6400 EM
Smart Array 6i
Smart Array P600
Smart Array P400i
Smart Array E200i
Smart Array E200
Smart Array E200i
Smart Array E200i
Smart Array E200i
Smart Array E500

Supported hardware

The **cciss** driver supports the following Smart Array boards:

Smart Array 5300
Smart Array 5i
Smart Array 532
Smart Array 5312
Smart Array 641
Smart Array 642
Smart Array 6400
Smart Array 6400 U320 Expansion Module
Smart Array 6i
Smart Array P600
Smart Array P800
Smart Array E400
Smart Array P400i
Smart Array E200
Smart Array E200i
Smart Array E500
Smart Array P700m
Smart Array P212
Smart Array P410
Smart Array P410i
Smart Array P411
Smart Array P812
Smart Array P712m
Smart Array P711m

Configuration details

To configure HP Smart Array controllers, use the HP Array Configuration Utility (either *hpacuxe*(8) or *hpacucli*(8)) or the Offline ROM-based Configuration Utility (ORCA) run from the Smart Array's option ROM at boot time.

FILES

Device nodes

The device naming scheme is as follows:

Major numbers:

104 cciss0
105 cciss1
106 cciss2
105 cciss3
108 cciss4
109 cciss5
110 cciss6
111 cciss7

Minor numbers:

```
b7 b6 b5 b4 b3 b2 b1 b0
|----+----| |----+----|
     |           |
     |           +-------- Partition ID (0=wholedev, 1-15 partition)
     |
     +-------------------- Logical Volume number
```

The device naming scheme is:

/dev/cciss/c0d0 Controller 0, disk 0, whole device
/dev/cciss/c0d0p1 Controller 0, disk 0, partition 1
/dev/cciss/c0d0p2 Controller 0, disk 0, partition 2
/dev/cciss/c0d0p3 Controller 0, disk 0, partition 3

/dev/cciss/c1d1 Controller 1, disk 1, whole device
/dev/cciss/c1d1p1 Controller 1, disk 1, partition 1
/dev/cciss/c1d1p2 Controller 1, disk 1, partition 2
/dev/cciss/c1d1p3 Controller 1, disk 1, partition 3

Files in /proc

The files */proc/driver/cciss/cciss[0-9]+* contain information about the configuration of each controller. For example:

```
$ cd /proc/driver/cciss
$ ls -l
total 0
-rw-r--r-- 1 root root 0 2010-09-10 10:38 cciss0
-rw-r--r-- 1 root root 0 2010-09-10 10:38 cciss1
-rw-r--r-- 1 root root 0 2010-09-10 10:38 cciss2
$ cat cciss2
cciss2: HP Smart Array P800 Controller
Board ID: 0x3223103c
Firmware Version: 7.14
IRQ: 16
Logical drives: 1
Current Q depth: 0
Current # commands on controller: 0
Max Q depth since init: 1
Max # commands on controller since init: 2
Max SG entries since init: 32
Sequential access devices: 0
```

```
cciss/c2d0:   36.38GB       RAID 0
```

Files in /sys

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/model*
Displays the SCSI INQUIRY page 0 model for logical drive *Y* of controller *X*.

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/rev*
Displays the SCSI INQUIRY page 0 revision for logical drive *Y* of controller *X*.

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/unique_id*
Displays the SCSI INQUIRY page 83 serial number for logical drive *Y* of controller *X*.

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/vendor*
Displays the SCSI INQUIRY page 0 vendor for logical drive *Y* of controller *X*.

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/block:cciss!cXdY*
A symbolic link to */sys/block/cciss!cXdY*.

*/sys/bus/pci/devices/*dev*/ccissX/rescan*
When this file is written to, the driver rescans the controller to discover any new, removed, or modified logical drives.

*/sys/bus/pci/devices/*dev*/ccissX/resettable*
A value of 1 displayed in this file indicates that the "reset_devices=1" kernel parameter (used by **kdump**) is honored by this controller. A value of 0 indicates that the "reset_devices=1" kernel parameter will not be honored. Some models of Smart Array are not able to honor this parameter.

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/lunid*
Displays the 8-byte LUN ID used to address logical drive *Y* of controller *X*.

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/raid_level*
Displays the RAID level of logical drive *Y* of controller *X*.

*/sys/bus/pci/devices/*dev*/ccissX/cXdY/usage_count*
Displays the usage count (number of opens) of logical drive *Y* of controller *X*.

SCSI tape drive and medium changer support

SCSI sequential access devices and medium changer devices are supported and appropriate device nodes are automatically created (e.g., */dev/st0*, */dev/st1*, etc.; see *st*(4) for more details.) You must enable "SCSI tape drive support for Smart Array 5xxx" and "SCSI support" in your kernel configuration to be able to use SCSI tape drives with your Smart Array 5xxx controller.

Additionally, note that the driver will not engage the SCSI core at init time. The driver must be directed to dynamically engage the SCSI core via the */proc* filesystem entry, which the "block" side of the driver creates as */proc/driver/cciss/cciss** at run time. This is because at driver init time, the SCSI core may not yet be initialized (because the driver is a block driver) and attempting to register it with the SCSI core in such a case would cause a hang. This is best done via an initialization script (typically in */etc/init.d*, but could vary depending on distribution). For example:

```
for x in /proc/driver/cciss/cciss[0-9]*
do
    echo "engage scsi" > $x
done
```

Once the SCSI core is engaged by the driver, it cannot be disengaged (except by unloading the driver, if it happens to be linked as a module.)

Note also that if no sequential access devices or medium changers are detected, the SCSI core will not be engaged by the action of the above script.

Hot plug support for SCSI tape drives

Hot plugging of SCSI tape drives is supported, with some caveats. The **cciss** driver must be informed that changes to the SCSI bus have been made. This may be done via the */proc* filesystem. For example:

```
echo "rescan" > /proc/scsi/cciss0/1
```

This causes the driver to:

(1) query the adapter about changes to the physical SCSI buses and/or fiber channel arbitrated loop, and

(2) make note of any new or removed sequential access devices or medium changers.

The driver will output messages indicating which devices have been added or removed and the controller, bus, target, and lun used to address each device. The driver then notifies the SCSI midlayer of these changes.

Note that the naming convention of the */proc* filesystem entries contains a number in addition to the driver name (e.g., "cciss0" instead of just "cciss", which you might expect).

Note: *Only* sequential access devices and medium changers are presented as SCSI devices to the SCSI midlayer by the **cciss** driver. Specifically, physical SCSI disk drives are *not* presented to the SCSI midlayer. The only disk devices that are presented to the kernel are logical drives that the array controller constructs from regions on the physical drives. The logical drives are presented to the block layer (not to the SCSI midlayer). It is important for the driver to prevent the kernel from accessing the physical drives directly, since these drives are used by the array controller to construct the logical drives.

SCSI error handling for tape drives and medium changers

The Linux SCSI midlayer provides an error-handling protocol that is initiated whenever a SCSI command fails to complete within a certain amount of time (which can vary depending on the command). The **cciss** driver participates in this protocol to some extent. The normal protocol is a four-step process:

(1) First, the device is told to abort the command.

(2) If that doesn't work, the device is reset.

(3) If that doesn't work, the SCSI bus is reset.

(4) If that doesn't work, the host bus adapter is reset.

The **cciss** driver is a block driver as well as a SCSI driver and only the tape drives and medium changers are presented to the SCSI midlayer. Furthermore, unlike more straightforward SCSI drivers, disk I/O continues through the block side during the SCSI error-recovery process. Therefore, the **cciss** driver implements only the first two of these actions, aborting the command, and resetting the device. Note also that most tape drives will not oblige in aborting commands, and sometimes it appears they will not even obey a reset command, though in most circumstances they will. If the command cannot be aborted and the device cannot be reset, the device will be set offline.

In the event that the error-handling code is triggered and a tape drive is successfully reset or the tardy command is successfully aborted, the tape drive may still not allow I/O to continue until some command is issued that positions the tape to a known position. Typically you must rewind the tape (by issuing *mt −f /dev/st0 rewind* for example) before I/O can proceed again to a tape drive that was reset.

NAME

console_codes − Linux console escape and control sequences

DESCRIPTION

The Linux console implements a large subset of the VT102 and ECMA-48 / ISO/IEC 6429 / ANSI X3.64 terminal controls, plus certain private-mode sequences for changing the color palette, character-set mapping, and so on. In the tabular descriptions below, the second column gives ECMA-48 or DEC mnemonics (the latter if prefixed with DEC) for the given function. Sequences without a mnemonic are neither ECMA-48 nor VT102.

After all the normal output processing has been done, and a stream of characters arrives at the console driver for actual printing, the first thing that happens is a translation from the code used for processing to the code used for printing.

If the console is in UTF-8 mode, then the incoming bytes are first assembled into 16-bit Unicode codes. Otherwise, each byte is transformed according to the current mapping table (which translates it to a Unicode value). See the **Character Sets** section below for discussion.

In the normal case, the Unicode value is converted to a font index, and this is stored in video memory, so that the corresponding glyph (as found in video ROM) appears on the screen. Note that the use of Unicode (and the design of the PC hardware) allows us to use 512 different glyphs simultaneously.

If the current Unicode value is a control character, or we are currently processing an escape sequence, the value will treated specially. Instead of being turned into a font index and rendered as a glyph, it may trigger cursor movement or other control functions. See the **Linux Console Controls** section below for discussion.

It is generally not good practice to hard-wire terminal controls into programs. Linux supports a *terminfo*(5) database of terminal capabilities. Rather than emitting console escape sequences by hand, you will almost always want to use a terminfo-aware screen library or utility such as *ncurses*(3), *tput*(1), or *reset*(1)

Linux console controls

This section describes all the control characters and escape sequences that invoke special functions (i.e., anything other than writing a glyph at the current cursor location) on the Linux console.

Control characters

A character is a control character if (before transformation according to the mapping table) it has one of the 14 codes 00 (NUL), 07 (BEL), 08 (BS), 09 (HT), 0a (LF), 0b (VT), 0c (FF), 0d (CR), 0e (SO), 0f (SI), 18 (CAN), 1a (SUB), 1b (ESC), 7f (DEL). One can set a "display control characters" mode (see below), and allow 07, 09, 0b, 18, 1a, 7f to be displayed as glyphs. On the other hand, in UTF-8 mode all codes 00–1f are regarded as control characters, regardless of any "display control characters" mode.

If we have a control character, it is acted upon immediately and then discarded (even in the middle of an escape sequence) and the escape sequence continues with the next character. (However, ESC starts a new escape sequence, possibly aborting a previous unfinished one, and CAN and SUB abort any escape sequence.) The recognized control characters are BEL, BS, HT, LF, VT, FF, CR, SO, SI, CAN, SUB, ESC, DEL, CSI. They do what one would expect:

BEL (0x07, ^**G**)
: beeps;

BS (0x08, ^**H**)
: backspaces one column (but not past the beginning of the line);

HT (0x09, ^**I**)
: goes to the next tab stop or to the end of the line if there is no earlier tab stop;

LF (0x0A, ^**J**)
VT (0x0B, ^**K**)
FF (0x0C, ^**L**)
: all give a linefeed, and if LF/NL (new-line mode) is set also a carriage return;

CR (0x0D, ^**M**)
: gives a carriage return;

SO (0x0E, ^**N**)
: activates the G1 character set;

SI (0x0F, ^**O**)
: activates the G0 character set;

CAN (0x18, ^**X**)
SUB (0x1A, ^**Z**)
: abort escape sequences;

ESC (0x1B, ^**[**)
: starts an escape sequence;

DEL (0x7F)
: is ignored;

CSI (0x9B)
: is equivalent to ESC [.

ESC- but not CSI-sequences

ESC c	RIS	Reset.
ESC D	IND	Linefeed.
ESC E	NEL	Newline.
ESC H	HTS	Set tab stop at current column.
ESC M	RI	Reverse linefeed.
ESC Z	DECID	DEC private identification. The kernel returns the string ESC [? 6 c, claiming that it is a VT102.
ESC 7	DECSC	Save current state (cursor coordinates, attributes, character sets pointed at by G0, G1).
ESC 8	DECRC	Restore state most recently saved by ESC 7.
ESC %		Start sequence selecting character set
ESC % @		Select default (ISO/IEC 646 / ISO/IEC 8859-1)
ESC % G		Select UTF-8
ESC % 8		Select UTF-8 (obsolete)
ESC # 8	DECALN	DEC screen alignment test − fill screen with E's.
ESC (		Start sequence defining G0 character set (followed by one of B, 0, U, K, as below)
ESC (B		Select default (ISO/IEC 8859-1 mapping).
ESC (0		Select VT100 graphics mapping.
ESC (U		Select null mapping − straight to character ROM.
ESC (K		Select user mapping − the map that is loaded by the utility*mapscrn*(8).
ESC)		Start sequence defining G1 (followed by one of B, 0, U, K, as above).
ESC >	DECPNM	Set numeric keypad mode
ESC =	DECPAM	Set application keypad mode
ESC]	OSC	Operating System Command prefix.
ESC] R		Reset palette.
ESC] P		Set palette, with parameter given in 7 hexadecimal digits *nrrggbb* after the final P. Here *n* is the color (0–15), and *rrggbb* indicates the red/green/blue values (0–255).

ECMA-48 CSI sequences

CSI (or ESC [) is followed by a sequence of parameters, at most NPAR (16), that are decimal numbers separated by semicolons. An empty or absent parameter is taken to be 0. The sequence of parameters may be preceded by a single question mark.

However, after CSI [(or ESC [[) a single character is read and this entire sequence is ignored. (The idea is to ignore an echoed function key.)

The action of a CSI sequence is determined by its final character.

@	ICH	Insert the indicated # of blank characters.
A	CUU	Move cursor up the indicated # of rows.
B	CUD	Move cursor down the indicated # of rows.
C	CUF	Move cursor right the indicated # of columns.

D	CUB	Move cursor left the indicated # of columns.
E	CNL	Move cursor down the indicated # of rows, to column 1.
F	CPL	Move cursor up the indicated # of rows, to column 1.
G	CHA	Move cursor to indicated column in current row.
H	CUP	Move cursor to the indicated row, column (origin at 1,1).
J	ED	Erase display (default: from cursor to end of display).
		ESC [1 J: erase from start to cursor.
		ESC [2 J: erase whole display.
		ESC [3 J: erase whole display including scroll-back buffer (since Linux 3.0).
K	EL	Erase line (default: from cursor to end of line).
		ESC [1 K: erase from start of line to cursor.
		ESC [2 K: erase whole line.
L	IL	Insert the indicated # of blank lines.
M	DL	Delete the indicated # of lines.
P	DCH	Delete the indicated # of characters on current line.
X	ECH	Erase the indicated # of characters on current line.
a	HPR	Move cursor right the indicated # of columns.
c	DA	Answer ESC [? 6 c: "I am a VT102".
d	VPA	Move cursor to the indicated row, current column.
e	VPR	Move cursor down the indicated # of rows.
f	HVP	Move cursor to the indicated row, column.
g	TBC	Without parameter: clear tab stop at current position.
		ESC [3 g: delete all tab stops.
h	SM	Set Mode (see below).
l	RM	Reset Mode (see below).
m	SGR	Set attributes (see below).
n	DSR	Status report (see below).
q	DECLL	Set keyboard LEDs.
		ESC [0 q: clear all LEDs
		ESC [1 q: set Scroll Lock LED
		ESC [2 q: set Num Lock LED
		ESC [3 q: set Caps Lock LED
r	DECSTBM	Set scrolling region; parameters are top and bottom row.
s	?	Save cursor location.
u	?	Restore cursor location.
`	HPA	Move cursor to indicated column in current row.

ECMA-48 Select Graphic Rendition

The ECMA-48 SGR sequence ESC [*parameters* m sets display attributes. Several attributes can be set in the same sequence, separated by semicolons. An empty parameter (between semicolons or string initiator or terminator) is interpreted as a zero.

param	result
0	reset all attributes to their defaults
1	set bold
2	set half-bright (simulated with color on a color display)
3	set italic (since Linux 2.6.22; simulated with color on a color display)
4	set underscore (simulated with color on a color display) (the colors used to simulate dim or underline are set using ESC] ...)
5	set blink
7	set reverse video
10	reset selected mapping, display control flag, and toggle meta flag (ECMA-48 says "primary font").
11	select null mapping, set display control flag, reset toggle meta flag (ECMA-48 says "first alternate font").
12	select null mapping, set display control flag, set toggle meta flag (ECMA-48 says "second alternate font"). The toggle meta flag causes the high bit of a byte to be toggled before the mapping table translation is done.

21 set underline; before Linux 4.17, this value set normal intensity (as is done in many other terminals)
22 set normal intensity
23 italic off (since Linux 2.6.22)
24 underline off
25 blink off
27 reverse video off
30 set black foreground
31 set red foreground
32 set green foreground
33 set brown foreground
34 set blue foreground
35 set magenta foreground
36 set cyan foreground
37 set white foreground
38 256/24-bit foreground color follows, shoehorned into 16 basic colors (before Linux 3.16: set underscore on, set default foreground color)
39 set default foreground color (before Linux 3.16: set underscore off, set default foreground color)
40 set black background
41 set red background
42 set green background
43 set brown background
44 set blue background
45 set magenta background
46 set cyan background
47 set white background
48 256/24-bit background color follows, shoehorned into 8 basic colors
49 set default background color
90..97 set foreground to bright versions of 30..37
100..107 set background, same as 40..47 (bright not supported)

Commands 38 and 48 require further arguments:
;5;x 256 color: values 0..15 are IBGR (black, red, green, ... white), 16..231 a 6x6x6 color cube, 232..255 a grayscale ramp
;2;r;g;b 24-bit color, r/g/b components are in the range 0..255

ECMA-48 Mode Switches

ESC [3 h
DECCRM (default off): Display control chars.

ESC [4 h
DECIM (default off): Set insert mode.

ESC [20 h
LF/NL (default off): Automatically follow echo of LF, VT, or FF with CR.

ECMA-48 Status Report Commands

ESC [5 n
Device status report (DSR): Answer is ESC [0 n (Terminal OK).

ESC [6 n
Cursor position report (CPR): Answer is ESC [*y* ; *x* R, where *x,y* is the cursor location.

DEC Private Mode (DECSET/DECRST) sequences

These are not described in ECMA-48. We list the Set Mode sequences; the Reset Mode sequences are obtained by replacing the final 'h' by 'l'.

ESC [? 1 h
DECCKM (default off): When set, the cursor keys send an ESC O prefix, rather than ESC [.

ESC [? 3 h
: DECCOLM (default off = 80 columns): 80/132 col mode switch. The driver sources note that this alone does not suffice; some user-mode utility such as *resizecons*(8) has to change the hardware registers on the console video card.

ESC [? 5 h
: DECSCNM (default off): Set reverse-video mode.

ESC [? 6 h
: DECOM (default off): When set, cursor addressing is relative to the upper left corner of the scrolling region.

ESC [? 7 h
: DECAWM (default on): Set autowrap on. In this mode, a graphic character emitted after column 80 (or column 132 of DECCOLM is on) forces a wrap to the beginning of the following line first.

ESC [? 8 h
: DECARM (default on): Set keyboard autorepeat on.

ESC [? 9 h
: X10 Mouse Reporting (default off): Set reporting mode to 1 (or reset to 0)—see below.

ESC [? 25 h
: DECTECM (default on): Make cursor visible.

ESC [? 1000 h
: X11 Mouse Reporting (default off): Set reporting mode to 2 (or reset to 0)—see below.

Linux Console Private CSI Sequences

The following sequences are neither ECMA-48 nor native VT102. They are native to the Linux console driver. Colors are in SGR parameters: 0 = black, 1 = red, 2 = green, 3 = brown, 4 = blue, 5 = magenta, 6 = cyan, 7 = white; 8–15 = bright versions of 0–7.

ESC [1 ; *n*] Set color *n* as the underline color.
ESC [2 ; *n*] Set color *n* as the dim color.
ESC [8] Make the current color pair the default attributes.
ESC [9 ; *n*] Set screen blank timeout to *n* minutes.
ESC [10 ; *n*] Set bell frequency in Hz.
ESC [11 ; *n*] Set bell duration in msec.
ESC [12 ; *n*] Bring specified console to the front.
ESC [13] Unblank the screen.
ESC [14 ; *n*] Set the VESA powerdown interval in minutes.
ESC [15] Bring the previous console to the front (since Linux 2.6.0).
ESC [16 ; *n*] Set the cursor blink interval in milliseconds (since Linux 4.2).

Character sets

The kernel knows about 4 translations of bytes into console-screen symbols. The four tables are: a) Latin1 −> PC, b) VT100 graphics −> PC, c) PC −> PC, d) user-defined.

There are two character sets, called G0 and G1, and one of them is the current character set. (Initially G0.) Typing **^N** causes G1 to become current, **^O** causes G0 to become current.

These variables G0 and G1 point at a translation table, and can be changed by the user. Initially they point at tables a) and b), respectively. The sequences ESC (B and ESC (0 and ESC (U and ESC (K cause G0 to point at translation table a), b), c), and d), respectively. The sequences ESC) B and ESC) 0 and ESC) U and ESC) K cause G1 to point at translation table a), b), c), and d), respectively.

The sequence ESC c causes a terminal reset, which is what you want if the screen is all garbled. The oft-advised "echo ^V^O" will make only G0 current, but there is no guarantee that G0 points at table a). In some distributions there is a program *reset*(1) that just does "echo ^[c". If your terminfo entry for the console is correct (and has an entry rs1=\Ec), then "tput reset" will also work.

The user-defined mapping table can be set using *mapscrn*(8)The result of the mapping is that if a symbol c is printed, the symbol s = map[c] is sent to the video memory. The bitmap that corresponds to s is found in the character ROM, and can be changed using *setfont*(8)

Mouse tracking

The mouse tracking facility is intended to return *xterm*(1)-compatible mouse status reports. Because the console driver has no way to know the device or type of the mouse, these reports are returned in the console input stream only when the virtual terminal driver receives a mouse update ioctl. These ioctls must be generated by a mouse-aware user-mode application such as the *gpm*(8) daemon.

The mouse tracking escape sequences generated by **xterm**(1) encode numeric parameters in a single character as *value*+040. For example, '!' is 1. The screen coordinate system is 1-based.

The X10 compatibility mode sends an escape sequence on button press encoding the location and the mouse button pressed. It is enabled by sending ESC [? 9 h and disabled with ESC [? 9 l. On button press, **xterm**(1) sends ESC [M *bxy* (6 characters). Here *b* is button−1, and *x* and *y* are the x and y coordinates of the mouse when the button was pressed. This is the same code the kernel also produces.

Normal tracking mode (not implemented in Linux 2.0.24) sends an escape sequence on both button press and release. Modifier information is also sent. It is enabled by sending ESC [? 1000 h and disabled with ESC [? 1000 l. On button press or release, **xterm**(1) sends ESC [M *bxy*. The low two bits of *b* encode button information: 0=MB1 pressed, 1=MB2 pressed, 2=MB3 pressed, 3=release. The upper bits encode what modifiers were down when the button was pressed and are added together: 4=Shift, 8=Meta, 16=Control. Again *x* and *y* are the x and y coordinates of the mouse event. The upper left corner is (1,1).

Comparisons with other terminals

Many different terminal types are described, like the Linux console, as being "VT100-compatible". Here we discuss differences between the Linux console and the two most important others, the DEC VT102 and *xterm*(1)

Control-character handling

The VT102 also recognized the following control characters:

NUL (0x00)
: was ignored;

ENQ (0x05)
: triggered an answerback message;

DC1 (0x11, **^Q**, XON)
: resumed transmission;

DC3 (0x13, **^S**, XOFF)
: caused VT100 to ignore (and stop transmitting) all codes except XOFF and XON.

VT100-like DC1/DC3 processing may be enabled by the terminal driver.

The *xterm*(1) program (in VT100 mode) recognizes the control characters BEL, BS, HT, LF, VT, FF, CR, SO, SI, ESC.

Escape sequences

VT100 console sequences not implemented on the Linux console:

ESC N	SS2	Single shift 2. (Select G2 character set for the next character only.)
ESC O	SS3	Single shift 3. (Select G3 character set for the next character only.)
ESC P	DCS	Device control string (ended by ESC \)
ESC X	SOS	Start of string.
ESC ^	PM	Privacy message (ended by ESC \)
ESC \	ST	String terminator
ESC * ...		Designate G2 character set
ESC + ...		Designate G3 character set

The program *xterm*(1) (in VT100 mode) recognizes ESC c, ESC # 8, ESC >, ESC =, ESC D, ESC E, ESC H, ESC M, ESC N, ESC O, ESC P ... ESC \, ESC Z (it answers ESC [? 1 ; 2 c, "I am a VT100 with advanced video option") and ESC ^ ... ESC \ with the same meanings as indicated above. It accepts ESC (, ESC), ESC *, ESC + followed by 0, A, B for the DEC special character and line drawing set, UK, and US-ASCII, respectively.

The user can configure **xterm**(1) to respond to VT220-specific control sequences, and it will identify itself as a VT52, VT100, and up depending on the way it is configured and initialized.

It accepts ESC] (OSC) for the setting of certain resources. In addition to the ECMA-48 string terminator (ST), **xterm**(1) accepts a BEL to terminate an OSC string. These are a few of the OSC control sequences recognized by **xterm**(1):

ESC] 0 ; *txt* ST	Set icon name and window title to *txt*.
ESC] 1 ; *txt* ST	Set icon name to *txt*.
ESC] 2 ; *txt* ST	Set window title to *txt*.
ESC] 4 ; *num*; *txt* ST	Set ANSI color *num* to *txt*.
ESC] 10 ; *txt* ST	Set dynamic text color to *txt*.
ESC] 4 6 ; *name* ST	Change log file to *name* (normally disabled by a compile-time option).
ESC] 5 0 ; *fn* ST	Set font to *fn*.

It recognizes the following with slightly modified meaning (saving more state, behaving closer to VT100/VT220):

ESC 7 DECSC	Save cursor
ESC 8 DECRC	Restore cursor

It also recognizes

ESC F		Cursor to lower left corner of screen (if enabled by*xterm*(1)'s **hpLowerleftBugCompat** resource).
ESC l		Memory lock (per HP terminals). Locks memory above the cursor.
ESC m		Memory unlock (per HP terminals).
ESC n	LS2	Invoke the G2 character set.
ESC o	LS3	Invoke the G3 character set.
ESC |	LS3R	Invoke the G3 character set as GR.
ESC }	LS2R	Invoke the G2 character set as GR.
ESC ~	LS1R	Invoke the G1 character set as GR.

It also recognizes ESC % and provides a more complete UTF-8 implementation than Linux console.

CSI Sequences

Old versions of **xterm**(1), for example, from X11R5, interpret the blink SGR as a bold SGR. Later versions which implemented ANSI colors, for example, XFree86 3.1.2A in 1995, improved this by allowing the blink attribute to be displayed as a color. Modern versions of xterm implement blink SGR as blinking text and still allow colored text as an alternate rendering of SGRs. Stock X11R6 versions did not recognize the color-setting SGRs until the X11R6.8 release, which incorporated XFree86 xterm. All ECMA-48 CSI sequences recognized by Linux are also recognized by *xterm*, however **xterm**(1) implements several ECMA-48 and DEC control sequences not recognized by Linux.

The **xterm**(1) program recognizes all of the DEC Private Mode sequences listed above, but none of the Linux private-mode sequences. For discussion of **xterm**(1)'s own private-mode sequences, refer to the *Xterm Control Sequences* document by Edward Moy, Stephen Gildea, and Thomas E. Dickey available with the X distribution. That document, though terse, is much longer than this manual page. For a chronological overview,

details changes to xterm.

The *vttest* program

demonstrates many of these control sequences. The **xterm**(1) source distribution also contains sample scripts which exercise other features.

NOTES

ESC 8 (DECRC) is not able to restore the character set changed with ESC %.

BUGS

In Linux 2.0.23, CSI is broken, and NUL is not ignored inside escape sequences.

Some older kernel versions (after Linux 2.0) interpret 8-bit control sequences. These "C1 controls" use codes between 128 and 159 to replace ESC [, ESC] and similar two-byte control sequence initiators. There are fragments of that in modern kernels (either overlooked or broken by changes to support UTF-8), but the implementation is incomplete and should be regarded as unreliable.

Linux "private mode" sequences do not follow the rules in ECMA-48 for private mode control sequences. In particular, those ending with] do not use a standard terminating character. The OSC (set palette) sequence is a greater problem, since **xterm**(1) may interpret this as a control sequence which requires a string terminator (ST). Unlike the **setterm**(1) sequences which will be ignored (since they are invalid control sequences), the palette sequence will make **xterm**(1) appear to hang (though pressing the return-key will fix that). To accommodate applications which have been hardcoded to use Linux control sequences, set the **xterm**(1) resource **brokenLinuxOSC** to true.

An older version of this document implied that Linux recognizes the ECMA-48 control sequence for invisible text. It is ignored.

NAME

cpuid − x86 CPUID access device

DESCRIPTION

CPUID provides an interface for querying information about the x86 CPU.

This device is accessed by *lseek*(2) or *pread*(2) to the appropriate CPUID level and reading in chunks of 16 bytes. A larger read size means multiple reads of consecutive levels.

The lower 32 bits of the file position is used as the incoming *%eax*, and the upper 32 bits of the file position as the incoming *%ecx*, the latter is intended for "counting" *eax* levels like *eax=4*.

This driver uses */dev/cpu/CPUNUM/cpuid*, where *CPUNUM* is the minor number, and on an SMP box will direct the access to CPU *CPUNUM* as listed in */proc/cpuinfo*.

This file is protected so that it can be read only by the user *root*, or members of the group *root*.

NOTES

The CPUID instruction can be directly executed by a program using inline assembler. However this device allows convenient access to all CPUs without changing process affinity.

Most of the information in *cpuid* is reported by the kernel in cooked form either in */proc/cpuinfo* or through subdirectories in */sys/devices/system/cpu*. Direct CPUID access through this device should only be used in exceptional cases.

The *cpuid* driver is not auto-loaded. On modular kernels you might need to use the following command to load it explicitly before use:

```
$ modprobe cpuid
```

There is no support for CPUID functions that require additional input registers.

Early i486 CPUs do not support the CPUID instruction; opening this device for those CPUs fails with EIO.

NAME

dsp56k − DSP56001 interface device

SYNOPSIS

#include <asm/dsp56k.h>

ssize_t read(int *fd***, void ****data***, size_t** *length***);**
ssize_t write(int *fd***, void ****data***, size_t** *length***);**

int ioctl(int *fd***, DSP56K_UPLOAD, struct dsp56k_upload ****program***);**
int ioctl(int *fd***, DSP56K_SET_TX_WSIZE, int** *wsize***);**
int ioctl(int *fd***, DSP56K_SET_RX_WSIZE, int** *wsize***);**
int ioctl(int *fd***, DSP56K_HOST_FLAGS, struct dsp56k_host_flags *** *flags***);**
int ioctl(int *fd***, DSP56K_HOST_CMD, int** *cmd***);**

CONFIGURATION

The *dsp56k* device is a character device with major number 55 and minor number 0.

DESCRIPTION

The Motorola DSP56001 is a fully programmable 24-bit digital signal processor found in Atari Falcon030-compatible computers. The *dsp56k* special file is used to control the DSP56001, and to send and receive data using the bidirectional handshaked host port.

To send a data stream to the signal processor, use *write*(2) to the device, and *read*(2) to receive processed data. The data can be sent or received in 8, 16, 24, or 32-bit quantities on the host side, but will always be seen as 24-bit quantities in the DSP56001.

The following *ioctl*(2) calls are used to control the *dsp56k* device:

DSP56K_UPLOAD
: resets the DSP56001 and uploads a program. The third *ioctl*(2) argument must be a pointer to a *struct dsp56k_upload* with members *bin* pointing to a DSP56001 binary program, and *len* set to the length of the program, counted in 24-bit words.

DSP56K_SET_TX_WSIZE
: sets the transmit word size. Allowed values are in the range 1 to 4, and is the number of bytes that will be sent at a time to the DSP56001. These data quantities will either be padded with bytes containing zero, or truncated to fit the native 24-bit data format of the DSP56001.

DSP56K_SET_RX_WSIZE
: sets the receive word size. Allowed values are in the range 1 to 4, and is the number of bytes that will be received at a time from the DSP56001. These data quantities will either truncated, or padded with a null byte ('\0'), to fit the native 24-bit data format of the DSP56001.

DSP56K_HOST_FLAGS
: read and write the host flags. The host flags are four general-purpose bits that can be read by both the hosting computer and the DSP56001. Bits 0 and 1 can be written by the host, and bits 2 and 3 can be written by the DSP56001.

  To access the host flags, the third *ioctl*(2) argument must be a pointer to a *struct dsp56k_host_flags*. If bit 0 or 1 is set in the *dir* member, the corresponding bit in *out* will be written to the host flags. The state of all host flags will be returned in the lower four bits of the *status* member.

DSP56K_HOST_CMD
: sends a host command. Allowed values are in the range 0 to 31, and is a user-defined command handled by the program running in the DSP56001.

NAME

fd − floppy disk device

CONFIGURATION

Floppy drives are block devices with major number 2. Typically they are owned by root:floppy (i.e., user root, group floppy) and have either mode 0660 (access checking via group membership) or mode 0666 (everybody has access). The minor numbers encode the device type, drive number, and controller number. For each device type (that is, combination of density and track count) there is a base minor number. To this base number, add the drive's number on its controller and 128 if the drive is on the secondary controller. In the following device tables, *n* represents the drive number.

Warning: if you use formats with more tracks than supported by your drive, you may cause it mechanical damage. Trying once if more tracks than the usual 40/80 are supported should not damage it, but no warranty is given for that. If you are not sure, don't create device entries for those formats, so as to prevent their usage.

Drive-independent device files which automatically detect the media format and capacity:

Name	Base minor #
fd*n*	0

5.25 inch double-density device files:

Name	Capacity KiB	Cyl.	Sect.	Heads	Base minor #
fd*n***d360**	360	40	9	2	4

5.25 inch high-density device files:

Name	Capacity KiB	Cyl.	Sect.	Heads	Base minor #
fd*n***h360**	360	40	9	2	20
fd*n***h410**	410	41	10	2	48
fd*n***h420**	420	42	10	2	64
fd*n***h720**	720	80	9	2	24
fd*n***h880**	880	80	11	2	80
fd*n***h1200**	1200	80	15	2	8
fd*n***h1440**	1440	80	18	2	40
fd*n***h1476**	1476	82	18	2	56
fd*n***h1494**	1494	83	18	2	72
fd*n***h1600**	1600	80	20	2	92

3.5 inch double-density device files:

Name	Capacity KiB	Cyl.	Sect.	Heads	Base minor #
fd*n***u360**	360	80	9	1	12
fd*n***u720**	720	80	9	2	16
fd*n***u800**	800	80	10	2	120
fd*n***u1040**	1040	80	13	2	84
fd*n***u1120**	1120	80	14	2	88

3.5 inch high-density device files:

Name	Capacity KiB	Cyl.	Sect.	Heads	Base minor #
fd*n***u360**	360	40	9	2	12
fd*n***u720**	720	80	9	2	16
fd*n***u820**	820	82	10	2	52
fd*n***u830**	830	83	10	2	68

3.5 inch extra-density device files:

Name	Capacity KiB	Cyl.	Sect.	Heads	Base minor #
fd*n*u2880	2880	80	36	2	32
fd*n*CompaQ	2880	80	36	2	36
fd*n*u3200	3200	80	40	2	104
fd*n*u3520	3520	80	44	2	108
fd*n*u3840	3840	80	48	2	112

DESCRIPTION

fd special files access the floppy disk drives in raw mode. The following *ioctl*(2) calls are supported by **fd** devices:

FDCLRPRM
clears the media information of a drive (geometry of disk in drive).

FDSETPRM
sets the media information of a drive. The media information will be lost when the media is changed.

FDDEFPRM
sets the media information of a drive (geometry of disk in drive). The media information will not be lost when the media is changed. This will disable autodetection. In order to reenable autodetection, you have to issue an **FDCLRPRM**.

FDGETDRVTYP
returns the type of a drive (name parameter). For formats which work in several drive types, **FDGETDRVTYP** returns a name which is appropriate for the oldest drive type which supports this format.

FDFLUSH
invalidates the buffer cache for the given drive.

FDSETMAXERRS
sets the error thresholds for reporting errors, aborting the operation, recalibrating, resetting, and reading sector by sector.

FDSETMAXERRS
gets the current error thresholds.

FDGETDRVTYP
gets the internal name of the drive.

FDWERRORCLR
clears the write error statistics.

FDWERRORGET
reads the write error statistics. These include the total number of write errors, the location and disk of the first write error, and the location and disk of the last write error. Disks are identified by a generation number which is incremented at (almost) each disk change.

FDTWADDLE
Switch the drive motor off for a few microseconds. This might be needed in order to access a disk whose sectors are too close together.

FDSETDRVPRM
sets various drive parameters.

FDGETDRVPRM
reads these parameters back.

FDGETDRVSTAT
gets the cached drive state (disk changed, write protected et al.)

FDPOLLDRVSTAT
polls the drive and return its state.

FDGETFDCSTAT
gets the floppy controller state.

FDRESET
resets the floppy controller under certain conditions.

FDRAWCMD
sends a raw command to the floppy controller.

For more precise information, consult also the <*linux/fd.h*> and <*linux/fdreg.h*> include files, as well as the *floppycontrol*(1) manual page.

FILES

*/dev/fd**

NOTES

The various formats permit reading and writing many types of disks. However, if a floppy is formatted with an inter-sector gap that is too small, performance may drop, to the point of needing a few seconds to access an entire track. To prevent this, use interleaved formats.

It is not possible to read floppies which are formatted using GCR (group code recording), which is used by Apple II and Macintosh computers (800k disks).

Reading floppies which are hard sectored (one hole per sector, with the index hole being a little skewed) is not supported. This used to be common with older 8-inch floppies.

NAME

full − always full device

CONFIGURATION

If your system does not have */dev/full* created already, it can be created with the following commands:

```
mknod -m 666 /dev/full c 1 7
chown root:root /dev/full
```

DESCRIPTION

The file */dev/full* has major device number 1 and minor device number 7.

Writes to the */dev/full* device fail with an **ENOSPC** error. This can be used to test how a program handles disk-full errors.

Reads from the */dev/full* device will return \0 characters.

Seeks on */dev/full* will always succeed.

FILES

/dev/full

NAME

fuse − Filesystem in Userspace (FUSE) device

SYNOPSIS

#include <linux/fuse.h>

DESCRIPTION

This device is the primary interface between the FUSE filesystem driver and a user-space process wishing to provide the filesystem (referred to in the rest of this manual page as the *filesystem daemon*). This manual page is intended for those interested in understanding the kernel interface itself. Those implementing a FUSE filesystem may wish to make use of a user-space library such as *libfuse* that abstracts away the low-level interface.

At its core, FUSE is a simple client-server protocol, in which the Linux kernel is the client and the daemon is the server. After obtaining a file descriptor for this device, the daemon may *read*(2) requests from that file descriptor and is expected to *write*(2) back its replies. It is important to note that a file descriptor is associated with a unique FUSE filesystem. In particular, opening a second copy of this device, will not allow access to resources created through the first file descriptor (and vice versa).

The basic protocol

Every message that is read by the daemon begins with a header described by the following structure:

```
struct fuse_in_header {
    uint32_t len;       /* Total length of the data,
                           including this header */
    uint32_t opcode;    /* The kind of operation (see below) */
    uint64_t unique;    /* A unique identifier for this request */
    uint64_t nodeid;    /* ID of the filesystem object
                           being operated on */
    uint32_t uid;       /* UID of the requesting process */
    uint32_t gid;       /* GID of the requesting process */
    uint32_t pid;       /* PID of the requesting process */
    uint32_t padding;
};
```

The header is followed by a variable-length data portion (which may be empty) specific to the requested operation (the requested operation is indicated by *opcode*).

The daemon should then process the request and if applicable send a reply (almost all operations require a reply; if they do not, this is documented below), by performing a *write*(2) to the file descriptor. All replies must start with the following header:

```
struct fuse_out_header {
    uint32_t len;       /* Total length of data written to
                           the file descriptor */
    int32_t  error;     /* Any error that occurred (0 if none) */
    uint64_t unique;    /* The value from the
                           corresponding request */
};
```

This header is also followed by (potentially empty) variable-sized data depending on the executed request. However, if the reply is an error reply (i.e., *error* is set), then no further payload data should be sent, independent of the request.

Exchanged messages

This section should contain documentation for each of the messages in the protocol. This manual page is currently incomplete, so not all messages are documented. For each message, first the struct sent by the kernel is given, followed by a description of the semantics of the message.

FUSE_INIT

```
struct fuse_init_in {
    uint32_t major;
    uint32_t minor;
    uint32_t max_readahead; /* Since protocol v7.6 */
    uint32_t flags;         /* Since protocol v7.6 */
```

```
};
```

This is the first request sent by the kernel to the daemon. It is used to negotiate the protocol version and other filesystem parameters. Note that the protocol version may affect the layout of any structure in the protocol (including this structure). The daemon must thus remember the negotiated version and flags for each session. As of the writing of this man page, the highest supported kernel protocol version is *7.26*.

Users should be aware that the descriptions in this manual page may be incomplete or incorrect for older or more recent protocol versions.

The reply for this request has the following format:

```
struct fuse_init_out {
    uint32_t major;
    uint32_t minor;
    uint32_t max_readahead;   /* Since v7.6 */
    uint32_t flags;           /* Since v7.6; some flags bits
                                 were introduced later */
    uint16_t max_background;  /* Since v7.13 */
    uint16_t congestion_threshold;  /* Since v7.13 */
    uint32_t max_write;       /* Since v7.5 */
    uint32_t time_gran;       /* Since v7.6 */
    uint32_t unused[9];
};
```

If the major version supported by the kernel is larger than that supported by the daemon, the reply shall consist of only *uint32_t major* (following the usual header), indicating the largest major version supported by the daemon. The kernel will then issue a new **FUSE_INIT** request conforming to the older version. In the reverse case, the daemon should quietly fall back to the kernel's major version.

The negotiated minor version is considered to be the minimum of the minor versions provided by the daemon and the kernel and both parties should use the protocol corresponding to said minor version.

FUSE_GETATTR

```
struct fuse_getattr_in {
    uint32_t getattr_flags;
    uint32_t dummy;
    uint64_t fh;      /* Set only if
                         (getattr_flags & FUSE_GETATTR_FH)
};
```

The requested operation is to compute the attributes to be returned by *stat*(2) and similar operations for the given filesystem object. The object for which the attributes should be computed is indicated either by *header->nodeid* or, if the **FUSE_GETATTR_FH** flag is set, by the file handle *fh*. The latter case of operation is analogous to *fstat*(2).

For performance reasons, these attributes may be cached in the kernel for a specified duration of time. While the cache timeout has not been exceeded, the attributes will be served from the cache and will not cause additional **FUSE_GETATTR** requests.

The computed attributes and the requested cache timeout should then be returned in the following structure:

```
struct fuse_attr_out {
    /* Attribute cache duration (seconds + nanoseconds) */
    uint64_t attr_valid;
    uint32_t attr_valid_nsec;
    uint32_t dummy;
    struct fuse_attr {
        uint64_t ino;
        uint64_t size;
        uint64_t blocks;
```

```
            uint64_t atime;
            uint64_t mtime;
            uint64_t ctime;
            uint32_t atimensec;
            uint32_t mtimensec;
            uint32_t ctimensec;
            uint32_t mode;
            uint32_t nlink;
            uint32_t uid;
            uint32_t gid;
            uint32_t rdev;
            uint32_t blksize;
            uint32_t padding;
        } attr;
    };
```

FUSE_ACCESS

```
    struct fuse_access_in {
        uint32_t mask;
        uint32_t padding;
    };
```

If the *default_permissions* mount options is not used, this request may be used for permissions checking. No reply data is expected, but errors may be indicated as usual by setting the *error* field in the reply header (in particular, access denied errors may be indicated by returning **-EACCES**).

FUSE_OPEN and **FUSE_OPENDIR**

```
    struct fuse_open_in {
        uint32_t flags;     /* The flags that were passed
                               to the open(2) */
        uint32_t unused;
    };
```

The requested operation is to open the node indicated by *header->nodeid*. The exact semantics of what this means will depend on the filesystem being implemented. However, at the very least the filesystem should validate that the requested *flags* are valid for the indicated resource and then send a reply with the following format:

```
    struct fuse_open_out {
        uint64_t fh;
        uint32_t open_flags;
        uint32_t padding;
    };
```

The *fh* field is an opaque identifier that the kernel will use to refer to this resource The *open_flags* field is a bit mask of any number of the flags that indicate properties of this file handle to the kernel:

FOPEN_DIRECT_IO
: Bypass page cache for this open file.

FOPEN_KEEP_CACHE
: Don't invalidate the data cache on open.

FOPEN_NONSEEKABLE
: The file is not seekable.

FUSE_READ and **FUSE_READDIR**

```
    struct fuse_read_in {
        uint64_t fh;
        uint64_t offset;
        uint32_t size;
        uint32_t read_flags;
```

```
    uint64_t lock_owner;
    uint32_t flags;
    uint32_t padding;
};
```

The requested action is to read up to *size* bytes of the file or directory, starting at *offset*. The bytes should be returned directly following the usual reply header.

FUSE_INTERRUPT

```
struct fuse_interrupt_in {
    uint64_t unique;
};
```

The requested action is to cancel the pending operation indicated by *unique*. This request requires no response. However, receipt of this message does not by itself cancel the indicated operation. The kernel will still expect a reply to said operation (e.g., an *EINTR* error or a short read). At most one **FUSE_INTERRUPT** request will be issued for a given operation. After issuing said operation, the kernel will wait uninterruptibly for completion of the indicated request.

FUSE_LOOKUP

Directly following the header is a filename to be looked up in the directory indicated by *header->nodeid*. The expected reply is of the form:

```
struct fuse_entry_out {
    uint64_t nodeid;            /* Inode ID */
    uint64_t generation;        /* Inode generation */
    uint64_t entry_valid;
    uint64_t attr_valid;
    uint32_t entry_valid_nsec;
    uint32_t attr_valid_nsec;
    struct fuse_attr attr;
};
```

The combination of *nodeid* and *generation* must be unique for the filesystem's lifetime.

The interpretation of timeouts and *attr* is as for **FUSE_GETATTR**.

FUSE_FLUSH

```
struct fuse_flush_in {
    uint64_t fh;
    uint32_t unused;
    uint32_t padding;
    uint64_t lock_owner;
};
```

The requested action is to flush any pending changes to the indicated file handle. No reply data is expected. However, an empty reply message still needs to be issued once the flush operation is complete.

FUSE_RELEASE and **FUSE_RELEASEDIR**

```
struct fuse_release_in {
    uint64_t fh;
    uint32_t flags;
    uint32_t release_flags;
    uint64_t lock_owner;
};
```

These are the converse of **FUSE_OPEN** and **FUSE_OPENDIR** respectively. The daemon may now free any resources associated with the file handle *fh* as the kernel will no longer refer to it. There is no reply data associated with this request, but a reply still needs to be issued once the request has been completely processed.

FUSE_STATFS

This operation implements *statfs*(2) for this filesystem. There is no input data associated with this request. The expected reply data has the following structure:

```
struct fuse_kstatfs {
    uint64_t blocks;
    uint64_t bfree;
    uint64_t bavail;
    uint64_t files;
    uint64_t ffree;
    uint32_t bsize;
    uint32_t namelen;
    uint32_t frsize;
    uint32_t padding;
    uint32_t spare[6];
};

struct fuse_statfs_out {
    struct fuse_kstatfs st;
};
```

For the interpretation of these fields, see *statfs*(2).

ERRORS

E2BIG Returned from *read*(2) operations when the kernel's request is too large for the provided buffer and the request was **FUSE_SETXATTR**.

EINVAL
Returned from *write*(2) if validation of the reply failed. Not all mistakes in replies will be caught by this validation. However, basic mistakes, such as short replies or an incorrect *unique* value, are detected.

EIO Returned from *read*(2) operations when the kernel's request is too large for the provided buffer.

Note: There are various ways in which incorrect use of these interfaces can cause operations on the provided filesystem's files and directories to fail with **EIO**. Among the possible incorrect uses are:

- changing *mode & S_IFMT* for an inode that has previously been reported to the kernel; or
- giving replies to the kernel that are shorter than what the kernel expected.

ENODEV
Returned from *read*(2) and *write*(2) if the FUSE filesystem was unmounted.

EPERM
Returned from operations on a */dev/fuse* file descriptor that has not been mounted.

STANDARDS

Linux.

NAME

hd − MFM/IDE hard disk devices

DESCRIPTION

The **hd*** devices are block devices to access MFM/IDE hard disk drives in raw mode. The master drive on the primary IDE controller (major device number 3) is **hda**; the slave drive is **hdb**. The master drive of the second controller (major device number 22) is **hdc** and the slave is **hdd**.

General IDE block device names have the form **hd***X*, or **hd***XP*, where *X* is a letter denoting the physical drive, and *P* is a number denoting the partition on that physical drive. The first form, **hd***X*, is used to address the whole drive. Partition numbers are assigned in the order the partitions are discovered, and only nonempty, nonextended partitions get a number. However, partition numbers 1–4 are given to the four partitions described in the MBR (the "primary" partitions), regardless of whether they are unused or extended. Thus, the first logical partition will be **hd***X***5**. Both DOS-type partitioning and BSD-disklabel partitioning are supported. You can have at most 63 partitions on an IDE disk.

For example, */dev/hda* refers to all of the first IDE drive in the system; and */dev/hdb3* refers to the third DOS "primary" partition on the second one.

They are typically created by:

```
mknod −m 660 /dev/hda b 3 0
mknod −m 660 /dev/hda1 b 3 1
mknod −m 660 /dev/hda2 b 3 2
...
mknod −m 660 /dev/hda8 b 3 8
mknod −m 660 /dev/hdb b 3 64
mknod −m 660 /dev/hdb1 b 3 65
mknod −m 660 /dev/hdb2 b 3 66
...
mknod −m 660 /dev/hdb8 b 3 72
chown root:disk /dev/hd*
```

NAME

hpsa − HP Smart Array SCSI driver

SYNOPSIS

modprobe hpsa [hpsa_allow_any=1]

DESCRIPTION

hpsa is a SCSI driver for HP Smart Array RAID controllers.

Options

hpsa_allow_any=1: This option allows the driver to attempt to operate on any HP Smart Array hardware RAID controller, even if it is not explicitly known to the driver. This allows newer hardware to work with older drivers. Typically this is used to allow installation of operating systems from media that predates the RAID controller, though it may also be used to enable **hpsa** to drive older controllers that would normally be handled by the *cciss*(4) driver. These older boards have not been tested and are not supported with **hpsa**, and *cciss*(4) should still be used for these.

Supported hardware

The **hpsa** driver supports the following Smart Array boards:

Smart Array P700M
Smart Array P212
Smart Array P410
Smart Array P410i
Smart Array P411
Smart Array P812
Smart Array P712m
Smart Array P711m
StorageWorks P1210m

Since Linux 4.14, the following Smart Array boards are also supported:

Smart Array 5300
Smart Array 5312
Smart Array 532
Smart Array 5i
Smart Array 6400
Smart Array 6400 EM
Smart Array 641
Smart Array 642
Smart Array 6i
Smart Array E200
Smart Array E200i
Smart Array E200i
Smart Array E200i
Smart Array E200i
Smart Array E500
Smart Array P400
Smart Array P400i
Smart Array P600
Smart Array P700m
Smart Array P800

Configuration details

To configure HP Smart Array controllers, use the HP Array Configuration Utility (either *hpacuxe*(8) or *hpacucli*(8)) or the Offline ROM-based Configuration Utility (ORCA) run from the Smart Array's option ROM at boot time.

FILES

Device nodes

Logical drives are accessed via the SCSI disk driver (**sd**(4)), tape drives via the SCSI tape driver (**st**(4)), and the RAID controller via the SCSI generic driver (**sg**(4)), with device nodes named */dev/sd**, */dev/st**, and */dev/sg**, respectively.

HPSA-specific host attribute files in /sys

/sys/class/scsi_host/host/rescan*

This is a write-only attribute. Writing to this attribute will cause the driver to scan for new, changed, or removed devices (e.g., hot-plugged tape drives, or newly configured or deleted logical drives, etc.) and notify the SCSI midlayer of any changes detected. Normally a rescan is triggered automatically by HP's Array Configuration Utility (either the GUI or the command-line variety); thus, for logical drive changes, the user should not normally have to use this attribute. This attribute may be useful when hot plugging devices like tape drives, or entire storage boxes containing preconfigured logical drives.

/sys/class/scsi_host/host/firmware_revision*

This attribute contains the firmware version of the Smart Array.

For example:

```
# cd /sys/class/scsi_host/host4
# cat firmware_revision
7.14
```

HPSA-specific disk attribute files in /sys

/sys/class/scsi_disk/c:b:t:l/device/unique_id

This attribute contains a 32 hex-digit unique ID for each logical drive.

For example:

```
# cd /sys/class/scsi_disk/4:0:0:0/device
# cat unique_id
600508B1001044395355323037570F77
```

/sys/class/scsi_disk/c:b:t:l/device/raid_level

This attribute contains the RAID level of each logical drive.

For example:

```
# cd /sys/class/scsi_disk/4:0:0:0/device
# cat raid_level
RAID 0
```

/sys/class/scsi_disk/c:b:t:l/device/lunid

This attribute contains the 16 hex-digit (8 byte) LUN ID by which a logical drive or physical device can be addressed. *c*:*b*:*t*:*l* are the controller, bus, target, and lun of the device.

For example:

```
# cd /sys/class/scsi_disk/4:0:0:0/device
# cat lunid
0x0000004000000000
```

Supported ioctl() operations

For compatibility with applications written for the *cciss*(4) driver, many, but not all of the ioctls supported by the *cciss*(4) driver are also supported by the **hpsa** driver. The data structures used by these ioctls are described in the Linux kernel source file *include/linux/cciss_ioctl.h*.

CCISS_DEREGDISK
CCISS_REGNEWDISK
CCISS_REGNEWD

These three ioctls all do exactly the same thing, which is to cause the driver to rescan for new devices. This does exactly the same thing as writing to the hpsa-specific host "rescan" attribute.

CCISS_GETPCIINFO

Returns PCI domain, bus, device, and function and "board ID" (PCI subsystem ID).

CCISS_GETDRIVVER

Returns driver version in three bytes encoded as:

```
(major_version << 16) | (minor_version << 8) |
    (subminor_version)
```

CCISS_PASSTHRU
CCISS_BIG_PASSTHRU
Allows "BMIC" and "CISS" commands to be passed through to the Smart Array. These are used extensively by the HP Array Configuration Utility, SNMP storage agents, and so on. See *cciss_vol_status* at for some examples.

NAME

initrd − boot loader initialized RAM disk

CONFIGURATION

/dev/initrd is a read-only block device assigned major number 1 and minor number 250. Typically */dev/initrd* is owned by root:disk with mode 0400 (read access by root only). If the Linux system does not have */dev/initrd* already created, it can be created with the following commands:

```
mknod −m 400 /dev/initrd b 1 250
chown root:disk /dev/initrd
```

Also, support for both "RAM disk" and "Initial RAM disk" (e.g., **CONFIG_BLK_DEV_RAM=y** and **CONFIG_BLK_DEV_INITRD=y**) must be compiled directly into the Linux kernel to use */dev/initrd*. When using */dev/initrd*, the RAM disk driver cannot be loaded as a module.

DESCRIPTION

The special file */dev/initrd* is a read-only block device. This device is a RAM disk that is initialized (e.g., loaded) by the boot loader before the kernel is started. The kernel then can use */dev/initrd*'s contents for a two-phase system boot-up.

In the first boot-up phase, the kernel starts up and mounts an initial root filesystem from the contents of */dev/initrd* (e.g., RAM disk initialized by the boot loader). In the second phase, additional drivers or other modules are loaded from the initial root device's contents. After loading the additional modules, a new root filesystem (i.e., the normal root filesystem) is mounted from a different device.

Boot-up operation

When booting up with **initrd**, the system boots as follows:

(1) The boot loader loads the kernel program and */dev/initrd*'s contents into memory.

(2) On kernel startup, the kernel uncompresses and copies the contents of the device */dev/initrd* onto device */dev/ram0* and then frees the memory used by */dev/initrd*.

(3) The kernel then read-write mounts the device */dev/ram0* as the initial root filesystem.

(4) If the indicated normal root filesystem is also the initial root filesystem (e.g., */dev/ram0*) then the kernel skips to the last step for the usual boot sequence.

(5) If the executable file */linuxrc* is present in the initial root filesystem, */linuxrc* is executed with UID 0. (The file */linuxrc* must have executable permission. The file */linuxrc* can be any valid executable, including a shell script.)

(6) If */linuxrc* is not executed or when */linuxrc* terminates, the normal root filesystem is mounted. (If */linuxrc* exits with any filesystems mounted on the initial root filesystem, then the behavior of the kernel is **UNSPECIFIED**. See the NOTES section for the current kernel behavior.)

(7) If the normal root filesystem has a directory */initrd*, the device */dev/ram0* is moved from / to */initrd*. Otherwise, if the directory */initrd* does not exist, the device */dev/ram0* is unmounted. (When moved from / to */initrd*, */dev/ram0* is not unmounted and therefore processes can remain running from */dev/ram0*. If directory */initrd* does not exist on the normal root filesystem and any processes remain running from */dev/ram0* when */linuxrc* exits, the behavior of the kernel is **UNSPECIFIED**. See the NOTES section for the current kernel behavior.)

(8) The usual boot sequence (e.g., invocation of */sbin/init*) is performed on the normal root filesystem.

Options

The following boot loader options, when used with **initrd**, affect the kernel's boot-up operation:

initrd= *filename*

Specifies the file to load as the contents of */dev/initrd*. For **LOADLIN** this is a command-line option. For **LILO** you have to use this command in the **LILO** configuration file */etc/lilo.config*. The filename specified with this option will typically be a gzipped filesystem image.

noinitrd

This boot option disables the two-phase boot-up operation. The kernel performs the usual boot sequence as if */dev/initrd* was not initialized. With this option, any contents of */dev/initrd* loaded into memory by the boot loader contents are preserved. This option permits the contents of */dev/initrd* to be any data and need not be limited to a filesystem image. However,

device */dev/initrd* is read-only and can be read only one time after system startup.

root=*device-name*
Specifies the device to be used as the normal root filesystem. For **LOADLIN** this is a command-line option. For **LILO** this is a boot time option or can be used as an option line in the **LILO** configuration file */etc/lilo.config*. The device specified by this option must be a mountable device having a suitable root filesystem.

Changing the normal root filesystem

By default, the kernel's settings (e.g., set in the kernel file with *rdev*(8) or compiled into the kernel file), or the boot loader option setting is used for the normal root filesystems. For an NFS-mounted normal root filesystem, one has to use the **nfs_root_name** and **nfs_root_addrs** boot options to give the NFS settings. For more information on NFS-mounted root see the kernel documentation file *Documentation/filesystems/nfs/nfsroot.txt* (or *Documentation/filesystems/nfsroot.txt* before Linux 2.6.33). For more information on setting the root filesystem see also the **LILO** and **LOADLIN** documentation.

It is also possible for the */linuxrc* executable to change the normal root device. For */linuxrc* to change the normal root device, */proc* must be mounted. After mounting */proc*, */linuxrc* changes the normal root device by writing into the proc files */proc/sys/kernel/real−root−dev*, */proc/sys/kernel/nfs−root−name*, and */proc/sys/kernel/nfs−root−addrs*. For a physical root device, the root device is changed by having */linuxrc* write the new root filesystem device number into */proc/sys/kernel/real−root−dev*. For an NFS root filesystem, the root device is changed by having */linuxrc* write the NFS setting into files */proc/sys/kernel/nfs−root−name* and */proc/sys/kernel/nfs−root−addrs* and then writing 0xff (e.g., the pseudo-NFS-device number) into file */proc/sys/kernel/real−root−dev*. For example, the following shell command line would change the normal root device to */dev/hdb1*:

```
echo 0x365 >/proc/sys/kernel/real-root-dev
```

For an NFS example, the following shell command lines would change the normal root device to the NFS directory */var/nfsroot* on a local networked NFS server with IP number 193.8.232.7 for a system with IP number 193.8.232.2 and named "idefix":

```
echo /var/nfsroot >/proc/sys/kernel/nfs-root-name
echo 193.8.232.2:193.8.232.7::255.255.255.0:idefix \
    >/proc/sys/kernel/nfs-root-addrs
echo 255 >/proc/sys/kernel/real-root-dev
```

Note: The use of */proc/sys/kernel/real−root−dev* to change the root filesystem is obsolete. See the Linux kernel source file *Documentation/admin−guide/initrd.rst* (or *Documentation/initrd.txt* before Linux 4.10) as well as *pivot_root*(2) and *pivot_root*(8) for information on the modern method of changing the root filesystem.

Usage

The main motivation for implementing **initrd** was to allow for modular kernel configuration at system installation.

A possible system installation scenario is as follows:

(1) The loader program boots from floppy or other media with a minimal kernel (e.g., support for */dev/ram*, */dev/initrd*, and the ext2 filesystem) and loads */dev/initrd* with a gzipped version of the initial filesystem.

(2) The executable */linuxrc* determines what is needed to (1) mount the normal root filesystem (i.e., device type, device drivers, filesystem) and (2) the distribution media (e.g., CD-ROM, network, tape, ...). This can be done by asking the user, by auto-probing, or by using a hybrid approach.

(3) The executable */linuxrc* loads the necessary modules from the initial root filesystem.

(4) The executable */linuxrc* creates and populates the root filesystem. (At this stage the normal root filesystem does not have to be a completed system yet.)

(5) The executable */linuxrc* sets */proc/sys/kernel/real−root−dev*, unmounts */proc*, the normal root filesystem and any other filesystems it has mounted, and then terminates.

(6) The kernel then mounts the normal root filesystem.

(7) Now that the filesystem is accessible and intact, the boot loader can be installed.

(8) The boot loader is configured to load into */dev/initrd* a filesystem with the set of modules that was used to bring up the system. (e.g., device */dev/ram0* can be modified, then unmounted, and finally, the image is written from */dev/ram0* to a file.)

(9) The system is now bootable and additional installation tasks can be performed.

The key role of */dev/initrd* in the above is to reuse the configuration data during normal system operation without requiring initial kernel selection, a large generic kernel or, recompiling the kernel.

A second scenario is for installations where Linux runs on systems with different hardware configurations in a single administrative network. In such cases, it may be desirable to use only a small set of kernels (ideally only one) and to keep the system-specific part of configuration information as small as possible. In this case, create a common file with all needed modules. Then, only the */linuxrc* file or a file executed by */linuxrc* would be different.

A third scenario is more convenient recovery disks. Because information like the location of the root filesystem partition is not needed at boot time, the system loaded from */dev/initrd* can use a dialog and/or auto-detection followed by a possible sanity check.

Last but not least, Linux distributions on CD-ROM may use **initrd** for easy installation from the CD-ROM. The distribution can use **LOADLIN** to directly load */dev/initrd* from CD-ROM without the need of any floppies. The distribution could also use a **LILO** boot floppy and then bootstrap a bigger RAM disk via */dev/initrd* from the CD-ROM.

FILES

/dev/initrd
/dev/ram0
/linuxrc
/initrd

NOTES

- With the current kernel, any filesystems that remain mounted when */dev/ram0* is moved from / to */initrd* continue to be accessible. However, the */proc/mounts* entries are not updated.
- With the current kernel, if directory */initrd* does not exist, then */dev/ram0* will **not** be fully unmounted if */dev/ram0* is used by any process or has any filesystem mounted on it. If */dev/ram0* is **not** fully unmounted, then */dev/ram0* will remain in memory.
- Users of */dev/initrd* should not depend on the behavior given in the above notes. The behavior may change in future versions of the Linux kernel.

NAME

lirc − lirc devices

DESCRIPTION

The */dev/lirc** character devices provide a low-level bidirectional interface to infra-red (IR) remotes. Most of these devices can receive, and some can send. When receiving or sending data, the driver works in two different modes depending on the underlying hardware.

Some hardware (typically TV-cards) decodes the IR signal internally and provides decoded button presses as scancode values. Drivers for this kind of hardware work in **LIRC_MODE_SCANCODE** mode. Such hardware usually does not support sending IR signals. Furthermore, such hardware can only decode a limited set of IR protocols, usually only the protocol of the specific remote which is bundled with, for example, a TV-card.

Other hardware provides a stream of pulse/space durations. Such drivers work in **LIRC_MODE_MODE2** mode. Such hardware can be used with (almost) any kind of remote. This type of hardware can also be used in **LIRC_MODE_SCANCODE** mode, in which case the kernel IR decoders will decode the IR. These decoders can be written in extended BPF (see *bpf*(2)) and attached to the **lirc** device. Sometimes, this kind of hardware also supports sending IR data.

The **LIRC_GET_FEATURES** ioctl (see below) allows probing for whether receiving and sending is supported, and in which modes, amongst other features.

Reading input with the LIRC_MODE_MODE2 mode

In the **LIRC_MODE_MODE2 mode**, the data returned by *read*(2) provides 32-bit values representing a space or a pulse duration. The time of the duration (microseconds) is encoded in the lower 24 bits. Pulse (also known as flash) indicates a duration of infrared light being detected, and space (also known as gap) indicates a duration with no infrared. If the duration of space exceeds the inactivity timeout, a special timeout package is delivered, which marks the end of a message. The upper 8 bits indicate the type of package:

LIRC_MODE2_SPACE
Value reflects a space duration (microseconds).

LIRC_MODE2_PULSE
Value reflects a pulse duration (microseconds).

LIRC_MODE2_FREQUENCY
Value reflects a frequency (Hz); see the **LIRC_SET_MEASURE_CARRIER_MODE** ioctl.

LIRC_MODE2_TIMEOUT
Value reflects a space duration (microseconds). The package reflects a timeout; see the **LIRC_SET_REC_TIMEOUT_REPORTS** ioctl.

LIRC_MODE2_OVERFLOW
The IR receiver encountered an overflow, and as a result data is missing (since Linux 5.18).

Reading input with the LIRC_MODE_SCANCODE mode

In the **LIRC_MODE_SCANCODE** mode, the data returned by *read*(2) reflects decoded button presses, in the struct *lirc_scancode*. The scancode is stored in the *scancode* field, and the IR protocol is stored in *rc_proto*. This field has one the values of the *enum rc_proto*.

Writing output with the LIRC_MODE_PULSE mode

The data written to the character device using *write*(2) is a pulse/space sequence of integer values. Pulses and spaces are only marked implicitly by their position. The data must start and end with a pulse, thus it must always include an odd number of samples. The *write*(2) function blocks until the data has been transmitted by the hardware. If more data is provided than the hardware can send, the *write*(2) call fails with the error **EINVAL**.

Writing output with the LIRC_MODE_SCANCODE mode

The data written to the character devices must be a single struct *lirc_scancode*. The *scancode* and *rc_proto* fields must filled in, all other fields must be 0. The kernel IR encoders will convert the scancode to pulses and spaces. The protocol or scancode is invalid, or the **lirc** device cannot transmit.

IOCTL COMMANDS

#include <linux/lirc.h> /* But see BUGS */

int ioctl(int fd, int cmd, int *val);

The following *ioctl*(2) operations are provided by the **lirc** character device to probe or change specific **lirc** hardware settings.

Always Supported Commands

*/dev/lirc** devices always support the following commands:

LIRC_GET_FEATURES (*void*)

Returns a bit mask of combined features bits; see FEATURES.

If a device returns an error code for **LIRC_GET_FEATURES**, it is safe to assume it is not a **lirc** device.

Optional Commands

Some **lirc** devices support the commands listed below. Unless otherwise stated, these fail with the error **ENOTTY** if the operation isn't supported, or with the error **EINVAL** if the operation failed, or invalid arguments were provided. If a driver does not announce support of certain features, invoking the corresponding ioctls will fail with the error **ENOTTY**.

LIRC_GET_REC_MODE (*void*)

If the **lirc** device has no receiver, this operation fails with the error **ENOTTY**. Otherwise, it returns the receive mode, which will be one of:

LIRC_MODE_MODE2

The driver returns a sequence of pulse/space durations.

LIRC_MODE_SCANCODE

The driver returns struct *lirc_scancode* values, each of which represents a decoded button press.

LIRC_SET_REC_MODE (*int*)

Set the receive mode. *val* is either **LIRC_MODE_SCANCODE** or **LIRC_MODE_MODE2**. If the **lirc** device has no receiver, this operation fails with the error **ENOTTY.**

LIRC_GET_SEND_MODE (*void*)

Return the send mode. **LIRC_MODE_PULSE** or **LIRC_MODE_SCANCODE** is supported. If the **lirc** device cannot send, this operation fails with the error **ENOTTY.**

LIRC_SET_SEND_MODE (*int*)

Set the send mode. *val* is either **LIRC_MODE_SCANCODE** or **LIRC_MODE_PULSE**. If the **lirc** device cannot send, this operation fails with the error **ENOTTY**.

LIRC_SET_SEND_CARRIER (*int*)

Set the modulation frequency. The argument is the frequency (Hz).

LIRC_SET_SEND_DUTY_CYCLE (*int*)

Set the carrier duty cycle. *val* is a number in the range [0,100] which describes the pulse width as a percentage of the total cycle. Currently, no special meaning is defined for 0 or 100, but the values are reserved for future use.

LIRC_GET_MIN_TIMEOUT(*void***)**
LIRC_GET_MAX_TIMEOUT(*void***)**

Some devices have internal timers that can be used to detect when there has been no IR activity for a long time. This can help *lircd*(8) in detecting that an IR signal is finished and can speed up the decoding process. These operations return integer values with the minimum/maximum timeout that can be set (microseconds). Some devices have a fixed timeout. For such drivers, **LIRC_GET_MIN_TIMEOUT** and **LIRC_GET_MAX_TIMEOUT** will fail with the error **ENOTTY**.

LIRC_SET_REC_TIMEOUT (*int*)

Set the integer value for IR inactivity timeout (microseconds). To be accepted, the value must be within the limits defined by **LIRC_GET_MIN_TIMEOUT** and **LIRC_GET_MAX_TIMEOUT**. A value of 0 (if supported by the hardware) disables all hardware timeouts and data should be reported as soon as possible. If the exact value cannot be set, then the next possible value *greater* than the given value should be set.

LIRC_GET_REC_TIMEOUT (*void*)
Return the current inactivity timeout (microseconds). Available since Linux 4.18.

LIRC_SET_REC_TIMEOUT_REPORTS (*int*)
Enable (*val* is 1) or disable (*val* is 0) timeout packages in **LIRC_MODE_MODE2**. The behavior of this operation has varied across kernel versions:

- Since Linux 5.17: timeout packages are always enabled and this ioctl is a no-op.
- Since Linux 4.16: timeout packages are enabled by default. Each time the **lirc** device is opened, the **LIRC_SET_REC_TIMEOUT** operation can be used to disable (and, if desired, to later re-enable) the timeout on the file descriptor.
- In Linux 4.15 and earlier: timeout packages are disabled by default, and enabling them (via **LIRC_SET_REC_TIMEOUT**) on any file descriptor associated with the **lirc** device has the effect of enabling timeouts for all file descriptors referring to that device (until timeouts are disabled again).

LIRC_SET_REC_CARRIER (*int*)
Set the upper bound of the receive carrier frequency (Hz). See **LIRC_SET_REC_CARRIER_RANGE**.

LIRC_SET_REC_CARRIER_RANGE (*int*)
Sets the lower bound of the receive carrier frequency (Hz). For this to take affect, first set the lower bound using the **LIRC_SET_REC_CARRIER_RANGE** ioctl, and then the upper bound using the **LIRC_SET_REC_CARRIER** ioctl.

LIRC_SET_MEASURE_CARRIER_MODE (*int*)
Enable (*val* is 1) or disable (*val* is 0) the measure mode. If enabled, from the next key press on, the driver will send **LIRC_MODE2_FREQUENCY** packets. By default, this should be turned off.

LIRC_GET_REC_RESOLUTION (*void*)
Return the driver resolution (microseconds).

LIRC_SET_TRANSMITTER_MASK (*int*)
Enable the set of transmitters specified in *val*, which contains a bit mask where each enabled transmitter is a 1. The first transmitter is encoded by the least significant bit, and so on. When an invalid bit mask is given, for example a bit is set even though the device does not have so many transmitters, this operation returns the number of available transmitters and does nothing otherwise.

LIRC_SET_WIDEBAND_RECEIVER (*int*)
Some devices are equipped with a special wide band receiver which is intended to be used to learn the output of an existing remote. This ioctl can be used to enable (*val* equals 1) or disable (*val* equals 0) this functionality. This might be useful for devices that otherwise have narrow band receivers that prevent them to be used with certain remotes. Wide band receivers may also be more precise. On the other hand, their disadvantage usually is reduced range of reception.

Note: wide band receiver may be implicitly enabled if you enable carrier reports. In that case, it will be disabled as soon as you disable carrier reports. Trying to disable a wide band receiver while carrier reports are active will do nothing.

FEATURES

the **LIRC_GET_FEATURES** ioctl returns a bit mask describing features of the driver. The following bits may be returned in the mask:

LIRC_CAN_REC_MODE2
The driver is capable of receiving using **LIRC_MODE_MODE2**.

LIRC_CAN_REC_SCANCODE
The driver is capable of receiving using **LIRC_MODE_SCANCODE**.

LIRC_CAN_SET_SEND_CARRIER
The driver supports changing the modulation frequency using **LIRC_SET_SEND_CARRIER**.

LIRC_CAN_SET_SEND_DUTY_CYCLE
The driver supports changing the duty cycle using **LIRC_SET_SEND_DUTY_CYCLE**.

LIRC_CAN_SET_TRANSMITTER_MASK
The driver supports changing the active transmitter(s) using **LIRC_SET_TRANSMITTER_MASK**.

LIRC_CAN_SET_REC_CARRIER
The driver supports setting the receive carrier frequency using **LIRC_SET_REC_CARRIER**. Any **lirc** device since the drivers were merged in Linux 2.6.36 must have **LIRC_CAN_SET_REC_CARRIER_RANGE** set if **LIRC_CAN_SET_REC_CARRIER** feature is set.

LIRC_CAN_SET_REC_CARRIER_RANGE
The driver supports **LIRC_SET_REC_CARRIER_RANGE**. The lower bound of the carrier must first be set using the **LIRC_SET_REC_CARRIER_RANGE** ioctl, before using the **LIRC_SET_REC_CARRIER** ioctl to set the upper bound.

LIRC_CAN_GET_REC_RESOLUTION
The driver supports **LIRC_GET_REC_RESOLUTION**.

LIRC_CAN_SET_REC_TIMEOUT
The driver supports **LIRC_SET_REC_TIMEOUT**.

LIRC_CAN_MEASURE_CARRIER
The driver supports measuring of the modulation frequency using **LIRC_SET_MEASURE_CARRIER_MODE**.

LIRC_CAN_USE_WIDEBAND_RECEIVER
The driver supports learning mode using **LIRC_SET_WIDEBAND_RECEIVER**.

LIRC_CAN_SEND_PULSE
The driver supports sending using **LIRC_MODE_PULSE** or **LIRC_MODE_SCANCODE**

BUGS

Using these devices requires the kernel source header file *lirc.h*. This file is not available before Linux 4.6. Users of older kernels could use the file bundled in .

ir−ctl(1), **lircd**(8), **bpf**(2)

NAME

loop, loop-control − loop devices

SYNOPSIS

#include <linux/loop.h>

DESCRIPTION

The loop device is a block device that maps its data blocks not to a physical device such as a hard disk or optical disk drive, but to the blocks of a regular file in a filesystem or to another block device. This can be useful for example to provide a block device for a filesystem image stored in a file, so that it can be mounted with the *mount*(8) command. You could do

```
$ dd if=/dev/zero of=file.img bs=1MiB count=10
$ sudo losetup /dev/loop4 file.img
$ sudo mkfs -t ext4 /dev/loop4
$ sudo mkdir /myloopdev
$ sudo mount /dev/loop4 /myloopdev
```

See *losetup*(8) for another example.

A transfer function can be specified for each loop device for encryption and decryption purposes.

The following *ioctl*(2) operations are provided by the loop block device:

LOOP_SET_FD
Associate the loop device with the open file whose file descriptor is passed as the (third) *ioctl*(2) argument.

LOOP_CLR_FD
Disassociate the loop device from any file descriptor.

LOOP_SET_STATUS
Set the status of the loop device using the (third) *ioctl*(2) argument. This argument is a pointer to a *loop_info* structure, defined in <*linux/loop.h*> as:

```
struct loop_info {
    int           lo_number;      /* ioctl r/o */
    dev_t         lo_device;      /* ioctl r/o */
    unsigned long lo_inode;       /* ioctl r/o */
    dev_t         lo_rdevice;     /* ioctl r/o */
    int           lo_offset;
    int           lo_encrypt_type;
    int           lo_encrypt_key_size;  /* ioctl w/o */
    int           lo_flags;       /* ioctl r/w (r/o before
                                     Linux 2.6.25) */
    char          lo_name[LO_NAME_SIZE];
    unsigned char lo_encrypt_key[LO_KEY_SIZE];
                                  /* ioctl w/o */
    unsigned long lo_init[2];
    char          reserved[4];
};
```

The encryption type (*lo_encrypt_type*) should be one of **LO_CRYPT_NONE**, **LO_CRYPT_XOR**, **LO_CRYPT_DES**, **LO_CRYPT_FISH2**, **LO_CRYPT_BLOW**, **LO_CRYPT_CAST128**, **LO_CRYPT_IDEA**, **LO_CRYPT_DUMMY**, **LO_CRYPT_SKIPJACK**, or (since Linux 2.6.0) **LO_CRYPT_CRYPTOAPI**.

The *lo_flags* field is a bit mask that can include zero or more of the following:

LO_FLAGS_READ_ONLY
The loopback device is read-only.

LO_FLAGS_AUTOCLEAR (since Linux 2.6.25)
The loopback device will autodestruct on last close.

LO_FLAGS_PARTSCAN (since Linux 3.2)
Allow automatic partition scanning.

LO_FLAGS_DIRECT_IO (since Linux 4.10)
Use direct I/O mode to access the backing file.

The only *lo_flags* that can be modified by **LOOP_SET_STATUS** are **LO_FLAGS_AUTOCLEAR** and **LO_FLAGS_PARTSCAN**.

LOOP_GET_STATUS
Get the status of the loop device. The (third) *ioctl*(2) argument must be a pointer to a *struct loop_info*.

LOOP_CHANGE_FD (since Linux 2.6.5)
Switch the backing store of the loop device to the new file identified file descriptor specified in the (third) *ioctl*(2) argument, which is an integer. This operation is possible only if the loop device is read-only and the new backing store is the same size and type as the old backing store.

LOOP_SET_CAPACITY (since Linux 2.6.30)
Resize a live loop device. One can change the size of the underlying backing store and then use this operation so that the loop driver learns about the new size. This operation takes no argument.

LOOP_SET_DIRECT_IO (since Linux 4.10)
Set DIRECT I/O mode on the loop device, so that it can be used to open backing file. The (third) *ioctl*(2) argument is an unsigned long value. A nonzero represents direct I/O mode.

LOOP_SET_BLOCK_SIZE (since Linux 4.14)
Set the block size of the loop device. The (third) *ioctl*(2) argument is an unsigned long value. This value must be a power of two in the range [512,pagesize]; otherwise, an **EINVAL** error results.

LOOP_CONFIGURE (since Linux 5.8)
Setup and configure all loop device parameters in a single step using the (third) *ioctl*(2) argument. This argument is a pointer to a *loop_config* structure, defined in <*linux/loop.h*> as:

```
struct loop_config {
    __u32           fd;
    __u32           block_size;
    struct loop_info64  info;
    __u64           __reserved[8];
};
```

In addition to doing what **LOOP_SET_STATUS** can do, **LOOP_CONFIGURE** can also be used to do the following:

- set the correct block size immediately by setting *loop_config.block_size*;
- explicitly request direct I/O mode by setting **LO_FLAGS_DIRECT_IO** in *loop_config.info.lo_flags*; and
- explicitly request read-only mode by setting **LO_FLAGS_READ_ONLY** in *loop_config.info.lo_flags*.

Since Linux 2.6, there are two new *ioctl*(2) operations:

LOOP_SET_STATUS64
LOOP_GET_STATUS64
These are similar to **LOOP_SET_STATUS** and **LOOP_GET_STATUS** described above but use the *loop_info64* structure, which has some additional fields and a larger range for some other fields:

```
struct loop_info64 {
    uint64_t lo_device;           /* ioctl r/o */
    uint64_t lo_inode;            /* ioctl r/o */
    uint64_t lo_rdevice;          /* ioctl r/o */
    uint64_t lo_offset;
    uint64_t lo_sizelimit;  /* bytes, 0 == max available */
    uint32_t lo_number;           /* ioctl r/o */
    uint32_t lo_encrypt_type;
```

```
            uint32_t lo_encrypt_key_size; /* ioctl w/o */
            uint32_t lo_flags; i          /* ioctl r/w (r/o before
                                             Linux 2.6.25) */
            uint8_t  lo_file_name[LO_NAME_SIZE];
            uint8_t  lo_crypt_name[LO_NAME_SIZE];
            uint8_t  lo_encrypt_key[LO_KEY_SIZE]; /* ioctl w/o */
            uint64_t lo_init[2];
        };
```

/dev/loop-control

Since Linux 3.1, the kernel provides the */dev/loop−control* device, which permits an application to dynamically find a free device, and to add and remove loop devices from the system. To perform these operations, one first opens */dev/loop−control* and then employs one of the following *ioctl*(2) operations:

LOOP_CTL_GET_FREE

Allocate or find a free loop device for use. On success, the device number is returned as the result of the call. This operation takes no argument.

LOOP_CTL_ADD

Add the new loop device whose device number is specified as a long integer in the third *ioctl*(2) argument. On success, the device index is returned as the result of the call. If the device is already allocated, the call fails with the error **EEXIST**.

LOOP_CTL_REMOVE

Remove the loop device whose device number is specified as a long integer in the third *ioctl*(2) argument. On success, the device number is returned as the result of the call. If the device is in use, the call fails with the error **EBUSY**.

FILES

*/dev/loop**

The loop block special device files.

EXAMPLES

The program below uses the */dev/loop−control* device to find a free loop device, opens the loop device, opens a file to be used as the underlying storage for the device, and then associates the loop device with the backing store. The following shell session demonstrates the use of the program:

```
$ dd if=/dev/zero of=file.img bs=1MiB count=10
10+0 records in
10+0 records out
10485760 bytes (10 MB) copied, 0.00609385 s, 1.7 GB/s
$ sudo ./mnt_loop file.img
loopname = /dev/loop5
```

Program source

```
#include <fcntl.h>
#include <linux/loop.h>
#include <sys/ioctl.h>
#include <stdio.h>
#include <stdlib.h>
#include <unistd.h>

#define errExit(msg)    do { perror(msg); exit(EXIT_FAILURE); \
                        } while (0)

int
main(int argc, char *argv[])
{
    int loopctlfd, loopfd, backingfile;
    long devnr;
    char loopname[4096];
```

```
        if (argc != 2) {
            fprintf(stderr, "Usage: %s backing-file\n", argv[0]);
            exit(EXIT_FAILURE);
        }

        loopctlfd = open("/dev/loop-control", O_RDWR);
        if (loopctlfd == -1)
            errExit("open: /dev/loop-control");

        devnr = ioctl(loopctlfd, LOOP_CTL_GET_FREE);
        if (devnr == -1)
            errExit("ioctl-LOOP_CTL_GET_FREE");

        sprintf(loopname, "/dev/loop%ld", devnr);
        printf("loopname = %s\n", loopname);

        loopfd = open(loopname, O_RDWR);
        if (loopfd == -1)
            errExit("open: loopname");

        backingfile = open(argv[1], O_RDWR);
        if (backingfile == -1)
            errExit("open: backing-file");

        if (ioctl(loopfd, LOOP_SET_FD, backingfile) == -1)
            errExit("ioctl-LOOP_SET_FD");

        exit(EXIT_SUCCESS);
    }
```

SEE ALSO

losetup(8), *mount*(8)

NAME

lp − line printer devices

SYNOPSIS

#include <linux/lp.h>

CONFIGURATION

lp[0–2] are character devices for the parallel line printers; they have major number 6 and minor number 0–2. The minor numbers correspond to the printer port base addresses 0x03bc, 0x0378, and 0x0278. Usually they have mode 220 and are owned by user *root* and group *lp*. You can use printer ports either with polling or with interrupts. Interrupts are recommended when high traffic is expected, for example, for laser printers. For typical dot matrix printers, polling will usually be enough. The default is polling.

DESCRIPTION

The following *ioctl*(2) calls are supported:

int ioctl(int fd**, LPTIME, int** arg**)**

Sets the amount of time that the driver sleeps before rechecking the printer when the printer's buffer appears to be filled to *arg*. If you have a fast printer, decrease this number; if you have a slow printer, then increase it. This is in hundredths of a second, the default 2 being 0.02 seconds. It influences only the polling driver.

int ioctl(int fd**, LPCHAR, int** arg**)**

Sets the maximum number of busy-wait iterations which the polling driver does while waiting for the printer to get ready for receiving a character to *arg*. If printing is too slow, increase this number; if the system gets too slow, decrease this number. The default is 1000. It influences only the polling driver.

int ioctl(int fd**, LPABORT, int** arg**)**

If *arg* is 0, the printer driver will retry on errors, otherwise it will abort. The default is 0.

int ioctl(int fd**, LPABORTOPEN, int** arg**)**

If *arg* is 0, *open*(2) will be aborted on error, otherwise error will be ignored. The default is to ignore it.

int ioctl(int fd**, LPCAREFUL, int** arg**)**

If *arg* is 0, then the out-of-paper, offline, and error signals are required to be false on all writes, otherwise they are ignored. The default is to ignore them.

int ioctl(int fd**, LPWAIT, int** arg**)**

Sets the number of busy waiting iterations to wait before strobing the printer to accept a just-written character, and the number of iterations to wait before turning the strobe off again, to *arg*. The specification says this time should be 0.5 microseconds, but experience has shown the delay caused by the code is already enough. For that reason, the default value is 0. This is used for both the polling and the interrupt driver.

int ioctl(int fd**, LPSETIRQ, int** arg**)**

This *ioctl*(2) requires superuser privileges. It takes an *int* containing the new IRQ as argument. As a side effect, the printer will be reset. When *arg* is 0, the polling driver will be used, which is also default.

int ioctl(int fd**, LPGETIRQ, int ***arg**)**

Stores the currently used IRQ in *arg*.

int ioctl(int fd**, LPGETSTATUS, int ***arg**)**

Stores the value of the status port in *arg*. The bits have the following meaning:

LP_PBUSY	inverted busy input, active high
LP_PACK	unchanged acknowledge input, active low
LP_POUTPA	unchanged out-of-paper input, active high
LP_PSELECD	unchanged selected input, active high
LP_PERRORP	unchanged error input, active low

Refer to your printer manual for the meaning of the signals. Note that undocumented bits may also be set, depending on your printer.

int ioctl(int fd**, LPRESET)**
Resets the printer. No argument is used.

FILES

*/dev/lp**

SEE ALSO

chmod(1), *chown*(1), *mknod*(1), *lpcntl*(8), *tunelp*(8)

NAME

mem, kmem, port − system memory, kernel memory and system ports

DESCRIPTION

/dev/mem is a character device file that is an image of the main memory of the computer. It may be used, for example, to examine (and even patch) the system.

Byte addresses in */dev/mem* are interpreted as physical memory addresses. References to nonexistent locations cause errors to be returned.

Examining and patching is likely to lead to unexpected results when read-only or write-only bits are present.

Since Linux 2.6.26, and depending on the architecture, the **CONFIG_STRICT_DEVMEM** kernel configuration option limits the areas which can be accessed through this file. For example: on x86, RAM access is not allowed but accessing memory-mapped PCI regions is.

It is typically created by:

```
mknod −m 660 /dev/mem c 1 1
chown root:kmem /dev/mem
```

The file */dev/kmem* is the same as */dev/mem*, except that the kernel virtual memory rather than physical memory is accessed. Since Linux 2.6.26, this file is available only if the **CONFIG_DEVKMEM** kernel configuration option is enabled.

It is typically created by:

```
mknod −m 640 /dev/kmem c 1 2
chown root:kmem /dev/kmem
```

/dev/port is similar to */dev/mem*, but the I/O ports are accessed.

It is typically created by:

```
mknod −m 660 /dev/port c 1 4
chown root:kmem /dev/port
```

FILES

NAME

mouse − serial mouse interface

CONFIGURATION

Serial mice are connected to a serial RS232/V24 dialout line, see *ttyS*(4) for a description.

DESCRIPTION

Introduction

The pinout of the usual 9 pin plug as used for serial mice is:

pin	name	used for
2	RX	Data
3	TX	−12 V, Imax = 10 mA
4	DTR	+12 V, Imax = 10 mA
7	RTS	+12 V, Imax = 10 mA
5	GND	Ground

This is the specification, in fact 9 V suffices with most mice.

The mouse driver can recognize a mouse by dropping RTS to low and raising it again. About 14 ms later the mouse will send 0x4D ('M') on the data line. After a further 63 ms, a Microsoft-compatible 3-button mouse will send 0x33 ('3').

The relative mouse movement is sent as *dx* (positive means right) and *dy* (positive means down). Various mice can operate at different speeds. To select speeds, cycle through the speeds 9600, 4800, 2400, and 1200 bit/s, each time writing the two characters from the table below and waiting 0.1 seconds. The following table shows available speeds and the strings that select them:

bit/s	string
9600	*q
4800	*p
2400	*o
1200	*n

The first byte of a data packet can be used for synchronization purposes.

Microsoft protocol

The **Microsoft** protocol uses 1 start bit, 7 data bits, no parity and one stop bit at the speed of 1200 bits/sec. Data is sent to RxD in 3-byte packets. The *dx* and *dy* movements are sent as two's-complement, *lb* (*rb*) are set when the left (right) button is pressed:

byte	d6	d5	d4	d3	d2	d1	d0
1	1	lb	rb	dy7	dy6	dx7	dx6
2	0	dx5	dx4	dx3	dx2	dx1	dx0
3	0	dy5	dy4	dy3	dy2	dy1	dy0

3-button Microsoft protocol

Original Microsoft mice only have two buttons. However, there are some three button mice which also use the Microsoft protocol. Pressing or releasing the middle button is reported by sending a packet with zero movement and no buttons pressed. (Thus, unlike for the other two buttons, the status of the middle button is not reported in each packet.)

Logitech protocol

Logitech serial 3-button mice use a different extension of the Microsoft protocol: when the middle button is up, the above 3-byte packet is sent. When the middle button is down a 4-byte packet is sent, where the 4th byte has value 0x20 (or at least has the 0x20 bit set). In particular, a press of the middle button is reported as 0,0,0,0x20 when no other buttons are down.

Mousesystems protocol

The **Mousesystems** protocol uses 1 start bit, 8 data bits, no parity, and two stop bits at the speed of 1200 bits/sec. Data is sent to RxD in 5-byte packets. *dx* is sent as the sum of the two two's-complement values, *dy* is send as negated sum of the two two's-complement values. *lb* (*mb*, *rb*) are cleared when the left (middle, right) button is pressed:

byte	d7	d6	d5	d4	d3	d2	d1	d0
1	1	0	0	0	0	lb	mb	rb

2	0	dxa6	dxa5	dxa4	dxa3	dxa2	dxa1	dxa0
3	0	dya6	dya5	dya4	dya3	dya2	dya1	dya0
4	0	dxb6	dxb5	dxb4	dxb3	dxb2	dxb1	dxb0
5	0	dyb6	dyb5	dyb4	dyb3	dyb2	dyb1	dyb0

Bytes 4 and 5 describe the change that occurred since bytes 2 and 3 were transmitted.

Sun protocol

The **Sun** protocol is the 3-byte version of the above 5-byte Mousesystems protocol: the last two bytes are not sent.

MM protocol

The **MM** protocol uses 1 start bit, 8 data bits, odd parity, and one stop bit at the speed of 1200 bits/sec. Data is sent to RxD in 3-byte packets. *dx* and *dy* are sent as single signed values, the sign bit indicating a negative value. *lb* (*mb*, *rb*) are set when the left (middle, right) button is pressed:

byte	d7	d6	d5	d4	d3	d2	d1	d0
1	1	0	0	dxs	dys	lb	mb	rb
2	0	dx6	dx5	dx4	dx3	dx2	dx1	dx0
3	0	dy6	dy5	dy4	dy3	dy2	dy1	dy0

FILES

NAME

msr − x86 CPU MSR access device

DESCRIPTION

/dev/cpu/CPUNUM/msr provides an interface to read and write the model-specific registers (MSRs) of an x86 CPU. *CPUNUM* is the number of the CPU to access as listed in */proc/cpuinfo*.

The register access is done by opening the file and seeking to the MSR number as offset in the file, and then reading or writing in chunks of 8 bytes. An I/O transfer of more than 8 bytes means multiple reads or writes of the same register.

This file is protected so that it can be read and written only by the user *root*, or members of the group *root*.

NOTES

The *msr* driver is not auto-loaded. On modular kernels you might need to use the following command to load it explicitly before use:

```
$ modprobe msr
```

SEE ALSO

Intel Corporation Intel 64 and IA-32 Architectures Software Developer's Manual Volume 3B Appendix B, for an overview of the Intel CPU MSRs.

NAME

null, zero − data sink

DESCRIPTION

Data written to the */dev/null* and */dev/zero* special files is discarded.

Reads from */dev/null* always return end of file (i.e., *read*(2) returns 0), whereas reads from */dev/zero* always return bytes containing zero ('\0' characters).

These devices are typically created by:

```
mknod −m 666 /dev/null c 1 3
mknod −m 666 /dev/zero c 1 5
chown root:root /dev/null /dev/zero
```

FILES

/dev/null
/dev/zero

NOTES

If these devices are not writable and readable for all users, many programs will act strangely.

Since Linux 2.6.31, reads from */dev/zero* are interruptible by signals. (This change was made to help with bad latencies for large reads from */dev/zero*.)

SEE ALSO

chown(1), *mknod*(1), *full*(4)

NAME

ptmx, pts − pseudoterminal master and slave

DESCRIPTION

The file */dev/ptmx* (the pseudoterminal multiplexor device) is a character file with major number 5 and minor number 2, usually with mode 0666 and ownership root:root. It is used to create a pseudoterminal master and slave pair.

When a process opens */dev/ptmx*, it gets a file descriptor for a pseudoterminal master and a pseudoterminal slave device is created in the */dev/pts* directory. Each file descriptor obtained by opening */dev/ptmx* is an independent pseudoterminal master with its own associated slave, whose path can be found by passing the file descriptor to *ptsname*(3).

Before opening the pseudoterminal slave, you must pass the master's file descriptor to *grantpt*(3) and *unlockpt*(3).

Once both the pseudoterminal master and slave are open, the slave provides processes with an interface that is identical to that of a real terminal.

Data written to the slave is presented on the master file descriptor as input. Data written to the master is presented to the slave as input.

In practice, pseudoterminals are used for implementing terminal emulators such as *xterm*(1), in which data read from the pseudoterminal master is interpreted by the application in the same way a real terminal would interpret the data, and for implementing remote-login programs such as *sshd*(8), in which data read from the pseudoterminal master is sent across the network to a client program that is connected to a terminal or terminal emulator.

Pseudoterminals can also be used to send input to programs that normally refuse to read input from pipes (such as *su*(1), and *passwd*(1)).

FILES

/dev/ptmx, */dev/pts/**

NOTES

The Linux support for the above (known as UNIX 98 pseudoterminal naming) is done using the *devpts* filesystem, which should be mounted on */dev/pts*.

SEE ALSO

NAME

random, urandom − kernel random number source devices

SYNOPSIS

#include <linux/random.h>

int ioctl(*fd***, RND***request***,** *param***);**

DESCRIPTION

The character special files */dev/random* and */dev/urandom* (present since Linux 1.3.30) provide an interface to the kernel's random number generator. The file */dev/random* has major device number 1 and minor device number 8. The file */dev/urandom* has major device number 1 and minor device number 9.

The random number generator gathers environmental noise from device drivers and other sources into an entropy pool. The generator also keeps an estimate of the number of bits of noise in the entropy pool. From this entropy pool, random numbers are created.

Linux 3.17 and later provides the simpler and safer *getrandom*(2) interface which requires no special files; see the *getrandom*(2) manual page for details.

When read, the */dev/urandom* device returns random bytes using a pseudorandom number generator seeded from the entropy pool. Reads from this device do not block (i.e., the CPU is not yielded), but can incur an appreciable delay when requesting large amounts of data.

When read during early boot time, */dev/urandom* may return data prior to the entropy pool being initialized. If this is of concern in your application, use *getrandom*(2) or */dev/random* instead.

The */dev/random* device is a legacy interface which dates back to a time where the cryptographic primitives used in the implementation of */dev/urandom* were not widely trusted. It will return random bytes only within the estimated number of bits of fresh noise in the entropy pool, blocking if necessary. */dev/random* is suitable for applications that need high quality randomness, and can afford indeterminate delays.

When the entropy pool is empty, reads from */dev/random* will block until additional environmental noise is gathered. Since Linux 5.6, the **O_NONBLOCK** flag is ignored as */dev/random* will no longer block except during early boot process. In earlier versions, if *open*(2) is called for */dev/random* with the **O_NONBLOCK** flag, a subsequent *read*(2) will not block if the requested number of bytes is not available. Instead, the available bytes are returned. If no byte is available, *read*(2) will return −1 and *errno* will be set to **EAGAIN**.

The **O_NONBLOCK** flag has no effect when opening */dev/urandom*. When calling *read*(2) for the device */dev/urandom*, reads of up to 256 bytes will return as many bytes as are requested and will not be interrupted by a signal handler. Reads with a buffer over this limit may return less than the requested number of bytes or fail with the error **EINTR**, if interrupted by a signal handler.

Since Linux 3.16, a *read*(2) from */dev/urandom* will return at most 32 MB. A *read*(2) from */dev/random* will return at most 512 bytes (340 bytes before Linux 2.6.12).

Writing to */dev/random* or */dev/urandom* will update the entropy pool with the data written, but this will not result in a higher entropy count. This means that it will impact the contents read from both files, but it will not make reads from */dev/random* faster.

Usage

The */dev/random* interface is considered a legacy interface, and */dev/urandom* is preferred and sufficient in all use cases, with the exception of applications which require randomness during early boot time; for these applications, *getrandom*(2) must be used instead, because it will block until the entropy pool is initialized.

If a seed file is saved across reboots as recommended below, the output is cryptographically secure against attackers without local root access as soon as it is reloaded in the boot sequence, and perfectly adequate for network encryption session keys. (All major Linux distributions have saved the seed file across reboots since 2000 at least.) Since reads from */dev/random* may block, users will usually want to open it in nonblocking mode (or perform a read with timeout), and provide some sort of user notification if the desired entropy is not immediately available.

Configuration

If your system does not have */dev/random* and */dev/urandom* created already, they can be created with the following commands:

```
mknod −m 666 /dev/random c 1 8
mknod −m 666 /dev/urandom c 1 9
chown root:root /dev/random /dev/urandom
```

When a Linux system starts up without much operator interaction, the entropy pool may be in a fairly predictable state. This reduces the actual amount of noise in the entropy pool below the estimate. In order to counteract this effect, it helps to carry entropy pool information across shut-downs and start-ups. To do this, add the lines to an appropriate script which is run during the Linux system start-up sequence:

```
echo "Initializing random number generator..."
random_seed=/var/run/random−seed
# Carry a random seed from start−up to start−up
# Load and then save the whole entropy pool
if [ −f $random_seed ]; then
    cat $random_seed >/dev/urandom
else
    touch $random_seed
fi
chmod 600 $random_seed
poolfile=/proc/sys/kernel/random/poolsize
[ −r $poolfile ] && bits=$(cat $poolfile) || bits=4096
bytes=$(expr $bits / 8)
dd if=/dev/urandom of=$random_seed count=1 bs=$bytes
```

Also, add the following lines in an appropriate script which is run during the Linux system shutdown:

```
# Carry a random seed from shut−down to start−up
# Save the whole entropy pool
echo "Saving random seed..."
random_seed=/var/run/random−seed
touch $random_seed
chmod 600 $random_seed
poolfile=/proc/sys/kernel/random/poolsize
[ −r $poolfile ] && bits=$(cat $poolfile) || bits=4096
bytes=$(expr $bits / 8)
dd if=/dev/urandom of=$random_seed count=1 bs=$bytes
```

In the above examples, we assume Linux 2.6.0 or later, where */proc/sys/kernel/random/poolsize* returns the size of the entropy pool in bits (see below).

/proc interfaces

The files in the directory */proc/sys/kernel/random* (present since Linux 2.3.16) provide additional information about the */dev/random* device:

entropy_avail

This read-only file gives the available entropy, in bits. This will be a number in the range 0 to 4096.

poolsize

This file gives the size of the entropy pool. The semantics of this file vary across kernel versions:

Linux 2.4:

This file gives the size of the entropy pool in *bytes*. Normally, this file will have the value 512, but it is writable, and can be changed to any value for which an algorithm is available. The choices are 32, 64, 128, 256, 512, 1024, or 2048.

Linux 2.6 and later:

This file is read-only, and gives the size of the entropy pool in *bits*. It contains the value 4096.

read_wakeup_threshold
: This file contains the number of bits of entropy required for waking up processes that sleep waiting for entropy from */dev/random*. The default is 64.

write_wakeup_threshold
: This file contains the number of bits of entropy below which we wake up processes that do a *select*(2) or *poll*(2) for write access to */dev/random*. These values can be changed by writing to the files.

uuid and *boot_id*
: These read-only files contain random strings like 6fd5a44b−35f4−4ad4−a9b9−6b9be13e1fe9. The former is generated afresh for each read, the latter was generated once.

ioctl(2) interface

The following *ioctl*(2) requests are defined on file descriptors connected to either */dev/random* or */dev/urandom*. All requests performed will interact with the input entropy pool impacting both */dev/random* and */dev/urandom*. The **CAP_SYS_ADMIN** capability is required for all requests except **RNDGETENTCNT**.

RNDGETENTCNT
: Retrieve the entropy count of the input pool, the contents will be the same as the *entropy_avail* file under proc. The result will be stored in the int pointed to by the argument.

RNDADDTOENTCNT
: Increment or decrement the entropy count of the input pool by the value pointed to by the argument.

RNDGETPOOL
: Removed in Linux 2.6.9.

RNDADDENTROPY
: Add some additional entropy to the input pool, incrementing the entropy count. This differs from writing to */dev/random* or */dev/urandom*, which only adds some data but does not increment the entropy count. The following structure is used:

```
struct rand_pool_info {
    int    entropy_count;
    int    buf_size;
    __u32  buf[0];
};
```

Here *entropy_count* is the value added to (or subtracted from) the entropy count, and *buf* is the buffer of size *buf_size* which gets added to the entropy pool.

RNDZAPENTCNT
RNDCLEARPOOL
: Zero the entropy count of all pools and add some system data (such as wall clock) to the pools.

FILES

/dev/random
/dev/urandom

NOTES

For an overview and comparison of the various interfaces that can be used to obtain randomness, see *random*(7).

BUGS

During early boot time, reads from */dev/urandom* may return data prior to the entropy pool being initialized.

RFC 1750, "Randomness Recommendations for Security"

NAME

rtc − real-time clock

SYNOPSIS

#include <linux/rtc.h>

int ioctl(*fd*, **RTC_***request*, *param***);**

DESCRIPTION

This is the interface to drivers for real-time clocks (RTCs).

Most computers have one or more hardware clocks which record the current "wall clock" time. These are called "Real Time Clocks" (RTCs). One of these usually has battery backup power so that it tracks the time even while the computer is turned off. RTCs often provide alarms and other interrupts.

All i386 PCs, and ACPI-based systems, have an RTC that is compatible with the Motorola MC146818 chip on the original PC/AT. Today such an RTC is usually integrated into the mainboard's chipset (south bridge), and uses a replaceable coin-sized backup battery.

Non-PC systems, such as embedded systems built around system-on-chip processors, use other implementations. They usually won't offer the same functionality as the RTC from a PC/AT.

RTC vs system clock

RTCs should not be confused with the system clock, which is a software clock maintained by the kernel and used to implement *gettimeofday*(2) and *time*(2), as well as setting timestamps on files, and so on. The system clock reports seconds and microseconds since a start point, defined to be the POSIX Epoch: 1970-01-01 00:00:00 +0000 (UTC). (One common implementation counts timer interrupts, once per "jiffy", at a frequency of 100, 250, or 1000 Hz.) That is, it is supposed to report wall clock time, which RTCs also do.

A key difference between an RTC and the system clock is that RTCs run even when the system is in a low power state (including "off"), and the system clock can't. Until it is initialized, the system clock can only report time since system boot ... not since the POSIX Epoch. So at boot time, and after resuming from a system low power state, the system clock will often be set to the current wall clock time using an RTC. Systems without an RTC need to set the system clock using another clock, maybe across the network or by entering that data manually.

RTC functionality

RTCs can be read and written with *hwclock*(8), or directly with the *ioctl*(2) requests listed below.

Besides tracking the date and time, many RTCs can also generate interrupts

- on every clock update (i.e., once per second);
- at periodic intervals with a frequency that can be set to any power-of-2 multiple in the range 2 Hz to 8192 Hz;
- on reaching a previously specified alarm time.

Each of those interrupt sources can be enabled or disabled separately. On many systems, the alarm interrupt can be configured as a system wakeup event, which can resume the system from a low power state such as Suspend-to-RAM (STR, called S3 in ACPI systems), Hibernation (called S4 in ACPI systems), or even "off" (called S5 in ACPI systems). On some systems, the battery backed RTC can't issue interrupts, but another one can.

The */dev/rtc* (or */dev/rtc0*, */dev/rtc1*, etc.) device can be opened only once (until it is closed) and it is read-only. On *read*(2) and *select*(2) the calling process is blocked until the next interrupt from that RTC is received. Following the interrupt, the process can read a long integer, of which the least significant byte contains a bit mask encoding the types of interrupt that occurred, while the remaining 3 bytes contain the number of interrupts since the last *read*(2).

ioctl(2) interface

The following *ioctl*(2) requests are defined on file descriptors connected to RTC devices:

RTC_RD_TIME

Returns this RTC's time in the following structure:

```
struct rtc_time {
    int tm_sec;
```

```
        int tm_min;
        int tm_hour;
        int tm_mday;
        int tm_mon;
        int tm_year;
        int tm_wday;     /* unused */
        int tm_yday;     /* unused */
        int tm_isdst;    /* unused */
    };
```

The fields in this structure have the same meaning and ranges as for the *tm* structure described in *gmtime*(3). A pointer to this structure should be passed as the third *ioctl*(2) argument.

RTC_SET_TIME
: Sets this RTC's time to the time specified by the *rtc_time* structure pointed to by the third *ioctl*(2) argument. To set the RTC's time the process must be privileged (i.e., have the **CAP_SYS_TIME** capability).

RTC_ALM_READ
RTC_ALM_SET
: Read and set the alarm time, for RTCs that support alarms. The alarm interrupt must be separately enabled or disabled using the **RTC_AIE_ON**, **RTC_AIE_OFF** requests. The third *ioctl*(2) argument is a pointer to an *rtc_time* structure. Only the *tm_sec*, *tm_min*, and *tm_hour* fields of this structure are used.

RTC_IRQP_READ
RTC_IRQP_SET
: Read and set the frequency for periodic interrupts, for RTCs that support periodic interrupts. The periodic interrupt must be separately enabled or disabled using the **RTC_PIE_ON**, **RTC_PIE_OFF** requests. The third *ioctl*(2) argument is an *unsigned long* * or an *unsigned long*, respectively. The value is the frequency in interrupts per second. The set of allowable frequencies is the multiples of two in the range 2 to 8192. Only a privileged process (i.e., one having the **CAP_SYS_RESOURCE** capability) can set frequencies above the value specified in */proc/sys/dev/rtc/max−user−freq*. (This file contains the value 64 by default.)

RTC_AIE_ON
RTC_AIE_OFF
: Enable or disable the alarm interrupt, for RTCs that support alarms. The third *ioctl*(2) argument is ignored.

RTC_UIE_ON
RTC_UIE_OFF
: Enable or disable the interrupt on every clock update, for RTCs that support this once-per-second interrupt. The third *ioctl*(2) argument is ignored.

RTC_PIE_ON
RTC_PIE_OFF
: Enable or disable the periodic interrupt, for RTCs that support these periodic interrupts. The third *ioctl*(2) argument is ignored. Only a privileged process (i.e., one having the **CAP_SYS_RESOURCE** capability) can enable the periodic interrupt if the frequency is currently set above the value specified in */proc/sys/dev/rtc/max−user−freq*.

RTC_EPOCH_READ
RTC_EPOCH_SET
: Many RTCs encode the year in an 8-bit register which is either interpreted as an 8-bit binary number or as a BCD number. In both cases, the number is interpreted relative to this RTC's Epoch. The RTC's Epoch is initialized to 1900 on most systems but on Alpha and MIPS it might also be initialized to 1952, 1980, or 2000, depending on the value of an RTC register for the year. With some RTCs, these operations can be used to read or to set the RTC's Epoch, respectively. The third *ioctl*(2) argument is an *unsigned long* * or an *unsigned long*, respectively, and the value returned (or assigned) is the Epoch. To set the RTC's Epoch the process must be privileged (i.e., have the **CAP_SYS_TIME** capability).

RTC_WKALM_RD
RTC_WKALM_SET
Some RTCs support a more powerful alarm interface, using these ioctls to read or write the RTC's alarm time (respectively) with this structure:

```
struct rtc_wkalrm {
    unsigned char enabled;
    unsigned char pending;
    struct rtc_time time;
};
```

The *enabled* flag is used to enable or disable the alarm interrupt, or to read its current status; when using these calls, **RTC_AIE_ON** and **RTC_AIE_OFF** are not used. The *pending* flag is used by **RTC_WKALM_RD** to report a pending interrupt (so it's mostly useless on Linux, except when talking to the RTC managed by EFI firmware). The *time* field is as used with **RTC_ALM_READ** and **RTC_ALM_SET** except that the *tm_mday*, *tm_mon*, and *tm_year* fields are also valid. A pointer to this structure should be passed as the third *ioctl*(2) argument.

FILES

/dev/rtc
/dev/rtc0
/dev/rtc1
. . . RTC special character device files.

/proc/driver/rtc
status of the (first) RTC.

NOTES

When the kernel's system time is synchronized with an external reference using *adjtimex*(2) it will update a designated RTC periodically every 11 minutes. To do so, the kernel has to briefly turn off periodic interrupts; this might affect programs using that RTC.

An RTC's Epoch has nothing to do with the POSIX Epoch which is used only for the system clock.

If the year according to the RTC's Epoch and the year register is less than 1970 it is assumed to be 100 years later, that is, between 2000 and 2069.

Some RTCs support "wildcard" values in alarm fields, to support scenarios like periodic alarms at fifteen minutes after every hour, or on the first day of each month. Such usage is nonportable; portable user-space code expects only a single alarm interrupt, and will either disable or reinitialize the alarm after receiving it.

Some RTCs support periodic interrupts with periods that are multiples of a second rather than fractions of a second; multiple alarms; programmable output clock signals; nonvolatile memory; and other hardware capabilities that are not currently exposed by this API.

NAME

sd − driver for SCSI disk drives

SYNOPSIS

#include <linux/hdreg.h> /* for HDIO_GETGEO */
#include <linux/fs.h> /* for BLKGETSIZE and BLKRRPART */

CONFIGURATION

The block device name has the following form: **sd***lp*, where *l* is a letter denoting the physical drive, and *p* is a number denoting the partition on that physical drive. Often, the partition number, *p*, will be left off when the device corresponds to the whole drive.

SCSI disks have a major device number of 8, and a minor device number of the form (16 * *drive_number*) + *partition_number*, where *drive_number* is the number of the physical drive in order of detection, and *partition_number* is as follows:

- partition 0 is the whole drive
- partitions 1–4 are the DOS "primary" partitions
- partitions 5–8 are the DOS "extended" (or "logical") partitions

For example, */dev/sda* will have major 8, minor 0, and will refer to all of the first SCSI drive in the system; and */dev/sdb3* will have major 8, minor 19, and will refer to the third DOS "primary" partition on the second SCSI drive in the system.

At this time, only block devices are provided. Raw devices have not yet been implemented.

DESCRIPTION

The following *ioctl*s are provided:

HDIO_GETGEO

Returns the BIOS disk parameters in the following structure:

```
struct hd_geometry {
    unsigned char  heads;
    unsigned char  sectors;
    unsigned short cylinders;
    unsigned long  start;
};
```

A pointer to this structure is passed as the *ioctl*(2) parameter.

The information returned in the parameter is the disk geometry of the drive *as understood by DOS!* This geometry is *not* the physical geometry of the drive. It is used when constructing the drive's partition table, however, and is needed for convenient operation of *fdisk*(1), *efdisk*(1), and *lilo*(1)If the geometry information is not available, zero will be returned for all of the parameters.

BLKGETSIZE

Returns the device size in sectors. The *ioctl*(2) parameter should be a pointer to a *long*.

BLKRRPART

Forces a reread of the SCSI disk partition tables. No parameter is needed.

The SCSI *ioctl*(2) operations are also supported. If the *ioctl*(2) parameter is required, and it is NULL, then *ioctl*(2) fails with the error **EINVAL**.

FILES

/dev/sd[a−h]
the whole device

/dev/sd[a−h][0−8]

NAME

sk98lin − Marvell/SysKonnect Gigabit Ethernet driver v6.21

SYNOPSIS

insmod sk98lin.o [**Speed_A**=*i*,*j*,...] [**Speed_B**=*i*,*j*,...] [**AutoNeg_A**=*i*,*j*,...] [**AutoNeg_B**=*i*,*j*,...] [**DupCap_A**=*i*,*j*,...] [**DupCap_B**=*i*,*j*,...] [**FlowCtrl_A**=*i*,*j*,...] [**FlowCtrl_B**=*i*,*j*,...] [**Role_A**=*i*,*j*,...] [**Role_B**=*i*,*j*,...] [**ConType**=*i*,*j*,...] [**Moderation**=*i*,*j*,...] [**IntsPerSec**=*i*,*j*,...] [**PrefPort**=*i*,*j*,...] [**RlmtMode**=*i*,*j*,...]

DESCRIPTION

Note: This obsolete driver was removed in Linux 2.6.26.

sk98lin is the Gigabit Ethernet driver for Marvell and SysKonnect network adapter cards. It supports SysKonnect SK-98xx/SK-95xx compliant Gigabit Ethernet Adapter and any Yukon compliant chipset.

When loading the driver using insmod, parameters for the network adapter cards might be stated as a sequence of comma separated commands. If for instance two network adapters are installed and AutoNegotiation on Port A of the first adapter should be ON, but on the Port A of the second adapter switched OFF, one must enter:

```
insmod sk98lin.o AutoNeg_A=On,Off
```

After **sk98lin** is bound to one or more adapter cards and the */proc* filesystem is mounted on your system, a dedicated statistics file will be created in the folder */proc/net/sk98lin* for all ports of the installed network adapter cards. Those files are named *eth[x]*, where *x* is the number of the interface that has been assigned to a dedicated port by the system.

If loading is finished, any desired IP address can be assigned to the respective *eth[x]* interface using the *ifconfig*(8) command. This causes the adapter to connect to the Ethernet and to display a status message on the console saying "ethx: network connection up using port y" followed by the configured or detected connection parameters.

The **sk98lin** also supports large frames (also called jumbo frames). Using jumbo frames can improve throughput tremendously when transferring large amounts of data. To enable large frames, the MTU (maximum transfer unit) size for an interface is to be set to a high value. The default MTU size is 1500 and can be changed up to 9000 (bytes). Setting the MTU size can be done when assigning the IP address to the interface or later by using the *ifconfig*(8) command with the mtu parameter. If for instance eth0 needs an IP address and a large frame MTU size, the following two commands might be used:

```
ifconfig eth0 10.1.1.1
ifconfig eth0 mtu 9000
```

Those two commands might even be combined into one:

```
ifconfig eth0 10.1.1.1 mtu 9000
```

Note that large frames can be used only if permitted by your network infrastructure. This means, that any switch being used in your Ethernet must also support large frames. Quite some switches support large frames, but need to be configured to do so. Most of the times, their default setting is to support only standard frames with an MTU size of 1500 (bytes). In addition to the switches inside the network, all network adapters that are to be used must also be enabled regarding jumbo frames. If an adapter is not set to receive large frames, it will simply drop them.

Switching back to the standard Ethernet frame size can be done by using the *ifconfig*(8) command again:

```
ifconfig eth0 mtu 1500
```

The Marvell/SysKonnect Gigabit Ethernet driver for Linux is able to support VLAN and Link Aggregation according to IEEE standards 802.1, 802.1q, and 802.3ad. Those features are available only after installation of open source modules which can be found on the Internet:

VLAN:
Link Aggregation:

Note that Marvell/SysKonnect does not offer any support for these open source modules and does not take the responsibility for any kind of failures or problems arising when using these modules.

Parameters

Speed_A=*i,j,...*
This parameter is used to set the speed capabilities of port A of an adapter card. It is valid only for Yukon copper adapters. Possible values are: *10*, *100*, *1000*, or *Auto*; *Auto* is the default. Usually, the speed is negotiated between the two ports during link establishment. If this fails, a port can be forced to a specific setting with this parameter.

Speed_B=*i,j,...*
This parameter is used to set the speed capabilities of port B of an adapter card. It is valid only for Yukon copper adapters. Possible values are: *10*, *100*, *1000*, or *Auto*; *Auto* is the default. Usually, the speed is negotiated between the two ports during link establishment. If this fails, a port can be forced to a specific setting with this parameter.

AutoNeg_A=*i,j,...*
Enables or disables the use of autonegotiation of port A of an adapter card. Possible values are: *On*, *Off*, or *Sense*; *On* is the default. The *Sense* mode automatically detects whether the link partner supports auto-negotiation or not.

AutoNeg_B=*i,j,...*
Enables or disables the use of autonegotiation of port B of an adapter card. Possible values are: *On*, *Off*, or *Sense*; *On* is the default. The *Sense* mode automatically detects whether the link partner supports auto-negotiation or not.

DupCap_A=*i,j,...*
This parameter indicates the duplex mode to be used for port A of an adapter card. Possible values are: *Half*, *Full*, or *Both*; *Both* is the default. This parameter is relevant only if AutoNeg_A of port A is not set to *Sense*. If AutoNeg_A is set to *On*, all three values of DupCap_A (*Half*, *Full*, or *Both*) might be stated. If AutoNeg_A is set to *Off*, only DupCap_A values *Full* and *Half* are allowed. This DupCap_A parameter is useful if your link partner does not support all possible duplex combinations.

DupCap_B=*i,j,...*
This parameter indicates the duplex mode to be used for port B of an adapter card. Possible values are: *Half*, *Full*, or *Both*; *Both* is the default. This parameter is relevant only if AutoNeg_B of port B is not set to *Sense*. If AutoNeg_B is set to *On*, all three values of DupCap_B (*Half*, *Full*, or *Both*) might be stated. If AutoNeg_B is set to *Off*, only DupCap_B values *Full* and *Half* are allowed. This DupCap_B parameter is useful if your link partner does not support all possible duplex combinations.

FlowCtrl_A=*i,j,...*
This parameter can be used to set the flow control capabilities the port reports during auto-negotiation. Possible values are: *Sym*, *SymOrRem*, *LocSend*, or *None*; *SymOrRem* is the default. The different modes have the following meaning:

Sym = Symmetric
Both link partners are allowed to send PAUSE frames.

SymOrRem = SymmetricOrRemote
Both or only remote partner are allowed to send PAUSE frames.

LocSend = LocalSend
Only local link partner is allowed to send PAUSE frames.

None = None
No link partner is allowed to send PAUSE frames.

Note that this parameter is ignored if AutoNeg_A is set to *Off*.

FlowCtrl_B=*i,j,...*
This parameter can be used to set the flow control capabilities the port reports during auto-negotiation. Possible values are: *Sym*, *SymOrRem*, *LocSend*, or *None*; *SymOrRem* is the default. The different modes have the following meaning:

Sym = Symmetric
Both link partners are allowed to send PAUSE frames.

SymOrRem = SymmetricOrRemote
Both or only remote partner are allowed to send PAUSE frames.

LocSend = LocalSend
Only local link partner is allowed to send PAUSE frames.

None = None
No link partner is allowed to send PAUSE frames.

Note that this parameter is ignored if AutoNeg_B is set to *Off* .

Role_A=*i,j,...*
This parameter is valid only for 1000Base-T adapter cards. For two 1000Base-T ports to communicate, one must take the role of the master (providing timing information), while the other must be the slave. Possible values are: *Auto*, *Master*, or *Slave*; *Auto* is the default. Usually, the role of a port is negotiated between two ports during link establishment, but if that fails the port A of an adapter card can be forced to a specific setting with this parameter.

Role_B=*i,j,...*
This parameter is valid only for 1000Base-T adapter cards. For two 1000Base-T ports to communicate, one must take the role of the master (providing timing information), while the other must be the slave. Possible values are: *Auto*, *Master*, or *Slave*; *Auto* is the default. Usually, the role of a port is negotiated between two ports during link establishment, but if that fails the port B of an adapter card can be forced to a specific setting with this parameter.

ConType=*i,j,...*
This parameter is a combination of all five per-port parameters within one single parameter. This simplifies the configuration of both ports of an adapter card. The different values of this variable reflect the most meaningful combinations of port parameters. Possible values and their corresponding combination of per-port parameters:

ConType	**DupCap**	**AutoNeg**	**FlowCtrl**	**Role**	**Speed**
Auto	Both	On	SymOrRem	Auto	Auto
100FD	Full	Off	None	Auto	100
100HD	Half	Off	None	Auto	100
10FD	Full	Off	None	Auto	10
10HD	Half	Off	None	Auto	10

Stating any other port parameter together with this *ConType* parameter will result in a merged configuration of those settings. This is due to the fact, that the per-port parameters (e.g., *Speed_A*) have a higher priority than the combined variable *ConType*.

Moderation=*i,j,...*
Interrupt moderation is employed to limit the maximum number of interrupts the driver has to serve. That is, one or more interrupts (which indicate any transmit or receive packet to be processed) are queued until the driver processes them. When queued interrupts are to be served, is determined by the *IntsPerSec* parameter, which is explained later below. Possible moderation modes are: *None*, *Static*, or *Dynamic*; *None* is the default. The different modes have the following meaning:

None No interrupt moderation is applied on the adapter card. Therefore, each transmit or receive interrupt is served immediately as soon as it appears on the interrupt line of the adapter card.

Static Interrupt moderation is applied on the adapter card. All transmit and receive interrupts are queued until a complete moderation interval ends. If such a moderation interval ends, all queued interrupts are processed in one big bunch without any delay. The term *Static* reflects the fact, that interrupt moderation is always enabled, regardless how much network load is currently passing via a particular interface. In addition, the duration of the moderation interval has a fixed length that never changes while the driver is operational.

Dynamic Interrupt moderation might be applied on the adapter card, depending on the load of the system. If the driver detects that the system load is too high, the driver tries to shield the system against too much network load by enabling interrupt moderation. If—at a later time—the CPU utilization decreases again (or if the network load is negligible), the interrupt moderation will automatically be disabled.

Interrupt moderation should be used when the driver has to handle one or more interfaces with a high network load, which—as a consequence—leads also to a high CPU utilization. When moderation is applied in such high network load situations, CPU load might be reduced by 20–30% on slow computers.

Note that the drawback of using interrupt moderation is an increase of the round-trip-time (RTT), due to the queuing and serving of interrupts at dedicated moderation times.

IntsPerSec=*i,j,...*

This parameter determines the length of any interrupt moderation interval. Assuming that static interrupt moderation is to be used, an *IntsPerSec* parameter value of 2000 will lead to an interrupt moderation interval of 500 microseconds. Possible values for this parameter are in the range of 30...40000 (interrupts per second). The default value is 2000.

This parameter is used only if either static or dynamic interrupt moderation is enabled on a network adapter card. This parameter is ignored if no moderation is applied.

Note that the duration of the moderation interval is to be chosen with care. At first glance, selecting a very long duration (e.g., only 100 interrupts per second) seems to be meaningful, but the increase of packet-processing delay is tremendous. On the other hand, selecting a very short moderation time might compensate the use of any moderation being applied.

PrefPort=*i,j,...*

This parameter is used to force the preferred port to A or B (on dual-port network adapters). The preferred port is the one that is used if both ports A and B are detected as fully functional. Possible values are: *A* or *B*; *A* is the default.

RlmtMode=*i,j,...*

RLMT monitors the status of the port. If the link of the active port fails, RLMT switches immediately to the standby link. The virtual link is maintained as long as at least one "physical" link is up. This parameters states how RLMT should monitor both ports. Possible values are: *CheckLinkState*, *CheckLocalPort*, *CheckSeg*, or *DualNet*; *CheckLinkState* is the default. The different modes have the following meaning:

CheckLinkState Check link state only: RLMT uses the link state reported by the adapter hardware for each individual port to determine whether a port can be used for all network traffic or not.

CheckLocalPort In this mode, RLMT monitors the network path between the two ports of an adapter by regularly exchanging packets between them. This mode requires a network configuration in which the two ports are able to "see" each other (i.e., there must not be any router between the ports).

CheckSeg Check local port and segmentation: This mode supports the same functions as the CheckLocalPort mode and additionally checks network segmentation between the ports. Therefore, this mode is to be used only if Gigabit Ethernet switches are installed on the network that have been configured to use the Spanning Tree protocol.

DualNet In this mode, ports A and B are used as separate devices. If you have a dual port adapter, port A will be configured as *eth[x]* and port B as *eth[x+1]*. Both ports can be used independently with distinct IP addresses. The preferred port setting is not used. RLMT is turned off.

Note that RLMT modes *CheckLocalPort* and *CheckLinkState* are designed to operate in configurations where a network path between the ports on one adapter exists. Moreover, they are not designed to work where adapters are connected back-to-back.

FILES

/proc/net/sk98lin/eth[x]

The statistics file of a particular interface of an adapter card. It contains generic information about the adapter card plus a detailed summary of all transmit and receive counters.

/usr/src/linux/Documentation/networking/sk98lin.txt

This is the *README* file of the *sk98lin* driver. It contains a detailed installation HOWTO and describes all parameters of the driver. It denotes also common problems and provides the solution to them.

NAME

smartpqi − Microchip Smart Storage SCSI driver

SYNOPSIS

modprobe smartpqi [**disable_device_id_wildcards=**{**0**|**1**}] [**disable_heartbeat=**{**0**|**1**}]
[**disable_ctrl_shutdown=**{**0**|**1**}] [**lockup_action=**{**none**|**reboot**|**panic**}]
[**expose_ld_first=**{**0**|**1**}] [**hide_vsep=**{**0**|**1**}]
[**disable_managed_interrupts=**{**0**|**1**}] [**ctrl_ready_timeout=**{**0**|[**30**,**1800**]}]

DESCRIPTION

smartpqi is a SCSI driver for Microchip Smart Storage controllers.

Supported *ioctl*() operations

For compatibility with applications written for the *cciss*(4) and *hpsa*(4) drivers, many, but not all of the *ioctl*(2) operations supported by the **hpsa** driver are also supported by the **smartpqi** driver. The data structures used by these operations are described in the Linux kernel source file *include/linux/cciss_ioctl.h*.

CCISS_DEREGDISK
CCISS_REGNEWDISK
CCISS_REGNEWD
: These operations all do exactly the same thing, which is to cause the driver to re-scan for new devices. This does exactly the same thing as writing to the **smartpqi**-specific host *rescan* attribute.

CCISS_GETPCIINFO
: This operation returns the PCI domain, bus, device, and function and "board ID" (PCI subsystem ID).

CCISS_GETDRIVVER
: This operation returns the driver version in four bytes, encoded as:

```
(major_version << 28) | (minor_version << 24) |
        (release << 16) | revision
```

CCISS_PASSTHRU
: Allows BMIC and CISS commands to be passed through to the controller.

Boot options

disable_device_id_wildcards={**0**|**1**}
: Disables support for device ID wildcards. The default value is 0 (wildcards are enabled).

disable_heartbeat={**0**|**1**}
: Disables support for the controller's heartbeat check. This parameter is used for debugging purposes. The default value is 0 (the controller's heartbeat check is enabled).

disable_ctrl_shutdown={**0**|**1**}
: Disables support for shutting down the controller in the event of a controller lockup. The default value is 0 (controller will be shut down).

lockup_action={**none**|**reboot**|**panic**}
: Specifies the action the driver takes when a controller lockup is detected. The default action is **none**.

parameter	action
none	take controller offline only
reboot	reboot the system
panic	panic the system

expose_ld_first={**0**|**1**}
: This option exposes logical devices to the OS before physical devices. The default value is 0 (physical devices exposed first).

hide_vsep={**0**|**1**}
: This option disables exposure of the virtual SEP to the OS. The default value is 0 (virtual SEP is exposed).

disable_managed_interrupts={**0**|**1**}
Disables driver utilization of Linux kernel managed interrupts for controllers. The managed interrupts feature automatically distributes interrupts to all available CPUs and assigns SMP affinity. The default value is 0 (managed interrupts enabled).

ctrl_ready_timeout={**0**|[**30**,**1800**]}
This option specifies the timeout in seconds for the driver to wait for the controller to be ready. The valid range is 0 or [**30**, **1800**]. The default value is 0, which causes the driver to use a timeout of 180 seconds.

FILES

Device nodes

Disk drives are accessed via the SCSI disk driver (*sd*), tape drives via the SCSI tape driver (*st*), and the RAID controller via the SCSI generic driver (*sg*), with device nodes named */dev/sd**, */dev/st**, and */dev/sg**, respectively.

SmartPQI-specific host attribute files in */sys*

/sys/class/scsi_host/host/rescan*
The host *rescan* attribute is a write-only attribute. Writing to this attribute will cause the driver to scan for new, changed, or removed devices (e.g., hot-plugged tape drives, or newly configured or deleted logical volumes) and notify the SCSI mid-layer of any changes detected. Usually this action is triggered automatically by configuration changes, so the user should not normally have to write to this file. Doing so may be useful when hot-plugging devices such as tape drives or entire storage boxes containing pre-configured logical volumes.

/sys/class/scsi_host/host/lockup_action*
The host *lockup_action* attribute is a read/write attribute. This attribute will cause the driver to perform a specific action in the unlikely event that a controller lockup has been detected. See **OPTIONS** above for an explanation of the *lockup_action* values.

/sys/class/scsi_host/host/driver_version*
The *driver_version* attribute is read-only. This attribute contains the smartpqi driver version.

For example:

```
$ cat /sys/class/scsi_host/host1/driver_version
1.1.2-126
```

/sys/class/scsi_host/host/firmware_version*
The *firmware_version* attribute is read-only. This attribute contains the controller firmware version.

For example:

```
$ cat /sys/class/scsi_host/host1/firmware_version
1.29-112
```

/sys/class/scsi_host/host/model*
The *model* attribute is read-only. This attribute contains the product identification string of the controller.

For example:

```
$ cat /sys/class/scsi_host/host1/model
1100-16i
```

/sys/class/scsi_host/host/serial_number*
The *serial_number* attribute is read-only. This attribute contains the unique identification number of the controller.

For example:

```
$ cat /sys/class/scsi_host/host1/serial_number
6A316373777
```

/sys/class/scsi_host/host/vendor*
The *vendor* attribute is read-only. This attribute contains the vendor identification string of the controller.

For example:

```
$ cat /sys/class/scsi_host/host1/vendor
Adaptec
```

/sys/class/scsi_host/host/enable_stream_detection*
The *enable_stream_detection* attribute is read-write. This attribute enables/disables stream detection in the driver. Enabling stream detection can improve sequential write performance for ioaccel-enabled volumes. See the **ssd_smart_path_enabled** disk attribute section for details on ioaccel-enabled volumes. The default value is 1 (stream detection enabled).

Enable example:

```
$ echo 1 > /sys/class/scsi_host/host1/enable_stream_detection
```

/sys/class/scsi_host/host/enable_r5_writes*
The *enable_r5_writes* attribute is read-write. This attribute enables/disables RAID 5 write operations for ioaccel-enabled volumes. Enabling can improve sequential write performance. See the **ssd_smart_path_enabled** disk attribute section for details on ioaccel-enabled volumes. The default value is 1 (RAID 5 writes enabled).

Enable example:

```
$ echo 1 > /sys/class/scsi_host/host1/enable_r5_writes
```

/sys/class/scsi_host/host/enable_r6_writes*
The *enable_r6_writes* attribute is read-write. This attribute enables/disables RAID 6 write operations for ioaccel-enabled volumes. Enabling can improve sequential write performance. See the **ssd_smart_path_enabled** disk attribute section for details on ioaccel-enabled volumes. The default value is 1 (RAID 6 writes enabled).

Enable example:

```
$ echo 1 > /sys/class/scsi_host/host1/enable_r6_writes
```

SmartPQI-specific disk attribute files in */sys*
In the file specifications below, *c* stands for the number of the appropriate SCSI controller, *b* is the bus number, *t* the target number, and *l* is the logical unit number (LUN).

*/sys/class/scsi_disk/*c:b:t:l*/device/raid_level*
The *raid_level* attribute is read-only. This attribute contains the RAID level of the logical volume.

For example:

```
$ cat /sys/class/scsi_disk/4:0:0:0/device/raid_level
RAID 0
```

*/sys/class/scsi_disk/*c:b:t:l*/device/sas_address*
The *sas_address* attribute is read-only. This attribute contains the SAS address of the device.

For example:

```
$ cat /sys/class/scsi_disk/1:0:3:0/device/sas_address
0x5001173d028543a2
```

*/sys/class/scsi_disk/*c:b:t:l*/device/ssd_smart_path_enabled*
The *ssd_smart_path_enabled* attribute is read-only. This attribute is for ioaccel-enabled volumes. (Ioaccel is an alternative driver submission path that allows the driver to send I/O requests directly to backend SCSI devices, bypassing the controller firmware. This results in an increase in performance. This method is used for HBA disks and for logical volumes comprised of SSDs.) Contains 1 if ioaccel is enabled for the volume and 0 otherwise.

For example:

```
$ cat /sys/class/scsi_disk/1:0:3:0/device/ssd_smart_path_enabled
```

*/sys/class/scsi_disk/*c:b:t:l*/device/lunid*
The *lunid* attribute is read-only. This attribute contains the SCSI LUN ID for the device.

For example:

```
$ cat /sys/class/scsi_disk/13:1:0:3/device/lunid
0x0300004000000000
```

/sys/class/scsi_disk/ c:b:t:l*/device/unique_id*
: The *unique_id* attribute is read-only. This attribute contains a 16-byte ID that uniquely identifies the device within the controller.

  For example:

```
$ cat /sys/class/scsi_disk/13:1:0:3/device/unique_id
600508B1001C6D4723A8E98D704FDB94
```

/sys/class/scsi_disk/ c:b:t:l*/device/path_info*
: The *path_info* attribute is read-only. This attribute contains the *c*:*b*:*t*:*l* of the device along with the device type and whether the device is Active or Inactive. If the device is an HBA device, *path_info* will also display the PORT, BOX, and BAY the device is plugged into.

  For example:

```
$ cat /sys/class/scsi_disk/13:1:0:3/device/path_info
[13:1:0:3]    Direct-Access     Active

$ cat /sys/class/scsi_disk/12:0:9:0/device/path_info
[12:0:9:0]  Direct-Access   PORT: C1 BOX: 1 BAY: 14 Inactive
[12:0:9:0]  Direct-Access   PORT: C0 BOX: 1 BAY: 14 Active
```

/sys/class/scsi_disk/ c:b:t:l*/device/raid_bypass_cnt*
: The *raid_bypass_cnt* attribute is read-only. This attribute contains the number of I/O requests that have gone through the ioaccel path for ioaccel-enabled volumes. See the **ssd_smart_path_enabled** disk attribute section for details on ioaccel-enabled volumes.

  For example:

```
$ cat /sys/class/scsi_disk/13:1:0:3/device/raid_bypass_cnt
0x300
```

/sys/class/scsi_disk/ c:b:t:l*/device/sas_ncq_prio_enable*
: The *sas_ncq_prio_enable* attribute is read/write. This attribute enables SATA NCQ priority support. This attribute works only when device has NCQ support and controller firmware can handle IO with NCQ priority attribute.

  For example:

```
$ echo 1 > /sys/class/scsi_disk/13:1:0:3/device/sas_ncq_prio_enable
```

VERSIONS

The **smartpqi** driver was added in Linux 4.9.

NOTES

Configuration

To configure a Microchip Smart Storage controller, refer to the User Guide for the controller, which can be found by searching for the specific controller at .

HISTORY

/sys/class/scsi_host/host/version* was replaced by two sysfs entries:

/sys/class/scsi_host/host/driver_version*

/sys/class/scsi_host/host/firmware_version*

NAME

st − SCSI tape device

SYNOPSIS

#include <sys/mtio.h>

int ioctl(int *fd***, int** *request* **[, (void *)***arg3***]);**
int ioctl(int *fd***, MTIOCTOP, (struct mtop *)***mt_cmd***);**
int ioctl(int *fd***, MTIOCGET, (struct mtget *)***mt_status***);**
int ioctl(int *fd***, MTIOCPOS, (struct mtpos *)***mt_pos***);**

DESCRIPTION

The **st** driver provides the interface to a variety of SCSI tape devices. Currently, the driver takes control of all detected devices of type "sequential-access". The **st** driver uses major device number 9.

Each device uses eight minor device numbers. The lowermost five bits in the minor numbers are assigned sequentially in the order of detection. In the 2.6 kernel, the bits above the eight lowermost bits are concatenated to the five lowermost bits to form the tape number. The minor numbers can be grouped into two sets of four numbers: the principal (auto-rewind) minor device numbers, *n*, and the "no-rewind" device numbers, (*n* + 128). Devices opened using the principal device number will be sent a **REWIND** command when they are closed. Devices opened using the "no-rewind" device number will not. (Note that using an auto-rewind device for positioning the tape with, for instance, mt does not lead to the desired result: the tape is rewound after the mt command and the next command starts from the beginning of the tape).

Within each group, four minor numbers are available to define devices with different characteristics (block size, compression, density, etc.) When the system starts up, only the first device is available. The other three are activated when the default characteristics are defined (see below). (By changing compile-time constants, it is possible to change the balance between the maximum number of tape drives and the number of minor numbers for each drive. The default allocation allows control of 32 tape drives. For instance, it is possible to control up to 64 tape drives with two minor numbers for different options.)

Devices are typically created by:

```
mknod −m 666 /dev/st0 c 9 0
mknod −m 666 /dev/st0l c 9 32
mknod −m 666 /dev/st0m c 9 64
mknod −m 666 /dev/st0a c 9 96
mknod −m 666 /dev/nst0 c 9 128
mknod −m 666 /dev/nst0l c 9 160
mknod −m 666 /dev/nst0m c 9 192
mknod −m 666 /dev/nst0a c 9 224
```

There is no corresponding block device.

The driver uses an internal buffer that has to be large enough to hold at least one tape block. Before Linux 2.1.121, the buffer is allocated as one contiguous block. This limits the block size to the largest contiguous block of memory the kernel allocator can provide. The limit is currently 128 kB for 32-bit architectures and 256 kB for 64-bit architectures. In newer kernels the driver allocates the buffer in several parts if necessary. By default, the maximum number of parts is 16. This means that the maximum block size is very large (2 MB if allocation of 16 blocks of 128 kB succeeds).

The driver's internal buffer size is determined by a compile-time constant which can be overridden with a kernel startup option. In addition to this, the driver tries to allocate a larger temporary buffer at run time if necessary. However, run-time allocation of large contiguous blocks of memory may fail and it is advisable not to rely too much on dynamic buffer allocation before Linux 2.1.121 (this applies also to demand-loading the driver with kerneld or kmod).

The driver does not specifically support any tape drive brand or model. After system start-up the tape device options are defined by the drive firmware. For example, if the drive firmware selects fixed-block mode, the tape device uses fixed-block mode. The options can be changed with explicit *ioctl*(2) calls and remain in effect when the device is closed and reopened. Setting the options affects both the auto-rewind and the nonrewind device.

Different options can be specified for the different devices within the subgroup of four. The options

take effect when the device is opened. For example, the system administrator can define one device that writes in fixed-block mode with a certain block size, and one which writes in variable-block mode (if the drive supports both modes).

The driver supports **tape partitions** if they are supported by the drive. (Note that the tape partitions have nothing to do with disk partitions. A partitioned tape can be seen as several logical tapes within one medium.) Partition support has to be enabled with an *ioctl*(2). The tape location is preserved within each partition across partition changes. The partition used for subsequent tape operations is selected with an *ioctl*(2). The partition switch is executed together with the next tape operation in order to avoid unnecessary tape movement. The maximum number of partitions on a tape is defined by a compile-time constant (originally four). The driver contains an *ioctl*(2) that can format a tape with either one or two partitions.

Device */dev/tape* is usually created as a hard or soft link to the default tape device on the system.

Starting from Linux 2.6.2, the driver exports in the sysfs directory */sys/class/scsi_tape* the attached devices and some parameters assigned to the devices.

Data transfer

The driver supports operation in both fixed-block mode and variable-block mode (if supported by the drive). In fixed-block mode the drive writes blocks of the specified size and the block size is not dependent on the byte counts of the write system calls. In variable-block mode one tape block is written for each write call and the byte count determines the size of the corresponding tape block. Note that the blocks on the tape don't contain any information about the writing mode: when reading, the only important thing is to use commands that accept the block sizes on the tape.

In variable-block mode the read byte count does not have to match the tape block size exactly. If the byte count is larger than the next block on tape, the driver returns the data and the function returns the actual block size. If the block size is larger than the byte count, an error is returned.

In fixed-block mode the read byte counts can be arbitrary if buffering is enabled, or a multiple of the tape block size if buffering is disabled. Before Linux 2.1.121 allow writes with arbitrary byte count if buffering is enabled. In all other cases (before Linux 2.1.121 with buffering disabled or newer kernel) the write byte count must be a multiple of the tape block size.

In Linux 2.6, the driver tries to use direct transfers between the user buffer and the device. If this is not possible, the driver's internal buffer is used. The reasons for not using direct transfers include improper alignment of the user buffer (default is 512 bytes but this can be changed by the HBA driver), one or more pages of the user buffer not reachable by the SCSI adapter, and so on.

A filemark is automatically written to tape if the last tape operation before close was a write.

When a filemark is encountered while reading, the following happens. If there are data remaining in the buffer when the filemark is found, the buffered data is returned. The next read returns zero bytes. The following read returns data from the next file. The end of recorded data is signaled by returning zero bytes for two consecutive read calls. The third read returns an error.

Ioctls

The driver supports three *ioctl*(2) requests. Requests not recognized by the **st** driver are passed to the **SCSI** driver. The definitions below are from */usr/include/linux/mtio.h*:

MTIOCTOP — perform a tape operation

This request takes an argument of type *(struct mtop *)*. Not all drives support all operations. The driver returns an **EIO** error if the drive rejects an operation.

```
/* Structure for MTIOCTOP - mag tape op command: */
struct mtop {
    short   mt_op;       /* operations defined below */
    int     mt_count;    /* how many of them */
};
```

Magnetic tape operations for normal tape use:

MTBSF

Backward space over *mt_count* filemarks.

MTBSFM
Backward space over *mt_count* filemarks. Reposition the tape to the EOT side of the last filemark.

MTBSR
Backward space over *mt_count* records (tape blocks).

MTBSS
Backward space over *mt_count* setmarks.

MTCOMPRESSION
Enable compression of tape data within the drive if *mt_count* is nonzero and disable compression if *mt_count* is zero. This command uses the MODE page 15 supported by most DATs.

MTEOM
Go to the end of the recorded media (for appending files).

MTERASE
Erase tape. With Linux 2.6, short erase (mark tape empty) is performed if the argument is zero. Otherwise, long erase (erase all) is done.

MTFSF
Forward space over *mt_count* filemarks.

MTFSFM
Forward space over *mt_count* filemarks. Reposition the tape to the BOT side of the last filemark.

MTFSR
Forward space over *mt_count* records (tape blocks).

MTFSS
Forward space over *mt_count* setmarks.

MTLOAD
Execute the SCSI load command. A special case is available for some HP autoloaders. If *mt_count* is the constant **MT_ST_HPLOADER_OFFSET** plus a number, the number is sent to the drive to control the autoloader.

MTLOCK
Lock the tape drive door.

MTMKPART
Format the tape into one or two partitions. If *mt_count* is positive, it gives the size of partition 1 and partition 0 contains the rest of the tape. If *mt_count* is zero, the tape is formatted into one partition. From Linux 4.6, a negative *mt_count* specifies the size of partition 0 and the rest of the tape contains partition 1. The physical ordering of partitions depends on the drive. This command is not allowed for a drive unless the partition support is enabled for the drive (see **MT_ST_CAN_PARTITIONS** below).

MTNOP
No op—flushes the driver's buffer as a side effect. Should be used before reading status with **MTIOCGET**.

MTOFFL
Rewind and put the drive off line.

MTRESET
Reset drive.

MTRETEN
Re-tension tape.

MTREW
Rewind.

MTSEEK
Seek to the tape block number specified in *mt_count*. This operation requires either a SCSI-2 drive that supports the **LOCATE** command (device-specific address) or a Tandberg-

compatible SCSI-1 drive (Tandberg, Archive Viper, Wangtek, ...). The block number should be one that was previously returned by **MTIOCPOS** if device-specific addresses are used.

MTSETBLK
Set the drive's block length to the value specified in *mt_count*. A block length of zero sets the drive to variable block size mode.

MTSETDENSITY
Set the tape density to the code in *mt_count*. The density codes supported by a drive can be found from the drive documentation.

MTSETPART
The active partition is switched to *mt_count*. The partitions are numbered from zero. This command is not allowed for a drive unless the partition support is enabled for the drive (see **MT_ST_CAN_PARTITIONS** below).

MTUNLOAD
Execute the SCSI unload command (does not eject the tape).

MTUNLOCK
Unlock the tape drive door.

MTWEOF
Write *mt_count* filemarks.

MTWSM
Write *mt_count* setmarks.

Magnetic tape operations for setting of device options (by the superuser):

MTSETDRVBUFFER
Set various drive and driver options according to bits encoded in *mt_count*. These consist of the drive's buffering mode, a set of Boolean driver options, the buffer write threshold, defaults for the block size and density, and timeouts (only since Linux 2.1). A single operation can affect only one item in the list below (the Booleans counted as one item.)

A value having zeros in the high-order 4 bits will be used to set the drive's buffering mode. The buffering modes are:

0 The drive will not report **GOOD** status on write commands until the data blocks are actually written to the medium.

1 The drive may report **GOOD** status on write commands as soon as all the data has been transferred to the drive's internal buffer.

2 The drive may report **GOOD** status on write commands as soon as (a) all the data has been transferred to the drive's internal buffer, and (b) all buffered data from different initiators has been successfully written to the medium.

To control the write threshold the value in *mt_count* must include the constant **MT_ST_WRITE_THRESHOLD** bitwise ORed with a block count in the low 28 bits. The block count refers to 1024-byte blocks, not the physical block size on the tape. The threshold cannot exceed the driver's internal buffer size (see DESCRIPTION, above).

To set and clear the Boolean options the value in *mt_count* must include one of the constants **MT_ST_BOOLEANS**, **MT_ST_SETBOOLEANS**, **MT_ST_CLEARBOOLEANS**, or **MT_ST_DEFBOOLEANS** bitwise ORed with whatever combination of the following options is desired. Using **MT_ST_BOOLEANS** the options can be set to the values defined in the corresponding bits. With **MT_ST_SETBOOLEANS** the options can be selectively set and with **MT_ST_DEFBOOLEANS** selectively cleared.

The default options for a tape device are set with **MT_ST_DEFBOOLEANS**. A nonactive tape device (e.g., device with minor 32 or 160) is activated when the default options for it are defined the first time. An activated device inherits from the device activated at start-up the options not set explicitly.

The Boolean options are:

MT_ST_BUFFER_WRITES (Default: true)
Buffer all write operations in fixed-block mode. If this option is false and the drive uses a fixed block size, then all write operations must be for a multiple of the block size. This option must be set false to write reliable multivolume archives.

MT_ST_ASYNC_WRITES (Default: true)
When this option is true, write operations return immediately without waiting for the data to be transferred to the drive if the data fits into the driver's buffer. The write threshold determines how full the buffer must be before a new SCSI write command is issued. Any errors reported by the drive will be held until the next operation. This option must be set false to write reliable multivolume archives.

MT_ST_READ_AHEAD (Default: true)
This option causes the driver to provide read buffering and read-ahead in fixed-block mode. If this option is false and the drive uses a fixed block size, then all read operations must be for a multiple of the block size.

MT_ST_TWO_FM (Default: false)
This option modifies the driver behavior when a file is closed. The normal action is to write a single filemark. If the option is true, the driver will write two filemarks and backspace over the second one.

Note: This option should not be set true for QIC tape drives since they are unable to overwrite a filemark. These drives detect the end of recorded data by testing for blank tape rather than two consecutive filemarks. Most other current drives also detect the end of recorded data and using two filemarks is usually necessary only when interchanging tapes with some other systems.

MT_ST_DEBUGGING (Default: false)
This option turns on various debugging messages from the driver (effective only if the driver was compiled with **DEBUG** defined nonzero).

MT_ST_FAST_EOM (Default: false)
This option causes the **MTEOM** operation to be sent directly to the drive, potentially speeding up the operation but causing the driver to lose track of the current file number normally returned by the **MTIOCGET** request. If **MT_ST_FAST_EOM** is false, the driver will respond to an **MTEOM** request by forward spacing over files.

MT_ST_AUTO_LOCK (Default: false)
When this option is true, the drive door is locked when the device file is opened and unlocked when it is closed.

MT_ST_DEF_WRITES (Default: false)
The tape options (block size, mode, compression, etc.) may change when changing from one device linked to a drive to another device linked to the same drive depending on how the devices are defined. This option defines when the changes are enforced by the driver using SCSI-commands and when the drives auto-detection capabilities are relied upon. If this option is false, the driver sends the SCSI-commands immediately when the device is changed. If the option is true, the SCSI-commands are not sent until a write is requested. In this case, the drive firmware is allowed to detect the tape structure when reading and the SCSI-commands are used only to make sure that a tape is written according to the correct specification.

MT_ST_CAN_BSR (Default: false)
When read-ahead is used, the tape must sometimes be spaced backward to the correct position when the device is closed and the SCSI command to space backward over records is used for this purpose. Some older drives can't process this command reliably and this option can be used to instruct the driver not to use the command. The end result is that, with read-ahead and fixed-block mode, the tape may not be correctly positioned within a file when the device is closed. With Linux 2.6, the default is true for drives supporting SCSI-3.

MT_ST_NO_BLKLIMS (Default: false)
Some drives don't accept the **READ BLOCK LIMITS** SCSI command. If this is used, the driver does not use the command. The drawback is that the driver can't

check before sending commands if the selected block size is acceptable to the drive.

MT_ST_CAN_PARTITIONS (Default: false)
This option enables support for several partitions within a tape. The option applies to all devices linked to a drive.

MT_ST_SCSI2LOGICAL (Default: false)
This option instructs the driver to use the logical block addresses defined in the SCSI-2 standard when performing the seek and tell operations (both with **MTSEEK** and **MTIOCPOS** commands and when changing tape partition). Otherwise, the device-specific addresses are used. It is highly advisable to set this option if the drive supports the logical addresses because they count also filemarks. There are some drives that support only the logical block addresses.

MT_ST_SYSV (Default: false)
When this option is enabled, the tape devices use the System V semantics. Otherwise, the BSD semantics are used. The most important difference between the semantics is what happens when a device used for reading is closed: in System V semantics the tape is spaced forward past the next filemark if this has not happened while using the device. In BSD semantics the tape position is not changed.

MT_NO_WAIT (Default: false)
Enables immediate mode (i.e., don't wait for the command to finish) for some commands (e.g., rewind).

An example:

```
struct mtop mt_cmd;
mt_cmd.mt_op = MTSETDRVBUFFER;
mt_cmd.mt_count = MT_ST_BOOLEANS |
        MT_ST_BUFFER_WRITES | MT_ST_ASYNC_WRITES;
ioctl(fd, MTIOCTOP, mt_cmd);
```

The default block size for a device can be set with **MT_ST_DEF_BLKSIZE** and the default density code can be set with **MT_ST_DEFDENSITY**. The values for the parameters are or'ed with the operation code.

With Linux 2.1.x and later, the timeout values can be set with the subcommand **MT_ST_SET_TIMEOUT** ORed with the timeout in seconds. The long timeout (used for rewinds and other commands that may take a long time) can be set with **MT_ST_SET_LONG_TIMEOUT**. The kernel defaults are very long to make sure that a successful command is not timed out with any drive. Because of this, the driver may seem stuck even if it is only waiting for the timeout. These commands can be used to set more practical values for a specific drive. The timeouts set for one device apply for all devices linked to the same drive.

Starting from Linux 2.4.19 and Linux 2.5.43, the driver supports a status bit which indicates whether the drive requests cleaning. The method used by the drive to return cleaning information is set using the **MT_ST_SEL_CLN** subcommand. If the value is zero, the cleaning bit is always zero. If the value is one, the TapeAlert data defined in the SCSI-3 standard is used (not yet implemented). Values 2–17 are reserved. If the lowest eight bits are >= 18, bits from the extended sense data are used. The bits 9–16 specify a mask to select the bits to look at and the bits 17–23 specify the bit pattern to look for. If the bit pattern is zero, one or more bits under the mask indicate the cleaning request. If the pattern is nonzero, the pattern must match the masked sense data byte.

MTIOCGET — get status
This request takes an argument of type *(struct mtget *)*.

```
/* structure for MTIOCGET - mag tape get status command */
struct mtget {
    long     mt_type;
    long     mt_resid;
    /* the following registers are device dependent */
    long     mt_dsreg;
```

```
        long     mt_gstat;
        long     mt_erreg;
        /* The next two fields are not always used */
        daddr_t  mt_fileno;
        daddr_t  mt_blkno;
    };
```

mt_type
: The header file defines many values for *mt_type*, but the current driver reports only the generic types **MT_ISSCSI1** (Generic SCSI-1 tape) and **MT_ISSCSI2** (Generic SCSI-2 tape).

mt_resid
: contains the current tape partition number.

mt_dsreg
: reports the drive's current settings for block size (in the low 24 bits) and density (in the high 8 bits). These fields are defined by **MT_ST_BLKSIZE_SHIFT**, **MT_ST_BLKSIZE_MASK**, **MT_ST_DENSITY_SHIFT**, and **MT_ST_DENSITY_MASK**.

mt_gstat
: reports generic (device independent) status information. The header file defines macros for testing these status bits:

  GMT_EOF(*x*)
  : The tape is positioned just after a filemark (always false after an **MTSEEK** operation).

  GMT_BOT(*x*)
  : The tape is positioned at the beginning of the first file (always false after an **MTSEEK** operation).

  GMT_EOT(*x*)
  : A tape operation has reached the physical End Of Tape.

  GMT_SM(*x*)
  : The tape is currently positioned at a setmark (always false after an **MTSEEK** operation).

  GMT_EOD(*x*)
  : The tape is positioned at the end of recorded data.

  GMT_WR_PROT(*x*)
  : The drive is write-protected. For some drives this can also mean that the drive does not support writing on the current medium type.

  GMT_ONLINE(*x*)
  : The last *open*(2) found the drive with a tape in place and ready for operation.

  GMT_D_6250(*x*)
  GMT_D_1600(*x*)
  GMT_D_800(*x*)
  : This "generic" status information reports the current density setting for 9-track ½" tape drives only.

  GMT_DR_OPEN(*x*)
  : The drive does not have a tape in place.

  GMT_IM_REP_EN(*x*)
  : Immediate report mode. This bit is set if there are no guarantees that the data has been physically written to the tape when the write call returns. It is set zero only when the driver does not buffer data and the drive is set not to buffer data.

  GMT_CLN(*x*)
  : The drive has requested cleaning. Implemented since Linux 2.4.19 and Linux 2.5.43.

mt_erreg
: The only field defined in *mt_erreg* is the recovered error count in the low 16 bits (as defined by **MT_ST_SOFTERR_SHIFT** and **MT_ST_SOFTERR_MASK**). Due to inconsistencies

in the way drives report recovered errors, this count is often not maintained (most drives do not by default report soft errors but this can be changed with a SCSI MODE SELECT command).

mt_fileno
reports the current file number (zero-based). This value is set to −1 when the file number is unknown (e.g., after **MTBSS** or **MTSEEK**).

mt_blkno
reports the block number (zero-based) within the current file. This value is set to −1 when the block number is unknown (e.g., after **MTBSF**, **MTBSS**, or **MTSEEK**).

MTIOCPOS — get tape position
This request takes an argument of type *(struct mtpos *)* and reports the drive's notion of the current tape block number, which is not the same as *mt_blkno* returned by **MTIOCGET**. This drive must be a SCSI-2 drive that supports the **READ POSITION** command (device-specific address) or a Tandberg-compatible SCSI-1 drive (Tandberg, Archive Viper, Wangtek, ...).

```
/* structure for MTIOCPOS - mag tape get position command */
struct mtpos {
    long mt_blkno;    /* current block number */
};
```

RETURN VALUE

EACCES
An attempt was made to write or erase a write-protected tape. (This error is not detected during *open*(2).)

EBUSY
The device is already in use or the driver was unable to allocate a buffer.

EFAULT
The command parameters point to memory not belonging to the calling process.

EINVAL
An *ioctl*(2) had an invalid argument, or a requested block size was invalid.

EIO The requested operation could not be completed.

ENOMEM
The byte count in *read*(2) is smaller than the next physical block on the tape. (Before Linux 2.2.18 and Linux 2.4.0 the extra bytes have been silently ignored.)

ENOSPC
A write operation could not be completed because the tape reached end-of-medium.

ENOSYS
Unknown *ioctl*(2).

ENXIO
During opening, the tape device does not exist.

EOVERFLOW
An attempt was made to read or write a variable-length block that is larger than the driver's internal buffer.

EROFS
Open is attempted with **O_WRONLY** or **O_RDWR** when the tape in the drive is write-protected.

NOTES

- When exchanging data between systems, both systems have to agree on the physical tape block size. The parameters of a drive after startup are often not the ones most operating systems use with these devices. Most systems use drives in variable-block mode if the drive supports that mode. This applies to most modern drives, including DATs, 8mm helical scan drives, DLTs, etc. It may be advisable to use these drives in variable-block mode also in Linux (i.e., use **MTSETBLK** or **MTSETDEFBLK** at system startup to set the mode), at least when exchanging data with a foreign system. The drawback of this is that a fairly large tape block size has to be used to get acceptable data transfer rates on the SCSI bus.
- Many programs (e.g., *tar*(1)) allow the user to specify the blocking factor on the command line. Note that this determines the physical block size on tape only in variable-block mode.
- In order to use SCSI tape drives, the basic SCSI driver, a SCSI-adapter driver and the SCSI tape driver must be either configured into the kernel or loaded as modules. If the SCSI-tape driver is not present, the drive is recognized but the tape support described in this page is not available.
- The driver writes error messages to the console/log. The SENSE codes written into some messages are automatically translated to text if verbose SCSI messages are enabled in kernel configuration.
- The driver's internal buffering allows good throughput in fixed-block mode also with small *read*(2) and *write*(2) byte counts. With direct transfers this is not possible and may cause a surprise when moving to the 2.6 kernel. The solution is to tell the software to use larger transfers (often telling it to use larger blocks). If this is not possible, direct transfers can be disabled.

NAME

tty − controlling terminal

DESCRIPTION

The file */dev/tty* is a character file with major number 5 and minor number 0, usually with mode 0666 and ownership root:tty. It is a synonym for the controlling terminal of a process, if any.

In addition to the *ioctl*(2) requests supported by the device that **tty** refers to, the *ioctl*(2) request **TIOCNOTTY** is supported.

TIOCNOTTY

Detach the calling process from its controlling terminal.

If the process is the session leader, then **SIGHUP** and **SIGCONT** signals are sent to the foreground process group and all processes in the current session lose their controlling tty.

This *ioctl*(2) call works only on file descriptors connected to */dev/tty*. It is used by daemon processes when they are invoked by a user at a terminal. The process attempts to open */dev/tty*. If the open succeeds, it detaches itself from the terminal by using **TIOCNOTTY**, while if the open fails, it is obviously not attached to a terminal and does not need to detach itself.

NAME

ttyS − serial terminal lines

DESCRIPTION

ttyS[0−3] are character devices for the serial terminal lines.

They are typically created by:

```
mknod −m 660 /dev/ttyS0 c 4 64 # base address 0x3f8
mknod −m 660 /dev/ttyS1 c 4 65 # base address 0x2f8
mknod −m 660 /dev/ttyS2 c 4 66 # base address 0x3e8
mknod −m 660 /dev/ttyS3 c 4 67 # base address 0x2e8
chown root:tty /dev/ttyS[0−3]
```

NAME

vcs, vcsa − virtual console memory

DESCRIPTION

/dev/vcs0 is a character device with major number 7 and minor number 0, usually with mode 0644 and ownership root:tty. It refers to the memory of the currently displayed virtual console terminal.

/dev/vcs[1−63] are character devices for virtual console terminals, they have major number 7 and minor number 1 to 63, usually mode 0644 and ownership root:tty. */dev/vcsa[0−63]* are the same, but using *unsigned short*s (in host byte order) that include attributes, and prefixed with four bytes giving the screen dimensions and cursor position: *lines*, *columns*, *x*, *y*. (*x* = *y* = 0 at the top left corner of the screen.)

When a 512-character font is loaded, the 9th bit position can be fetched by applying the *ioctl*(2) **VT_GETHIFONTMASK** operation (available since Linux 2.6.18) on */dev/tty[1−63]*; the value is returned in the *unsigned short* pointed to by the third *ioctl*(2) argument.

These devices replace the screendump *ioctl*(2) operations of *ioctl_console*(2), so the system administrator can control access using filesystem permissions.

The devices for the first eight virtual consoles may be created by:

```
for x in 0 1 2 3 4 5 6 7 8; do
    mknod −m 644 /dev/vcs$x c 7 $x;
    mknod −m 644 /dev/vcsa$x c 7 $[$x+128];
done
chown root:tty /dev/vcs*
```

No *ioctl*(2) requests are supported.

FILES

/dev/vcs[0−63]
/dev/vcsa[0−63]

VERSIONS

Introduced with Linux 1.1.92.

EXAMPLES

You may do a screendump on vt3 by switching to vt1 and typing

```
cat /dev/vcs3 >foo
```

Note that the output does not contain newline characters, so some processing may be required, like in

```
fold −w 81 /dev/vcs3 | lpr
```

or (horrors)

```
setterm −dump 3 −file /proc/self/fd/1
```

The */dev/vcsa0* device is used for Braille support.

This program displays the character and screen attributes under the cursor of the second virtual console, then changes the background color there:

```
#include <unistd.h>
#include <stdlib.h>
#include <stdio.h>
#include <fcntl.h>
#include <sys/ioctl.h>
#include <linux/vt.h>

int
main(void)
{
    int fd;
    char *device = "/dev/vcsa2";
    char *console = "/dev/tty2";
    struct {unsigned char lines, cols, x, y;} scrn;
```

```
        unsigned short s;
        unsigned short mask;
        unsigned char attrib;
        int ch;

        fd = open(console, O_RDWR);
        if (fd < 0) {
            perror(console);
            exit(EXIT_FAILURE);
        }
        if (ioctl(fd, VT_GETHIFONTMASK, &mask) < 0) {
            perror("VT_GETHIFONTMASK");
            exit(EXIT_FAILURE);
        }
        (void) close(fd);
        fd = open(device, O_RDWR);
        if (fd < 0) {
            perror(device);
            exit(EXIT_FAILURE);
        }
        (void) read(fd, &scrn, 4);
        (void) lseek(fd, 4 + 2*(scrn.y*scrn.cols + scrn.x), SEEK_SET);
        (void) read(fd, &s, 2);
        ch = s & 0xff;
        if (s & mask)
            ch |= 0x100;
        attrib = ((s & ~mask) >> 8);
        printf("ch=%#03x attrib=%#02x\n", ch, attrib);
        s ^= 0x1000;
        (void) lseek(fd, -2, SEEK_CUR);
        (void) write(fd, &s, 2);
        exit(EXIT_SUCCESS);
    }
```

NAME

veth − Virtual Ethernet Device

DESCRIPTION

The **veth** devices are virtual Ethernet devices. They can act as tunnels between network namespaces to create a bridge to a physical network device in another namespace, but can also be used as standalone network devices.

veth devices are always created in interconnected pairs. A pair can be created using the command:

```
# ip link add <p1-name> type veth peer name <p2-name>
```

In the above, *p1-name* and *p2-name* are the names assigned to the two connected end points.

Packets transmitted on one device in the pair are immediately received on the other device. When either device is down, the link state of the pair is down.

veth device pairs are useful for combining the network facilities of the kernel together in interesting ways. A particularly interesting use case is to place one end of a **veth** pair in one network namespace and the other end in another network namespace, thus allowing communication between network namespaces. To do this, one can provide the **netns** parameter when creating the interfaces:

```
# ip link add <p1−name> netns <p1−ns> type veth peer <p2−name> netns <p2−ns>
```

or, for an existing **veth** pair, move one side to the other namespace:

```
# ip link set <p2−name> netns <p2−ns>
```

ethtool(8) can be used to find the peer of a **veth** network interface, using commands something like:

```
# ip link add ve_A type veth peer name ve_B   # Create veth pair
# ethtool −S ve_A         # Discover interface index of peer
NIC statistics:
     peer_ifindex: 16
# ip link | grep '^16:'   # Look up interface
16: ve_B@ve_A: <BROADCAST,MULTICAST,M−DOWN> mtu 1500 qdisc ...
```

NAME

wavelan − AT&T GIS WaveLAN ISA device driver

SYNOPSIS

insmod wavelan_cs.o [io=*B,B..***] [irq=***I,I..***] [name=***N,N..***]**

DESCRIPTION

This driver is obsolete: it was removed in Linux 2.6.35.

wavelan is the low-level device driver for the NCR / AT&T / Lucent **WaveLAN ISA** and Digital (DEC) **RoamAbout DS** wireless ethernet adapter. This driver is available as a module or might be compiled in the kernel. This driver supports multiple cards in both forms (up to 4) and allocates the next available ethernet device (eth0..eth#) for each card found, unless a device name is explicitly specified (see below). This device name will be reported in the kernel log file with the MAC address, NWID, and frequency used by the card.

Parameters

This section applies to the module form (parameters passed on the *insmod*(8) command line). If the driver is included in the kernel, use the *ether=IRQ,IO,NAME* syntax on the kernel command line.

io Specify the list of base addresses where to search for wavelan cards (setting by dip switch on the card). If you don't specify any io address, the driver will scan 0x390 and 0x3E0 addresses, which might conflict with other hardware...

irq Set the list of IRQs that each wavelan card should use (the value is saved in permanent storage for future use).

name Set the list of names to be used for each wavelan card device (name used by *ifconfig*(8)).

Wireless extensions

Use *iwconfig*(8) to manipulate wireless extensions.

NWID (or domain)

Set the network ID [*0* to *FFFF*] or disable it [*off*]. As the NWID is stored in the card Permanent Storage Area, it will be reused at any further invocation of the driver.

Frequency & channels

For the 2.4 GHz 2.00 Hardware, you are able to set the frequency by specifying one of the 10 defined channels (*2.412, 2.422, 2.425, 2.4305, 2.432, 2.442, 2.452, 2.460, 2.462* or *2.484*) or directly as a numeric value. The frequency is changed immediately and permanently. Frequency availability depends on the regulations...

Statistics spy

Set a list of MAC addresses in the driver (up to 8) and get the last quality of link for each of those (see *iwspy*(8)).

/proc/net/wireless

status is the status reported by the modem. *Link quality* reports the quality of the modulation on the air (direct sequence spread spectrum) [max = 16]. *Level* and *Noise* refer to the signal level and noise level [max = 64]. The *crypt discarded packet* and *misc discarded packet* counters are not implemented.

Private ioctl

You may use *iwpriv*(8) to manipulate private ioctls.

Quality and level threshold

Enables you to define the quality and level threshold used by the modem (packet below that level are discarded).

Histogram

This functionality makes it possible to set a number of signal level intervals and to count the number of packets received in each of those defined intervals. This distribution might be used to calculate the mean value and standard deviation of the signal level.

Specific notes

This driver fails to detect some **non-NCR/AT&T/Lucent** Wavelan cards. If this happens for you, you must look in the source code on how to add your card to the detection routine.

Some of the mentioned features are optional. You may enable or disable them by changing flags in the driver header and recompile.

NAME

acct − process accounting file

SYNOPSIS

#include <sys/acct.h>

DESCRIPTION

If the kernel is built with the process accounting option enabled (**CONFIG_BSD_PROCESS_ACCT**), then calling *acct*(2) starts process accounting, for example:

```
acct("/var/log/pacct");
```

When process accounting is enabled, the kernel writes a record to the accounting file as each process on the system terminates. This record contains information about the terminated process, and is defined in <*sys/acct.h*> as follows:

```
#define ACCT_COMM 16

typedef u_int16_t comp_t;

struct acct {
    char ac_flag;           /* Accounting flags */
    u_int16_t ac_uid;       /* Accounting user ID */
    u_int16_t ac_gid;       /* Accounting group ID */
    u_int16_t ac_tty;       /* Controlling terminal */
    u_int32_t ac_btime;     /* Process creation time
                               (seconds since the Epoch) */
    comp_t    ac_utime;     /* User CPU time */
    comp_t    ac_stime;     /* System CPU time */
    comp_t    ac_etime;     /* Elapsed time */
    comp_t    ac_mem;       /* Average memory usage (kB) */
    comp_t    ac_io;        /* Characters transferred (unused) */
    comp_t    ac_rw;        /* Blocks read or written (unused) */
    comp_t    ac_minflt;    /* Minor page faults */
    comp_t    ac_majflt;    /* Major page faults */
    comp_t    ac_swaps;     /* Number of swaps (unused) */
    u_int32_t ac_exitcode;  /* Process termination status
                               (see wait(2)) */
    char      ac_comm[ACCT_COMM+1];
                            /* Command name (basename of last
                               executed command; null-terminated) */
    char      ac_pad[X];    /* padding bytes */
};

enum {          /* Bits that may be set in ac_flag field */
    AFORK = 0x01,           /* Has executed fork, but no exec */
    ASU   = 0x02,           /* Used superuser privileges */
    ACORE = 0x08,           /* Dumped core */
    AXSIG = 0x10            /* Killed by a signal */
};
```

The *comp_t* data type is a floating-point value consisting of a 3-bit, base-8 exponent, and a 13-bit mantissa. A value, *c*, of this type can be converted to a (long) integer as follows:

```
v = (c & 0x1fff) << (((c >> 13) & 0x7) * 3);
```

The *ac_utime*, *ac_stime*, and *ac_etime* fields measure time in "clock ticks"; divide these values by *sysconf(_SC_CLK_TCK)* to convert them to seconds.

Version 3 accounting file format

Since Linux 2.6.8, an optional alternative version of the accounting file can be produced if the **CONFIG_BSD_PROCESS_ACCT_V3** option is set when building the kernel. With this option is set, the records written to the accounting file contain additional fields, and the width of *c_uid* and *ac_gid* fields is widened from 16 to 32 bits (in line with the increased size of UID and GIDs in Linux 2.4 and later).

The records are defined as follows:

```
struct acct_v3 {
    char      ac_flag;      /* Flags */
    char      ac_version;   /* Always set to ACCT_VERSION (3) */
    u_int16_t ac_tty;       /* Controlling terminal */
    u_int32_t ac_exitcode;  /* Process termination status */
    u_int32_t ac_uid;       /* Real user ID */
    u_int32_t ac_gid;       /* Real group ID */
    u_int32_t ac_pid;       /* Process ID */
    u_int32_t ac_ppid;      /* Parent process ID */
    u_int32_t ac_btime;     /* Process creation time */
    float     ac_etime;     /* Elapsed time */
    comp_t    ac_utime;     /* User CPU time */
    comp_t    ac_stime;     /* System time */
    comp_t    ac_mem;       /* Average memory usage (kB) */
    comp_t    ac_io;        /* Characters transferred (unused) */
    comp_t    ac_rw;        /* Blocks read or written
                               (unused) */
    comp_t    ac_minflt;    /* Minor page faults */
    comp_t    ac_majflt;    /* Major page faults */
    comp_t    ac_swaps;     /* Number of swaps (unused) */
    char      ac_comm[ACCT_COMM]; /* Command name */
};
```

VERSIONS

Although it is present on most systems, it is not standardized, and the details vary somewhat between systems.

STANDARDS

None.

HISTORY

glibc 2.6.

Process accounting originated on BSD.

NOTES

Records in the accounting file are ordered by termination time of the process.

Up to and including Linux 2.6.9, a separate accounting record is written for each thread created using the NPTL threading library; since Linux 2.6.10, a single accounting record is written for the entire process on termination of the last thread in the process.

The */proc/sys/kernel/acct* file, described in *proc*(5), defines settings that control the behavior of process accounting when disk space runs low.

NAME

charmap − character set description file

DESCRIPTION

A character set description (charmap) defines all available characters and their encodings in a character set. *localedef*(1) can use charmaps to create locale variants for different character sets.

Syntax

The charmap file starts with a header that may consist of the following keywords:

<*code_set_name*>
: is followed by the name of the character map.

<*comment_char*>
: is followed by a character that will be used as the comment character for the rest of the file. It defaults to the number sign (#).

<*escape_char*>
: is followed by a character that should be used as the escape character for the rest of the file to mark characters that should be interpreted in a special way. It defaults to the backslash (\).

<*mb_cur_max*>
: is followed by the maximum number of bytes for a character. The default value is 1.

<*mb_cur_min*>
: is followed by the minimum number of bytes for a character. This value must be less than or equal than <*mb_cur_max*>. If not specified, it defaults to <*mb_cur_max*>.

The character set definition section starts with the keyword *CHARMAP* in the first column.

The following lines may have one of the two following forms to define the character set:

<*character*> *byte-sequence comment*
: This form defines exactly one character and its byte sequence, *comment* being optional.

<*character*>..<*character*> *byte-sequence comment*
: This form defines a character range and its byte sequence, *comment* being optional.

The character set definition section ends with the string *END CHARMAP*.

The character set definition section may optionally be followed by a section to define widths of characters.

The *WIDTH_DEFAULT* keyword can be used to define the default width for all characters not explicitly listed. The default character width is 1.

The width section for individual characters starts with the keyword *WIDTH* in the first column.

The following lines may have one of the two following forms to define the widths of the characters:

<*character*> *width*
: This form defines the width of exactly one character.

<*character*>...<*character*> *width*
: This form defines the width for all the characters in the range.

The width definition section ends with the string *END WIDTH*.

FILES

/usr/share/i18n/charmaps
: Usual default character map path.

STANDARDS

POSIX.2.

EXAMPLES

The Euro sign is defined as follows in the *UTF−8* charmap:

```
<U20AC>     /xe2/x82/xac EURO SIGN
```

NAME

core − core dump file

DESCRIPTION

The default action of certain signals is to cause a process to terminate and produce a *core dump file*, a file containing an image of the process's memory at the time of termination. This image can be used in a debugger (e.g., *gdb*(1)) to inspect the state of the program at the time that it terminated. A list of the signals which cause a process to dump core can be found in *signal*(7).

A process can set its soft **RLIMIT_CORE** resource limit to place an upper limit on the size of the core dump file that will be produced if it receives a "core dump" signal; see *getrlimit*(2) for details.

There are various circumstances in which a core dump file is not produced:

- The process does not have permission to write the core file. (By default, the core file is called *core* or *core.pid*, where *pid* is the ID of the process that dumped core, and is created in the current working directory. See below for details on naming.) Writing the core file fails if the directory in which it is to be created is not writable, or if a file with the same name exists and is not writable or is not a regular file (e.g., it is a directory or a symbolic link).
- A (writable, regular) file with the same name as would be used for the core dump already exists, but there is more than one hard link to that file.
- The filesystem where the core dump file would be created is full; or has run out of inodes; or is mounted read-only; or the user has reached their quota for the filesystem.
- The directory in which the core dump file is to be created does not exist.
- The **RLIMIT_CORE** (core file size) or **RLIMIT_FSIZE** (file size) resource limits for the process are set to zero; see *getrlimit*(2) and the documentation of the shell's *ulimit* command (*limit* in *csh*(1)). However, **RLIMIT_CORE** will be ignored if the system is configured to pipe core dumps to a program.
- The binary being executed by the process does not have read permission enabled. (This is a security measure to ensure that an executable whose contents are not readable does not produce a—possibly readable—core dump containing an image of the executable.)
- The process is executing a set-user-ID (set-group-ID) program that is owned by a user (group) other than the real user (group) ID of the process, or the process is executing a program that has file capabilities (see *capabilities*(7)). (However, see the description of the *prctl*(2) **PR_SET_DUMPABLE** operation, and the description of the */proc/sys/fs/suid_dumpable* file in *proc*(5).)
- */proc/sys/kernel/core_pattern* is empty and */proc/sys/kernel/core_uses_pid* contains the value 0. (These files are described below.) Note that if */proc/sys/kernel/core_pattern* is empty and */proc/sys/kernel/core_uses_pid* contains the value 1, core dump files will have names of the form *.pid*, and such files are hidden unless one uses the *ls*(1) *−a* option.
- (Since Linux 3.7) The kernel was configured without the **CONFIG_COREDUMP** option.

In addition, a core dump may exclude part of the address space of the process if the *madvise*(2) **MADV_DONTDUMP** flag was employed.

On systems that employ *systemd*(1) as the *init* framework, core dumps may instead be placed in a location determined by *systemd*(1)See below for further details.

Naming of core dump files

By default, a core dump file is named *core*, but the */proc/sys/kernel/core_pattern* file (since Linux 2.6 and 2.4.21) can be set to define a template that is used to name core dump files. The template can contain % specifiers which are substituted by the following values when a core file is created:

%%
: A single % character.

%c
: Core file size soft resource limit of crashing process (since Linux 2.6.24).

%d
: Dump mode—same as value returned by *prctl*(2) **PR_GET_DUMPABLE** (since Linux 3.7).

%e
: The process or thread's *comm* value, which typically is the same as the executable filename (without path prefix, and truncated to a maximum of 15 characters), but may have been modified to be something different; see the discussion of */proc/*pid*/comm* and */proc/*pid*/task/*tid*/comm* in *proc*(5).

%E Pathname of executable, with slashes ('/') replaced by exclamation marks ('!') (since Linux 3.0).
%g Numeric real GID of dumped process.
%h Hostname (same as *nodename* returned by **uname**(2)).
%i TID of thread that triggered core dump, as seen in the PID namespace in which the thread resides (since Linux 3.18).
%I TID of thread that triggered core dump, as seen in the initial PID namespace (since Linux 3.18).
%p PID of dumped process, as seen in the PID namespace in which the process resides.
%P PID of dumped process, as seen in the initial PID namespace (since Linux 3.12).
%s Number of signal causing dump.
%t Time of dump, expressed as seconds since the Epoch, 1970-01-01 00:00:00 +0000 (UTC).
%u Numeric real UID of dumped process.

A single % at the end of the template is dropped from the core filename, as is the combination of a % followed by any character other than those listed above. All other characters in the template become a literal part of the core filename. The template may include '/' characters, which are interpreted as delimiters for directory names. The maximum size of the resulting core filename is 128 bytes (64 bytes before Linux 2.6.19). The default value in this file is "core". For backward compatibility, if */proc/sys/kernel/core_pattern* does not include *%p* and */proc/sys/kernel/core_uses_pid* (see below) is nonzero, then .PID will be appended to the core filename.

Paths are interpreted according to the settings that are active for the crashing process. That means the crashing process's mount namespace (see *mount_namespaces*(7)), its current working directory (found via *getcwd*(2)), and its root directory (see *chroot*(2)).

Since Linux 2.4, Linux has also provided a more primitive method of controlling the name of the core dump file. If the */proc/sys/kernel/core_uses_pid* file contains the value 0, then a core dump file is simply named *core*. If this file contains a nonzero value, then the core dump file includes the process ID in a name of the form *core.PID*.

Since Linux 3.6, if */proc/sys/fs/suid_dumpable* is set to 2 ("suidsafe"), the pattern must be either an absolute pathname (starting with a leading '/' character) or a pipe, as defined below.

Piping core dumps to a program

Since Linux 2.6.19, Linux supports an alternate syntax for the */proc/sys/kernel/core_pattern* file. If the first character of this file is a pipe symbol (|), then the remainder of the line is interpreted as the command-line for a user-space program (or script) that is to be executed.

Since Linux 5.3.0, the pipe template is split on spaces into an argument list *before* the template parameters are expanded. In earlier kernels, the template parameters are expanded first and the resulting string is split on spaces into an argument list. This means that in earlier kernels executable names added by the *%e* and *%E* template parameters could get split into multiple arguments. So the core dump handler needs to put the executable names as the last argument and ensure it joins all parts of the executable name using spaces. Executable names with multiple spaces in them are not correctly represented in earlier kernels, meaning that the core dump handler needs to use mechanisms to find the executable name.

Instead of being written to a file, the core dump is given as standard input to the program. Note the following points:

- The program must be specified using an absolute pathname (or a pathname relative to the root directory, */*), and must immediately follow the '|' character.
- The command-line arguments can include any of the % specifiers listed above. For example, to pass the PID of the process that is being dumped, specify *%p* in an argument.
- The process created to run the program runs as user and group *root*.
- Running as *root* does not confer any exceptional security bypasses. Namely, LSMs (e.g., SELinux) are still active and may prevent the handler from accessing details about the crashed process via */proc/*pid.
- The program pathname is interpreted with respect to the initial mount namespace as it is always executed there. It is not affected by the settings (e.g., root directory, mount namespace, current working directory) of the crashing process.

- The process runs in the initial namespaces (PID, mount, user, and so on) and not in the namespaces of the crashing process. One can utilize specifiers such as *%P* to find the right */proc/*pid directory and probe/enter the crashing process's namespaces if needed.
- The process starts with its current working directory as the root directory. If desired, it is possible change to the working directory of the dumping process by employing the value provided by the *%P* specifier to change to the location of the dumping process via */proc/*pid*/cwd*.
- Command-line arguments can be supplied to the program (since Linux 2.6.24), delimited by white space (up to a total line length of 128 bytes).
- The **RLIMIT_CORE** limit is not enforced for core dumps that are piped to a program via this mechanism.

/proc/sys/kernel/core_pipe_limit

When collecting core dumps via a pipe to a user-space program, it can be useful for the collecting program to gather data about the crashing process from that process's */proc/*pid directory. In order to do this safely, the kernel must wait for the program collecting the core dump to exit, so as not to remove the crashing process's */proc/*pid files prematurely. This in turn creates the possibility that a misbehaving collecting program can block the reaping of a crashed process by simply never exiting.

Since Linux 2.6.32, the */proc/sys/kernel/core_pipe_limit* can be used to defend against this possibility. The value in this file defines how many concurrent crashing processes may be piped to user-space programs in parallel. If this value is exceeded, then those crashing processes above this value are noted in the kernel log and their core dumps are skipped.

A value of 0 in this file is special. It indicates that unlimited processes may be captured in parallel, but that no waiting will take place (i.e., the collecting program is not guaranteed access to */proc/<crashing−PID>*). The default value for this file is 0.

Controlling which mappings are written to the core dump

Since Linux 2.6.23, the Linux-specific */proc/*pid*/coredump_filter* file can be used to control which memory segments are written to the core dump file in the event that a core dump is performed for the process with the corresponding process ID.

The value in the file is a bit mask of memory mapping types (see *mmap*(2)). If a bit is set in the mask, then memory mappings of the corresponding type are dumped; otherwise they are not dumped. The bits in this file have the following meanings:

bit 0 Dump anonymous private mappings.
bit 1 Dump anonymous shared mappings.
bit 2 Dump file-backed private mappings.
bit 3 Dump file-backed shared mappings.
bit 4 (since Linux 2.6.24)
Dump ELF headers.
bit 5 (since Linux 2.6.28)
Dump private huge pages.
bit 6 (since Linux 2.6.28)
Dump shared huge pages.
bit 7 (since Linux 4.4)
Dump private DAX pages.
bit 8 (since Linux 4.4)
Dump shared DAX pages.

By default, the following bits are set: 0, 1, 4 (if the **CONFIG_CORE_DUMP_DEFAULT_ELF_HEADERS** kernel configuration option is enabled), and 5. This default can be modified at boot time using the *coredump_filter* boot option.

The value of this file is displayed in hexadecimal. (The default value is thus displayed as 33.)

Memory-mapped I/O pages such as frame buffer are never dumped, and virtual DSO (**vdso**(7)) pages are always dumped, regardless of the *coredump_filter* value.

A child process created via *fork*(2) inherits its parent's *coredump_filter* value; the *coredump_filter* value is preserved across an *execve*(2).

It can be useful to set *coredump_filter* in the parent shell before running a program, for example:

```
$ echo 0x7 > /proc/self/coredump_filter
$ ./some_program
```

This file is provided only if the kernel was built with the **CONFIG_ELF_CORE** configuration option.

Core dumps and systemd

On systems using the *systemd*(1) *init* framework, core dumps may be placed in a location determined by *systemd*(1)To do this, *systemd*(1) employs the *core_pattern* feature that allows piping core dumps to a program. One can verify this by checking whether core dumps are being piped to the *systemd-coredump*(8) program:

```
$ cat /proc/sys/kernel/core_pattern
|/usr/lib/systemd/systemd-coredump %P %u %g %s %t %c %e
```

In this case, core dumps will be placed in the location configured for *systemd-coredump*(8), typically as *lz4*(1) compressed files in the directory */var/lib/systemd/coredump/*. One can list the core dumps that have been recorded by *systemd-coredump*(8) using *coredumpctl*(1):

```
$ coredumpctl list | tail -5
Wed 2017-10-11 22:25:30 CEST  2748 1000 1000 3 present  /usr/bin/sleep
Thu 2017-10-12 06:29:10 CEST  2716 1000 1000 3 present  /usr/bin/sleep
Thu 2017-10-12 06:30:50 CEST  2767 1000 1000 3 present  /usr/bin/sleep
Thu 2017-10-12 06:37:40 CEST  2918 1000 1000 3 present  /usr/bin/cat
Thu 2017-10-12 08:13:07 CEST  2955 1000 1000 3 present  /usr/bin/cat
```

The information shown for each core dump includes the date and time of the dump, the PID, UID, and GID of the dumping process, the signal number that caused the core dump, and the pathname of the executable that was being run by the dumped process. Various options to *coredumpctl*(1) allow a specified coredump file to be pulled from the *systemd*(1) location into a specified file. For example, to extract the core dump for PID 2955 shown above to a file named *core* in the current directory, one could use:

```
$ coredumpctl dump 2955 -o core
```

For more extensive details, see the *coredumpctl*(1) manual page.

To (persistently) disable the *systemd*(1) mechanism that archives core dumps, restoring to something more like traditional Linux behavior, one can set an override for the *systemd*(1) mechanism, using something like:

```
# echo "kernel.core_pattern=core.%p" > \
                /etc/sysctl.d/50-coredump.conf
# /lib/systemd/systemd-sysctl
```

It is also possible to temporarily (i.e., until the next reboot) change the *core_pattern* setting using a command such as the following (which causes the names of core dump files to include the executable name as well as the number of the signal which triggered the core dump):

```
# sysctl -w kernel.core_pattern="%e-%s.core"
```

NOTES

The *gdb*(1) *gcore* command can be used to obtain a core dump of a running process.

In Linux versions up to and including 2.6.27, if a multithreaded process (or, more precisely, a process that shares its memory with another process by being created with the **CLONE_VM** flag of *clone*(2)) dumps core, then the process ID is always appended to the core filename, unless the process ID was already included elsewhere in the filename via a *%p* specification in */proc/sys/kernel/core_pattern*. (This is primarily useful when employing the obsolete LinuxThreads implementation, where each thread of a process has a different PID.)

EXAMPLES

The program below can be used to demonstrate the use of the pipe syntax in the */proc/sys/kernel/core_pattern* file. The following shell session demonstrates the use of this program (compiled to create an executable named *core_pattern_pipe_test*):

```
$ cc -o core_pattern_pipe_test core_pattern_pipe_test.c
$ su
Password:
```

```
# echo "|$PWD/core_pattern_pipe_test %p UID=%u GID=%g sig=%s" > \
    /proc/sys/kernel/core_pattern
# exit
$ sleep 100
^\                      # type control-backslash
Quit (core dumped)
$ cat core.info
argc=5
argc[0]=</home/mtk/core_pattern_pipe_test>
argc[1]=<20575>
argc[2]=<UID=1000>
argc[3]=<GID=100>
argc[4]=<sig=3>
Total bytes in core dump: 282624
```

Program source

```
/* core_pattern_pipe_test.c */

#define _GNU_SOURCE
#include <sys/stat.h>

NAME

dir_colors − configuration file for dircolors(1)

DESCRIPTION

The program *ls*(1) uses the environment variable **LS_COLORS** to determine the colors in which the filenames are to be displayed. This environment variable is usually set by a command like

eval `dircolors some_path/dir_colors`

found in a system default shell initialization file, like */etc/profile* or */etc/csh.cshrc*. (See also *dircolors*(1)Usually, the file used here is */etc/DIR_COLORS* and can be overridden by a *.dir_colors* file in one's home directory.

This configuration file consists of several statements, one per line. Anything right of a hash mark (#) is treated as a comment, if the hash mark is at the beginning of a line or is preceded by at least one whitespace. Blank lines are ignored.

The *global* section of the file consists of any statement before the first **TERM** statement. Any statement in the global section of the file is considered valid for all terminal types. Following the global section is one or more *terminal-specific* sections, preceded by one or more **TERM** statements which specify the terminal types (as given by the **TERM** environment variable) the following declarations apply to. It is always possible to override a global declaration by a subsequent terminal-specific one.

The following statements are recognized; case is insignificant:

TERM *terminal-type*
: Starts a terminal-specific section and specifies which terminal it applies to. Multiple **TERM** statements can be used to create a section which applies for several terminal types.

COLOR yes|all|no|none|tty
: (Slackware only; ignored by GNU *dircolors*(1)Specifies that colorization should always be enabled (*yes* or *all*), never enabled (*no* or *none*), or enabled only if the output is a terminal (*tty*). The default is *no*.

EIGHTBIT yes|no
: (Slackware only; ignored by GNU *dircolors*(1)Specifies that eight-bit ISO/IEC 8859 characters should be enabled by default. For compatibility reasons, this can also be specified as 1 for *yes* or 0 for *no*. The default is *no*.

OPTIONS *options*
: (Slackware only; ignored by GNU *dircolors*(1)Adds command-line options to the default **ls** command line. The options can be any valid **ls** command-line options, and should include the leading minus sign. Note that **dircolors** does not verify the validity of these options.

NORMAL *color-sequence*
: Specifies the color used for normal (nonfilename) text.

  Synonym: **NORM**.

FILE *color-sequence*
: Specifies the color used for a regular file.

DIR *color-sequence*
: Specifies the color used for directories.

LINK *color-sequence*
: Specifies the color used for a symbolic link.

  Synonyms: **LNK**, **SYMLINK**.

ORPHAN *color-sequence*
: Specifies the color used for an orphaned symbolic link (one which points to a nonexistent file). If this is unspecified, **ls** will use the **LINK** color instead.

MISSING *color-sequence*
: Specifies the color used for a missing file (a nonexistent file which nevertheless has a symbolic link pointing to it). If this is unspecified, **ls** will use the **FILE** color instead.

FIFO *color-sequence*
Specifies the color used for a FIFO (named pipe).

Synonym: **PIPE**.

SOCK *color-sequence*
Specifies the color used for a socket.

DOOR *color-sequence*
(Supported since fileutils 4.1) Specifies the color used for a door (Solaris 2.5 and later).

BLK *color-sequence*
Specifies the color used for a block device special file.

Synonym: **BLOCK**.

CHR *color-sequence*
Specifies the color used for a character device special file.

Synonym: **CHAR**.

EXEC *color-sequence*
Specifies the color used for a file with the executable attribute set.

SUID *color-sequence*
Specifies the color used for a file with the set-user-ID attribute set.

Synonym: **SETUID**.

SGID *color-sequence*
Specifies the color used for a file with the set-group-ID attribute set.

Synonym: **SETGID**.

STICKY *color-sequence*
Specifies the color used for a directory with the sticky attribute set.

STICKY_OTHER_WRITABLE *color-sequence*
Specifies the color used for an other-writable directory with the executable attribute set.

Synonym: **OWT**.

OTHER_WRITABLE *color-sequence*
Specifies the color used for an other-writable directory without the executable attribute set.

Synonym: **OWR**.

LEFTCODE *color-sequence*
Specifies the *left code* for non-ISO/IEC 6429 terminals (see below).

Synonym: **LEFT**.

RIGHTCODE *color-sequence*
Specifies the *right code* for non-ISO/IEC 6429 terminals (see below).

Synonym: **RIGHT**.

ENDCODE *color-sequence*
Specifies the *end code* for non-ISO/IEC 6429 terminals (see below).

Synonym: **END**.

*******extension color-sequence*
Specifies the color used for any file that ends in *extension*.

.*extension color-sequence*
Same as *******.extension*. Specifies the color used for any file that ends in *.extension*. Note that the period is included in the extension, which makes it impossible to specify an extension not starting with a period, such as **~** for **emacs** backup files. This form should be considered obsolete.

ISO/IEC 6429 (ANSI) color sequences
Most color-capable ASCII terminals today use ISO/IEC 6429 (ANSI) color sequences, and many common terminals without color capability, including **xterm** and the widely used and cloned DEC VT100,

will recognize ISO/IEC 6429 color codes and harmlessly eliminate them from the output or emulate them. **ls** uses ISO/IEC 6429 codes by default, assuming colorization is enabled.

ISO/IEC 6429 color sequences are composed of sequences of numbers separated by semicolons. The most common codes are:

0	to restore default color
1	for brighter colors
4	for underlined text
5	for flashing text
30	for black foreground
31	for red foreground
32	for green foreground
33	for yellow (or brown) foreground
34	for blue foreground
35	for purple foreground
36	for cyan foreground
37	for white (or gray) foreground
40	for black background
41	for red background
42	for green background
43	for yellow (or brown) background
44	for blue background
45	for purple background
46	for cyan background
47	for white (or gray) background

Not all commands will work on all systems or display devices.

ls uses the following defaults:

NORMAL	0	Normal (nonfilename) text
FILE	0	Regular file
DIR	32	Directory
LINK	36	Symbolic link
ORPHAN	undefined	Orphaned symbolic link
MISSING	undefined	Missing file
FIFO	31	Named pipe (FIFO)
SOCK	33	Socket
BLK	44;37	Block device
CHR	44;37	Character device
EXEC	35	Executable file

A few terminal programs do not recognize the default properly. If all text gets colorized after you do a directory listing, change the **NORMAL** and **FILE** codes to the numerical codes for your normal foreground and background colors.

Other terminal types (advanced configuration)

If you have a color-capable (or otherwise highlighting) terminal (or printer!) which uses a different set of codes, you can still generate a suitable setup. To do so, you will have to use the **LEFTCODE**, **RIGHTCODE**, and **ENDCODE** definitions.

When writing out a filename, **ls** generates the following output sequence: **LEFTCODE** *typecode* **RIGHTCODE** *filename* **ENDCODE**, where the *typecode* is the color sequence that depends on the type or name of file. If the **ENDCODE** is undefined, the sequence **LEFTCODE NORMAL RIGHTCODE** will be used instead. The purpose of the left- and rightcodes is merely to reduce the amount of typing necessary (and to hide ugly escape codes away from the user). If they are not appropriate for your terminal, you can eliminate them by specifying the respective keyword on a line by itself.

NOTE: If the **ENDCODE** is defined in the global section of the setup file, it *cannot* be undefined in a terminal-specific section of the file. This means any **NORMAL** definition will have no effect. A different **ENDCODE** can, however, be specified, which would have the same effect.

Escape sequences

To specify control- or blank characters in the color sequences or filename extensions, either C-style \-escaped notation or **stty**-style ^-notation can be used. The C-style notation includes the following characters:

\a	Bell (ASCII 7)
\b	Backspace (ASCII 8)
\e	Escape (ASCII 27)
\f	Form feed (ASCII 12)
\n	Newline (ASCII 10)
\r	Carriage Return (ASCII 13)
\t	Tab (ASCII 9)
\v	Vertical Tab (ASCII 11)
\?	Delete (ASCII 127)
nnn	Any character (octal notation)
\x*nnn*	Any character (hexadecimal notation)
_	Space
\\	Backslash (\)
\^	Caret (^)
\#	Hash mark (#)

Note that escapes are necessary to enter a space, backslash, caret, or any control character anywhere in the string, as well as a hash mark as the first character.

FILES

/etc/DIR_COLORS
System-wide configuration file.

~/.dir_colors
Per-user configuration file.

This page describes the **dir_colors** file format as used in the fileutils-4.1 package; other versions may differ slightly.

NOTES

The default **LEFTCODE** and **RIGHTCODE** definitions, which are used by ISO/IEC 6429 terminals are:

LEFTCODE	\e[
RIGHTCODE	m

The default **ENDCODE** is undefined.

NAME

elf − format of Executable and Linking Format (ELF) files

SYNOPSIS

#include <elf.h>

DESCRIPTION

The header file <*elf.h*> defines the format of ELF executable binary files. Amongst these files are normal executable files, relocatable object files, core files, and shared objects.

An executable file using the ELF file format consists of an ELF header, followed by a program header table or a section header table, or both. The ELF header is always at offset zero of the file. The program header table and the section header table's offset in the file are defined in the ELF header. The two tables describe the rest of the particularities of the file.

This header file describes the above mentioned headers as C structures and also includes structures for dynamic sections, relocation sections and symbol tables.

Basic types

The following types are used for N-bit architectures (N=32,64, *ElfN* stands for *Elf32* or *Elf64*, *uintN_t* stands for *uint32_t* or *uint64_t*):

```
ElfN_Addr       Unsigned program address, uintN_t
ElfN_Off        Unsigned file offset, uintN_t
ElfN_Section    Unsigned section index, uint16_t
ElfN_Versym     Unsigned version symbol information, uint16_t
Elf_Byte        unsigned char
ElfN_Half       uint16_t
ElfN_Sword      int32_t
ElfN_Word       uint32_t
ElfN_Sxword     int64_t
ElfN_Xword      uint64_t
```

(Note: the *BSD terminology is a bit different. There, *Elf64_Half* is twice as large as *Elf32_Half*, and *Elf64Quarter* is used for *uint16_t*. In order to avoid confusion these types are replaced by explicit ones in the below.)

All data structures that the file format defines follow the "natural" size and alignment guidelines for the relevant class. If necessary, data structures contain explicit padding to ensure 4-byte alignment for 4-byte objects, to force structure sizes to a multiple of 4, and so on.

ELF header (Ehdr)

The ELF header is described by the type *Elf32_Ehdr* or *Elf64_Ehdr*:

```
#define EI_NIDENT 16

typedef struct {
    unsigned char e_ident[EI_NIDENT];
    uint16_t      e_type;
    uint16_t      e_machine;
    uint32_t      e_version;
    ElfN_Addr     e_entry;
    ElfN_Off      e_phoff;
    ElfN_Off      e_shoff;
    uint32_t      e_flags;
    uint16_t      e_ehsize;
    uint16_t      e_phentsize;
    uint16_t      e_phnum;
    uint16_t      e_shentsize;
    uint16_t      e_shnum;
    uint16_t      e_shstrndx;
} ElfN_Ehdr;
```

The fields have the following meanings:

e_ident This array of bytes specifies how to interpret the file, independent of the processor or the file's remaining contents. Within this array everything is named by macros, which start with the prefix **EI_** and may contain values which start with the prefix **ELF**. The following macros are defined:

EI_MAG0
The first byte of the magic number. It must be filled with **ELFMAG0**. (0: 0x7f)

EI_MAG1
The second byte of the magic number. It must be filled with **ELFMAG1**. (1: 'E')

EI_MAG2
The third byte of the magic number. It must be filled with **ELFMAG2**. (2: 'L')

EI_MAG3
The fourth byte of the magic number. It must be filled with **ELFMAG3**. (3: 'F')

EI_CLASS
The fifth byte identifies the architecture for this binary:

ELFCLASSNONE
This class is invalid.
ELFCLASS32 This defines the 32-bit architecture. It supports machines with files and virtual address spaces up to 4 Gigabytes.
ELFCLASS64 This defines the 64-bit architecture.

EI_DATA
The sixth byte specifies the data encoding of the processor-specific data in the file. Currently, these encodings are supported:

ELFDATANONE
Unknown data format.
ELFDATA2LSB
Two's complement, little-endian.
ELFDATA2MSB
Two's complement, big-endian.

EI_VERSION
The seventh byte is the version number of the ELF specification:

EV_NONE Invalid version.
EV_CURRENT
Current version.

EI_OSABI
The eighth byte identifies the operating system and ABI to which the object is targeted. Some fields in other ELF structures have flags and values that have platform-specific meanings; the interpretation of those fields is determined by the value of this byte. For example:

ELFOSABI_NONE Same as ELFOSABI_SYSV
ELFOSABI_SYSV UNIX System V ABI
ELFOSABI_HPUX HP-UX ABI
ELFOSABI_NETBSD NetBSD ABI
ELFOSABI_LINUX Linux ABI
ELFOSABI_SOLARIS Solaris ABI
ELFOSABI_IRIX IRIX ABI
ELFOSABI_FREEBSD
FreeBSD ABI
ELFOSABI_TRU64 TRU64 UNIX ABI
ELFOSABI_ARM ARM architecture ABI
ELFOSABI_STANDALONE
Stand-alone (embedded) ABI

EI_ABIVERSION
The ninth byte identifies the version of the ABI to which the object is targeted. This field is used to distinguish among incompatible versions of an ABI. The interpretation of this version number is dependent on the ABI identified by the **EI_OSABI** field. Applications conforming to this specification use the value 0.

EI_PAD
Start of padding. These bytes are reserved and set to zero. Programs which read them should ignore them. The value for **EI_PAD** will change in the future if currently unused bytes are given meanings.

EI_NIDENT
The size of the *e_ident* array.

e_type This member of the structure identifies the object file type:

ET_NONE	An unknown type.
ET_REL	A relocatable file.
ET_EXEC	An executable file.
ET_DYN	A shared object.
ET_CORE	A core file.

e_machine
This member specifies the required architecture for an individual file. For example:

EM_NONE	An unknown machine
EM_M32	AT&T WE 32100
EM_SPARC	Sun Microsystems SPARC
EM_386	Intel 80386
EM_68K	Motorola 68000
EM_88K	Motorola 88000
EM_860	Intel 80860
EM_MIPS	MIPS RS3000 (big-endian only)
EM_PARISC	HP/PA
EM_SPARC32PLUS	SPARC with enhanced instruction set
EM_PPC	PowerPC
EM_PPC64	PowerPC 64-bit
EM_S390	IBM S/390
EM_ARM	Advanced RISC Machines
EM_SH	Renesas SuperH
EM_SPARCV9	SPARC v9 64-bit
EM_IA_64	Intel Itanium
EM_X86_64	AMD x86-64
EM_VAX	DEC Vax

e_version
This member identifies the file version:

EV_NONE	Invalid version
EV_CURRENT	Current version

e_entry This member gives the virtual address to which the system first transfers control, thus starting the process. If the file has no associated entry point, this member holds zero.

e_phoff
This member holds the program header table's file offset in bytes. If the file has no program header table, this member holds zero.

e_shoff This member holds the section header table's file offset in bytes. If the file has no section header table, this member holds zero.

e_flags This member holds processor-specific flags associated with the file. Flag names take the form EF_'machine_flag'. Currently, no flags have been defined.

e_ehsize
: This member holds the ELF header's size in bytes.

e_phentsize
: This member holds the size in bytes of one entry in the file's program header table; all entries are the same size.

e_phnum
: This member holds the number of entries in the program header table. Thus the product of *e_phentsize* and *e_phnum* gives the table's size in bytes. If a file has no program header, *e_phnum* holds the value zero.

  If the number of entries in the program header table is larger than or equal to **PN_XNUM** (0xffff), this member holds **PN_XNUM** (0xffff) and the real number of entries in the program header table is held in the *sh_info* member of the initial entry in section header table. Otherwise, the *sh_info* member of the initial entry contains the value zero.

  PN_XNUM
  : This is defined as 0xffff, the largest number *e_phnum* can have, specifying where the actual number of program headers is assigned.

e_shentsize
: This member holds a sections header's size in bytes. A section header is one entry in the section header table; all entries are the same size.

e_shnum
: This member holds the number of entries in the section header table. Thus the product of *e_shentsize* and *e_shnum* gives the section header table's size in bytes. If a file has no section header table, *e_shnum* holds the value of zero.

  If the number of entries in the section header table is larger than or equal to **SHN_LORESERVE** (0xff00), *e_shnum* holds the value zero and the real number of entries in the section header table is held in the *sh_size* member of the initial entry in section header table. Otherwise, the *sh_size* member of the initial entry in the section header table holds the value zero.

e_shstrndx
: This member holds the section header table index of the entry associated with the section name string table. If the file has no section name string table, this member holds the value **SHN_UNDEF**.

  If the index of section name string table section is larger than or equal to **SHN_LORESERVE** (0xff00), this member holds **SHN_XINDEX** (0xffff) and the real index of the section name string table section is held in the *sh_link* member of the initial entry in section header table. Otherwise, the *sh_link* member of the initial entry in section header table contains the value zero.

Program header (Phdr)

An executable or shared object file's program header table is an array of structures, each describing a segment or other information the system needs to prepare the program for execution. An object file *segment* contains one or more *sections*. Program headers are meaningful only for executable and shared object files. A file specifies its own program header size with the ELF header's *e_phentsize* and *e_phnum* members. The ELF program header is described by the type *Elf32_Phdr* or *Elf64_Phdr* depending on the architecture:

```
typedef struct {
    uint32_t   p_type;
    Elf32_Off  p_offset;
    Elf32_Addr p_vaddr;
    Elf32_Addr p_paddr;
    uint32_t   p_filesz;
    uint32_t   p_memsz;
    uint32_t   p_flags;
    uint32_t   p_align;
} Elf32_Phdr;

typedef struct {
```

```
        uint32_t   p_type;
        uint32_t   p_flags;
        Elf64_Off  p_offset;
        Elf64_Addr p_vaddr;
        Elf64_Addr p_paddr;
        uint64_t   p_filesz;
        uint64_t   p_memsz;
        uint64_t   p_align;
    } Elf64_Phdr;
```

The main difference between the 32-bit and the 64-bit program header lies in the location of the *p_flags* member in the total struct.

p_type This member of the structure indicates what kind of segment this array element describes or how to interpret the array element's information.

PT_NULL
The array element is unused and the other members' values are undefined. This lets the program header have ignored entries.

PT_LOAD
The array element specifies a loadable segment, described by *p_filesz* and *p_memsz*. The bytes from the file are mapped to the beginning of the memory segment. If the segment's memory size *p_memsz* is larger than the file size *p_filesz*, the "extra" bytes are defined to hold the value 0 and to follow the segment's initialized area. The file size may not be larger than the memory size. Loadable segment entries in the program header table appear in ascending order, sorted on the *p_vaddr* member.

PT_DYNAMIC
The array element specifies dynamic linking information.

PT_INTERP
The array element specifies the location and size of a null-terminated pathname to invoke as an interpreter. This segment type is meaningful only for executable files (though it may occur for shared objects). However it may not occur more than once in a file. If it is present, it must precede any loadable segment entry.

PT_NOTE
The array element specifies the location of notes (ElfN_Nhdr).

PT_SHLIB
This segment type is reserved but has unspecified semantics. Programs that contain an array element of this type do not conform to the ABI.

PT_PHDR
The array element, if present, specifies the location and size of the program header table itself, both in the file and in the memory image of the program. This segment type may not occur more than once in a file. Moreover, it may occur only if the program header table is part of the memory image of the program. If it is present, it must precede any loadable segment entry.

PT_LOPROC
PT_HIPROC
Values in the inclusive range [**PT_LOPROC**, **PT_HIPROC**] are reserved for processor-specific semantics.

PT_GNU_STACK
GNU extension which is used by the Linux kernel to control the state of the stack via the flags set in the *p_flags* member.

p_offset
This member holds the offset from the beginning of the file at which the first byte of the segment resides.

p_vaddr
This member holds the virtual address at which the first byte of the segment resides in memory.

p_paddr
On systems for which physical addressing is relevant, this member is reserved for the segment's physical address. Under BSD this member is not used and must be zero.

p_filesz
This member holds the number of bytes in the file image of the segment. It may be zero.

p_memsz
This member holds the number of bytes in the memory image of the segment. It may be zero.

p_flags This member holds a bit mask of flags relevant to the segment:

PF_X An executable segment.
PF_W A writable segment.
PF_R A readable segment.

A text segment commonly has the flags **PF_X** and **PF_R**. A data segment commonly has **PF_W** and **PF_R**.

p_align
This member holds the value to which the segments are aligned in memory and in the file. Loadable process segments must have congruent values for *p_vaddr* and *p_offset*, modulo the page size. Values of zero and one mean no alignment is required. Otherwise, *p_align* should be a positive, integral power of two, and *p_vaddr* should equal *p_offset*, modulo *p_align*.

Section header (Shdr)
A file's section header table lets one locate all the file's sections. The section header table is an array of *Elf32_Shdr* or *Elf64_Shdr* structures. The ELF header's *e_shoff* member gives the byte offset from the beginning of the file to the section header table. *e_shnum* holds the number of entries the section header table contains. *e_shentsize* holds the size in bytes of each entry.

A section header table index is a subscript into this array. Some section header table indices are reserved: the initial entry and the indices between **SHN_LORESERVE** and **SHN_HIRESERVE**. The initial entry is used in ELF extensions for *e_phnum*, *e_shnum*, and *e_shstrndx*; in other cases, each field in the initial entry is set to zero. An object file does not have sections for these special indices:

SHN_UNDEF
This value marks an undefined, missing, irrelevant, or otherwise meaningless section reference.

SHN_LORESERVE
This value specifies the lower bound of the range of reserved indices.

SHN_LOPROC
SHN_HIPROC
Values greater in the inclusive range [**SHN_LOPROC**, **SHN_HIPROC**] are reserved for processor-specific semantics.

SHN_ABS
This value specifies the absolute value for the corresponding reference. For example, a symbol defined relative to section number **SHN_ABS** has an absolute value and is not affected by relocation.

SHN_COMMON
Symbols defined relative to this section are common symbols, such as FORTRAN COMMON or unallocated C external variables.

SHN_HIRESERVE
This value specifies the upper bound of the range of reserved indices. The system reserves indices between **SHN_LORESERVE** and **SHN_HIRESERVE**, inclusive. The section header table does not contain entries for the reserved indices.

The section header has the following structure:

```
typedef struct {
```

```
    uint32_t   sh_name;
    uint32_t   sh_type;
    uint32_t   sh_flags;
    Elf32_Addr sh_addr;
    Elf32_Off  sh_offset;
    uint32_t   sh_size;
    uint32_t   sh_link;
    uint32_t   sh_info;
    uint32_t   sh_addralign;
    uint32_t   sh_entsize;
} Elf32_Shdr;

typedef struct {
    uint32_t   sh_name;
    uint32_t   sh_type;
    uint64_t   sh_flags;
    Elf64_Addr sh_addr;
    Elf64_Off  sh_offset;
    uint64_t   sh_size;
    uint32_t   sh_link;
    uint32_t   sh_info;
    uint64_t   sh_addralign;
    uint64_t   sh_entsize;
} Elf64_Shdr;
```

No real differences exist between the 32-bit and 64-bit section headers.

sh_name

This member specifies the name of the section. Its value is an index into the section header string table section, giving the location of a null-terminated string.

sh_type

This member categorizes the section's contents and semantics.

SHT_NULL

This value marks the section header as inactive. It does not have an associated section. Other members of the section header have undefined values.

SHT_PROGBITS

This section holds information defined by the program, whose format and meaning are determined solely by the program.

SHT_SYMTAB

This section holds a symbol table. Typically, **SHT_SYMTAB** provides symbols for link editing, though it may also be used for dynamic linking. As a complete symbol table, it may contain many symbols unnecessary for dynamic linking. An object file can also contain a **SHT_DYNSYM** section.

SHT_STRTAB

This section holds a string table. An object file may have multiple string table sections.

SHT_RELA

This section holds relocation entries with explicit addends, such as type *Elf32_Rela* for the 32-bit class of object files. An object may have multiple relocation sections.

SHT_HASH

This section holds a symbol hash table. An object participating in dynamic linking must contain a symbol hash table. An object file may have only one hash table.

SHT_DYNAMIC

This section holds information for dynamic linking. An object file may have only one dynamic section.

SHT_NOTE
This section holds notes (ElfN_Nhdr).

SHT_NOBITS
A section of this type occupies no space in the file but otherwise resembles **SHT_PROGBITS**. Although this section contains no bytes, the *sh_offset* member contains the conceptual file offset.

SHT_REL
This section holds relocation offsets without explicit addends, such as type *Elf32_Rel* for the 32-bit class of object files. An object file may have multiple relocation sections.

SHT_SHLIB
This section is reserved but has unspecified semantics.

SHT_DYNSYM
This section holds a minimal set of dynamic linking symbols. An object file can also contain a **SHT_SYMTAB** section.

SHT_LOPROC
SHT_HIPROC
Values in the inclusive range [**SHT_LOPROC**, **SHT_HIPROC**] are reserved for processor-specific semantics.

SHT_LOUSER
This value specifies the lower bound of the range of indices reserved for application programs.

SHT_HIUSER
This value specifies the upper bound of the range of indices reserved for application programs. Section types between **SHT_LOUSER** and **SHT_HIUSER** may be used by the application, without conflicting with current or future system-defined section types.

sh_flags
Sections support one-bit flags that describe miscellaneous attributes. If a flag bit is set in *sh_flags*, the attribute is "on" for the section. Otherwise, the attribute is "off" or does not apply. Undefined attributes are set to zero.

SHF_WRITE
This section contains data that should be writable during process execution.

SHF_ALLOC
This section occupies memory during process execution. Some control sections do not reside in the memory image of an object file. This attribute is off for those sections.

SHF_EXECINSTR
This section contains executable machine instructions.

SHF_MASKPROC
All bits included in this mask are reserved for processor-specific semantics.

sh_addr
If this section appears in the memory image of a process, this member holds the address at which the section's first byte should reside. Otherwise, the member contains zero.

sh_offset
This member's value holds the byte offset from the beginning of the file to the first byte in the section. One section type, **SHT_NOBITS**, occupies no space in the file, and its *sh_offset* member locates the conceptual placement in the file.

sh_size This member holds the section's size in bytes. Unless the section type is **SHT_NOBITS**, the section occupies *sh_size* bytes in the file. A section of type **SHT_NOBITS** may have a nonzero size, but it occupies no space in the file.

sh_link This member holds a section header table index link, whose interpretation depends on the section type.

sh_info This member holds extra information, whose interpretation depends on the section type.

sh_addralign
Some sections have address alignment constraints. If a section holds a doubleword, the system must ensure doubleword alignment for the entire section. That is, the value of *sh_addr* must be congruent to zero, modulo the value of *sh_addralign*. Only zero and positive integral powers of two are allowed. The value 0 or 1 means that the section has no alignment constraints.

sh_entsize
Some sections hold a table of fixed-sized entries, such as a symbol table. For such a section, this member gives the size in bytes for each entry. This member contains zero if the section does not hold a table of fixed-size entries.

Various sections hold program and control information:

.bss This section holds uninitialized data that contributes to the program's memory image. By definition, the system initializes the data with zeros when the program begins to run. This section is of type **SHT_NOBITS**. The attribute types are **SHF_ALLOC** and **SHF_WRITE**.

.comment
This section holds version control information. This section is of type **SHT_PROGBITS**. No attribute types are used.

.ctors This section holds initialized pointers to the C++ constructor functions. This section is of type **SHT_PROGBITS**. The attribute types are **SHF_ALLOC** and **SHF_WRITE**.

.data This section holds initialized data that contribute to the program's memory image. This section is of type **SHT_PROGBITS**. The attribute types are **SHF_ALLOC** and **SHF_WRITE**.

.data1 This section holds initialized data that contribute to the program's memory image. This section is of type **SHT_PROGBITS**. The attribute types are **SHF_ALLOC** and **SHF_WRITE**.

.debug This section holds information for symbolic debugging. The contents are unspecified. This section is of type **SHT_PROGBITS**. No attribute types are used.

.dtors This section holds initialized pointers to the C++ destructor functions. This section is of type **SHT_PROGBITS**. The attribute types are **SHF_ALLOC** and **SHF_WRITE**.

.dynamic
This section holds dynamic linking information. The section's attributes will include the **SHF_ALLOC** bit. Whether the **SHF_WRITE** bit is set is processor-specific. This section is of type **SHT_DYNAMIC**. See the attributes above.

.dynstr This section holds strings needed for dynamic linking, most commonly the strings that represent the names associated with symbol table entries. This section is of type **SHT_STRTAB**. The attribute type used is **SHF_ALLOC**.

.dynsym
This section holds the dynamic linking symbol table. This section is of type **SHT_DYNSYM**. The attribute used is **SHF_ALLOC**.

.fini This section holds executable instructions that contribute to the process termination code. When a program exits normally the system arranges to execute the code in this section. This section is of type **SHT_PROGBITS**. The attributes used are **SHF_ALLOC** and **SHF_EXECINSTR**.

.gnu.version
This section holds the version symbol table, an array of *ElfN_Half* elements. This section is of type **SHT_GNU_versym**. The attribute type used is **SHF_ALLOC**.

.gnu.version_d
This section holds the version symbol definitions, a table of *ElfN_Verdef* structures. This section is of type **SHT_GNU_verdef**. The attribute type used is **SHF_ALLOC**.

.gnu.version_r
This section holds the version symbol needed elements, a table of *ElfN_Verneed* structures. This section is of type **SHT_GNU_versym**. The attribute type used is **SHF_ALLOC**.

.got This section holds the global offset table. This section is of type **SHT_PROGBITS**. The attributes are processor-specific.

.hash This section holds a symbol hash table. This section is of type **SHT_HASH**. The attribute used is **SHF_ALLOC**.

.init This section holds executable instructions that contribute to the process initialization code. When a program starts to run the system arranges to execute the code in this section before calling the main program entry point. This section is of type **SHT_PROGBITS**. The attributes used are **SHF_ALLOC** and **SHF_EXECINSTR**.

.interp This section holds the pathname of a program interpreter. If the file has a loadable segment that includes the section, the section's attributes will include the **SHF_ALLOC** bit. Otherwise, that bit will be off. This section is of type **SHT_PROGBITS**.

.line This section holds line number information for symbolic debugging, which describes the correspondence between the program source and the machine code. The contents are unspecified. This section is of type **SHT_PROGBITS**. No attribute types are used.

.note This section holds various notes. This section is of type **SHT_NOTE**. No attribute types are used.

.note.ABI-tag
This section is used to declare the expected run-time ABI of the ELF image. It may include the operating system name and its run-time versions. This section is of type **SHT_NOTE**. The only attribute used is **SHF_ALLOC**.

.note.gnu.build-id
This section is used to hold an ID that uniquely identifies the contents of the ELF image. Different files with the same build ID should contain the same executable content. See the **--build-id** option to the GNU linker (**ld** (1)) for more details. This section is of type **SHT_NOTE**. The only attribute used is **SHF_ALLOC**.

.note.GNU-stack
This section is used in Linux object files for declaring stack attributes. This section is of type **SHT_PROGBITS**. The only attribute used is **SHF_EXECINSTR**. This indicates to the GNU linker that the object file requires an executable stack.

.note.openbsd.ident
OpenBSD native executables usually contain this section to identify themselves so the kernel can bypass any compatibility ELF binary emulation tests when loading the file.

.plt This section holds the procedure linkage table. This section is of type **SHT_PROGBITS**. The attributes are processor-specific.

.relNAME
This section holds relocation information as described below. If the file has a loadable segment that includes relocation, the section's attributes will include the **SHF_ALLOC** bit. Otherwise, the bit will be off. By convention, "NAME" is supplied by the section to which the relocations apply. Thus a relocation section for **.text** normally would have the name **.rel.text**. This section is of type **SHT_REL**.

.relaNAME
This section holds relocation information as described below. If the file has a loadable segment that includes relocation, the section's attributes will include the **SHF_ALLOC** bit. Otherwise, the bit will be off. By convention, "NAME" is supplied by the section to which the relocations apply. Thus a relocation section for **.text** normally would have the name **.rela.text**. This section is of type **SHT_RELA**.

.rodata This section holds read-only data that typically contributes to a nonwritable segment in the process image. This section is of type **SHT_PROGBITS**. The attribute used is **SHF_ALLOC**.

.rodata1
: This section holds read-only data that typically contributes to a nonwritable segment in the process image. This section is of type **SHT_PROGBITS**. The attribute used is **SHF_ALLOC**.

.shstrtab
: This section holds section names. This section is of type **SHT_STRTAB**. No attribute types are used.

.strtab
: This section holds strings, most commonly the strings that represent the names associated with symbol table entries. If the file has a loadable segment that includes the symbol string table, the section's attributes will include the **SHF_ALLOC** bit. Otherwise, the bit will be off. This section is of type **SHT_STRTAB**.

.symtab
: This section holds a symbol table. If the file has a loadable segment that includes the symbol table, the section's attributes will include the **SHF_ALLOC** bit. Otherwise, the bit will be off. This section is of type **SHT_SYMTAB**.

.text
: This section holds the "text", or executable instructions, of a program. This section is of type **SHT_PROGBITS**. The attributes used are **SHF_ALLOC** and **SHF_EXECINSTR**.

String and symbol tables

String table sections hold null-terminated character sequences, commonly called strings. The object file uses these strings to represent symbol and section names. One references a string as an index into the string table section. The first byte, which is index zero, is defined to hold a null byte ('\0'). Similarly, a string table's last byte is defined to hold a null byte, ensuring null termination for all strings.

An object file's symbol table holds information needed to locate and relocate a program's symbolic definitions and references. A symbol table index is a subscript into this array.

```
typedef struct {
    uint32_t      st_name;
    Elf32_Addr    st_value;
    uint32_t      st_size;
    unsigned char st_info;
    unsigned char st_other;
    uint16_t      st_shndx;
} Elf32_Sym;

typedef struct {
    uint32_t      st_name;
    unsigned char st_info;
    unsigned char st_other;
    uint16_t      st_shndx;
    Elf64_Addr    st_value;
    uint64_t      st_size;
} Elf64_Sym;
```

The 32-bit and 64-bit versions have the same members, just in a different order.

st_name
: This member holds an index into the object file's symbol string table, which holds character representations of the symbol names. If the value is nonzero, it represents a string table index that gives the symbol name. Otherwise, the symbol has no name.

st_value
: This member gives the value of the associated symbol.

st_size
: Many symbols have associated sizes. This member holds zero if the symbol has no size or an unknown size.

st_info
: This member specifies the symbol's type and binding attributes:

  STT_NOTYPE
  : The symbol's type is not defined.

STT_OBJECT
The symbol is associated with a data object.

STT_FUNC
The symbol is associated with a function or other executable code.

STT_SECTION
The symbol is associated with a section. Symbol table entries of this type exist primarily for relocation and normally have **STB_LOCAL** bindings.

STT_FILE
By convention, the symbol's name gives the name of the source file associated with the object file. A file symbol has **STB_LOCAL** bindings, its section index is **SHN_ABS**, and it precedes the other **STB_LOCAL** symbols of the file, if it is present.

STT_LOPROC
STT_HIPROC
Values in the inclusive range [**STT_LOPROC**, **STT_HIPROC**] are reserved for processor-specific semantics.

STB_LOCAL
Local symbols are not visible outside the object file containing their definition. Local symbols of the same name may exist in multiple files without interfering with each other.

STB_GLOBAL
Global symbols are visible to all object files being combined. One file's definition of a global symbol will satisfy another file's undefined reference to the same symbol.

STB_WEAK
Weak symbols resemble global symbols, but their definitions have lower precedence.

STB_LOPROC
STB_HIPROC
Values in the inclusive range [**STB_LOPROC**, **STB_HIPROC**] are reserved for processor-specific semantics.

There are macros for packing and unpacking the binding and type fields:

ELF32_ST_BIND(*info***)**
ELF64_ST_BIND(*info***)**
Extract a binding from an *st_info* value.

ELF32_ST_TYPE(*info***)**
ELF64_ST_TYPE(*info***)**
Extract a type from an *st_info* value.

ELF32_ST_INFO(*bind***, *** type***)**
ELF64_ST_INFO(*bind***, *** type***)**
Convert a binding and a type into an *st_info* value.

st_other
This member defines the symbol visibility.

STV_DEFAULT
Default symbol visibility rules. Global and weak symbols are available to other modules; references in the local module can be interposed by definitions in other modules.

STV_INTERNAL
Processor-specific hidden class.

STV_HIDDEN
Symbol is unavailable to other modules; references in the local module always resolve to the local symbol (i.e., the symbol can't be interposed by definitions in other modules).

STV_PROTECTED
Symbol is available to other modules, but references in the local module always resolve to the local symbol.

There are macros for extracting the visibility type:

ELF32_ST_VISIBILITY(other) or *ELF64_ST_VISIBILITY*(other)

st_shndx
Every symbol table entry is "defined" in relation to some section. This member holds the relevant section header table index.

Relocation entries (Rel & Rela)
Relocation is the process of connecting symbolic references with symbolic definitions. Relocatable files must have information that describes how to modify their section contents, thus allowing executable and shared object files to hold the right information for a process's program image. Relocation entries are these data.

Relocation structures that do not need an addend:

```
typedef struct {
    Elf32_Addr r_offset;
    uint32_t   r_info;
} Elf32_Rel;

typedef struct {
    Elf64_Addr r_offset;
    uint64_t   r_info;
} Elf64_Rel;
```

Relocation structures that need an addend:

```
typedef struct {
    Elf32_Addr r_offset;
    uint32_t   r_info;
    int32_t    r_addend;
} Elf32_Rela;

typedef struct {
    Elf64_Addr r_offset;
    uint64_t   r_info;
    int64_t    r_addend;
} Elf64_Rela;
```

r_offset
This member gives the location at which to apply the relocation action. For a relocatable file, the value is the byte offset from the beginning of the section to the storage unit affected by the relocation. For an executable file or shared object, the value is the virtual address of the storage unit affected by the relocation.

r_info This member gives both the symbol table index with respect to which the relocation must be made and the type of relocation to apply. Relocation types are processor-specific. When the text refers to a relocation entry's relocation type or symbol table index, it means the result of applying **ELF[32|64]_R_TYPE** or **ELF[32|64]_R_SYM**, respectively, to the entry's *r_info* member.

r_addend
This member specifies a constant addend used to compute the value to be stored into the relocatable field.

Dynamic tags (Dyn)
The *.dynamic* section contains a series of structures that hold relevant dynamic linking information. The *d_tag* member controls the interpretation of *d_un*.

```
typedef struct {
    Elf32_Sword    d_tag;
    union {
        Elf32_Word d_val;
```

```
        Elf32_Addr d_ptr;
    } d_un;
} Elf32_Dyn;
extern Elf32_Dyn _DYNAMIC[];

typedef struct {
    Elf64_Sxword    d_tag;
    union {
        Elf64_Xword d_val;
        Elf64_Addr  d_ptr;
    } d_un;
} Elf64_Dyn;
extern Elf64_Dyn _DYNAMIC[];
```

d_tag This member may have any of the following values:

DT_NULL Marks end of dynamic section

DT_NEEDED
String table offset to name of a needed library

DT_PLTRELSZ
Size in bytes of PLT relocation entries

DT_PLTGOT
Address of PLT and/or GOT

DT_HASH Address of symbol hash table

DT_STRTAB
Address of string table

DT_SYMTAB
Address of symbol table

DT_RELA Address of Rela relocation table

DT_RELASZ
Size in bytes of the Rela relocation table

DT_RELAENT
Size in bytes of a Rela relocation table entry

DT_STRSZ Size in bytes of string table

DT_SYMENT
Size in bytes of a symbol table entry

DT_INIT Address of the initialization function

DT_FINI Address of the termination function

DT_SONAME
String table offset to name of shared object

DT_RPATH String table offset to library search path (deprecated)

DT_SYMBOLIC
Alert linker to search this shared object before the executable for symbols

DT_REL Address of Rel relocation table

DT_RELSZ Size in bytes of Rel relocation table

DT_RELENT
Size in bytes of a Rel table entry

DT_PLTREL
Type of relocation entry to which the PLT refers (Rela or Rel)

DT_DEBUG Undefined use for debugging

DT_TEXTREL
Absence of this entry indicates that no relocation entries should apply to a non-writable segment

DT_JMPREL
Address of relocation entries associated solely with the PLT

DT_BIND_NOW
Instruct dynamic linker to process all relocations before transferring control to the executable

DT_RUNPATH
String table offset to library search path

DT_LOPROC
DT_HIPROC
Values in the inclusive range [**DT_LOPROC**, **DT_HIPROC**] are reserved for processor-specific semantics

d_val This member represents integer values with various interpretations.

d_ptr This member represents program virtual addresses. When interpreting these addresses, the actual address should be computed based on the original file value and memory base address. Files do not contain relocation entries to fixup these addresses.

_DYNAMIC
Array containing all the dynamic structures in the *.dynamic* section. This is automatically populated by the linker.

Notes (Nhdr)

ELF notes allow for appending arbitrary information for the system to use. They are largely used by core files (*e_type* of **ET_CORE**), but many projects define their own set of extensions. For example, the GNU tool chain uses ELF notes to pass information from the linker to the C library.

Note sections contain a series of notes (see the *struct* definitions below). Each note is followed by the name field (whose length is defined in *n_namesz*) and then by the descriptor field (whose length is defined in *n_descsz*) and whose starting address has a 4 byte alignment. Neither field is defined in the note struct due to their arbitrary lengths.

An example for parsing out two consecutive notes should clarify their layout in memory:

```
void *memory, *name, *desc;
Elf64_Nhdr *note, *next_note;

/* The buffer is pointing to the start of the section/segment. */
note = memory;

/* If the name is defined, it follows the note. */
name = note->n_namesz == 0 ? NULL : memory + sizeof(*note);

/* If the descriptor is defined, it follows the name
   (with alignment). */

desc = note->n_descsz == 0 ? NULL :
       memory + sizeof(*note) + ALIGN_UP(note->n_namesz, 4);

/* The next note follows both (with alignment). */
next_note = memory + sizeof(*note) +
                     ALIGN_UP(note->n_namesz, 4) +
                     ALIGN_UP(note->n_descsz, 4);
```

Keep in mind that the interpretation of *n_type* depends on the namespace defined by the *n_namesz* field. If the *n_namesz* field is not set (e.g., is 0), then there are two sets of notes: one for core files and one for all other ELF types. If the namespace is unknown, then tools will usually fallback to these sets of notes as well.

```
typedef struct {
    Elf32_Word n_namesz;
    Elf32_Word n_descsz;
    Elf32_Word n_type;
} Elf32_Nhdr;

typedef struct {
    Elf64_Word n_namesz;
    Elf64_Word n_descsz;
    Elf64_Word n_type;
} Elf64_Nhdr;
```

n_namesz
: The length of the name field in bytes. The contents will immediately follow this note in memory. The name is null terminated. For example, if the name is "GNU", then *n_namesz* will be set to 4.

n_descsz
: The length of the descriptor field in bytes. The contents will immediately follow the name field in memory.

n_type Depending on the value of the name field, this member may have any of the following values:

Core files (e_type = ET_CORE)
: Notes used by all core files. These are highly operating system or architecture specific and often require close coordination with kernels, C libraries, and debuggers. These are used when the namespace is the default (i.e., *n_namesz* will be set to 0), or a fallback when the namespace is unknown.

NT_PRSTATUS	prstatus struct
NT_FPREGSET	fpregset struct
NT_PRPSINFO	prpsinfo struct
NT_PRXREG	prxregset struct
NT_TASKSTRUCT	task structure
NT_PLATFORM	String from sysinfo(SI_PLATFORM)
NT_AUXV	auxv array
NT_GWINDOWS	gwindows struct
NT_ASRS	asrset struct
NT_PSTATUS	pstatus struct
NT_PSINFO	psinfo struct
NT_PRCRED	prcred struct
NT_UTSNAME	utsname struct
NT_LWPSTATUS	lwpstatus struct
NT_LWPSINFO	lwpinfo struct
NT_PRFPXREG	fprxregset struct
NT_SIGINFO	siginfo_t (size might increase over time)
NT_FILE	Contains information about mapped files
NT_PRXFPREG	user_fxsr_struct
NT_PPC_VMX	PowerPC Altivec/VMX registers
NT_PPC_SPE	PowerPC SPE/EVR registers
NT_PPC_VSX	PowerPC VSX registers
NT_386_TLS	i386 TLS slots (struct user_desc)
NT_386_IOPERM	x86 io permission bitmap (1=deny)
NT_X86_XSTATE	x86 extended state using xsave
NT_S390_HIGH_GPRS	s390 upper register halves
NT_S390_TIMER	s390 timer register
NT_S390_TODCMP	s390 time-of-day (TOD) clock comparator register
NT_S390_TODPREG	s390 time-of-day (TOD) programmable register
NT_S390_CTRS	s390 control registers

NT_S390_PREFIX s390 prefix register
NT_S390_LAST_BREAK
s390 breaking event address
NT_S390_SYSTEM_CALL
s390 system call restart data
NT_S390_TDB s390 transaction diagnostic block
NT_ARM_VFP ARM VFP/NEON registers
NT_ARM_TLS ARM TLS register
NT_ARM_HW_BREAK
ARM hardware breakpoint registers
NT_ARM_HW_WATCH
ARM hardware watchpoint registers
NT_ARM_SYSTEM_CALL
ARM system call number

n_name = GNU
Extensions used by the GNU tool chain.

NT_GNU_ABI_TAG
Operating system (OS) ABI information. The desc field will be 4 words:

[0] OS descriptor (**ELF_NOTE_OS_LINUX**, **ELF_NOTE_OS_GNU**, and so on)‘
[1] major version of the ABI
[2] minor version of the ABI
[3] subminor version of the ABI

NT_GNU_HWCAP
Synthetic hwcap information. The desc field begins with two words:

[0] number of entries
[1] bit mask of enabled entries

Then follow variable-length entries, one byte followed by a null-terminated hwcap name string. The byte gives the bit number to test if enabled, (1U << bit) & bit mask.

NT_GNU_BUILD_ID
Unique build ID as generated by the GNU *ld*(1) **−−build−id** option. The desc consists of any nonzero number of bytes.

NT_GNU_GOLD_VERSION
The desc contains the GNU Gold linker version used.

Default/unknown namespace (e_type != ET_CORE)
These are used when the namespace is the default (i.e., *n_namesz* will be set to 0), or a fallback when the namespace is unknown.

NT_VERSION
A version string of some sort.
NT_ARCH Architecture information.

NOTES

ELF first appeared in System V. The ELF format is an adopted standard.

The extensions for *e_phnum*, *e_shnum*, and *e_shstrndx* respectively are Linux extensions. Sun, BSD, and AMD64 also support them; for further information, look under SEE ALSO.

NAME

erofs − the Enhanced Read-Only File System

DESCRIPTION

erofs is a create-once read-only filesystem, with support for compression and a multi-device backing store.

There are two inode formats:

- 32-byte compact with 16-bit UID/GID, 32-bit file size, and no file times
- 64-byte extended with 32-bit UID/GID, 64-bit file size, and a modification time (*st_mtim*).

Mount options

user_xattr
nouser_xattr
: Controls whether *user* extended attributes are exposed. Defaults to yes.

acl
noacl
: Controls whether POSIX *acl*(5)s are exposed. Defaults to yes.

cache_strategy=**disabled**|**readahead**|**readaround**
: Cache allocation for compressed files: never, if reading from start of file, regardless of position. Defaults to **readaround**.

dax
dax=**always**|**never**
: Direct Access control. If **always** and the source device supports DAX, uncompressed non-inlined files will be read directly, without going through the page cache. **dax** is a synonym for **always**. Defaults to unset, which is equivalent to **never**.

device=*blobdev*
: Add extra device holding some of the data. Must be given as many times and in the same order as **−−blobdev** was to *mkfs.erofs*(1)

domain_id=*did*
fsid=*id*
: Control CacheFiles on-demand read support. To be documented.

VERSIONS

erofs images are versioned through the use of feature flags; these are listed in the **−E** section of *mkfs.erofs*(1),

CONFIGURATION

Linux must be configured with the **CONFIG_EROFS_FS** option to mount EROFS filesystems. There are sub-configuration items that restrict the availability of some of the parameters above.

SEE ALSO

mkfs.erofs(1), *fsck.erofs*(1), *dump.erofs*(1)

Documentation/filesystems/erofs.txt in the Linux source.

NAME

filesystems − Linux filesystem types: ext, ext2, ext3, ext4, hpfs, iso9660, JFS, minix, msdos, ncpfs nfs, ntfs, proc, Reiserfs, smb, sysv, umsdos, vfat, XFS, xiafs

DESCRIPTION

When, as is customary, the **proc** filesystem is mounted on */proc*, you can find in the file */proc/filesystems* which filesystems your kernel currently supports; see *proc*(5) for more details. There is also a legacy *sysfs*(2) system call (whose availability is controlled by the **CONFIG_SYSFS_SYSCALL** kernel build configuration option since Linux 3.15) that enables enumeration of the currently available filesystem types regardless of */proc* availability and/or sanity.

If you need a currently unsupported filesystem, insert the corresponding kernel module or recompile the kernel.

In order to use a filesystem, you have to *mount* it; see *mount*(2) and *mount*(8)

The following list provides a short description of the available or historically available filesystems in the Linux kernel. See the kernel documentation for a comprehensive description of all options and limitations.

erofs is the Enhanced Read-Only File System, stable since Linux 5.4. See *erofs*(5).

ext is an elaborate extension of the **minix** filesystem. It has been completely superseded by the second version of the extended filesystem (**ext2**) and has been removed from the kernel (in Linux 2.1.21).

ext2 is a disk filesystem that was used by Linux for fixed disks as well as removable media. The second extended filesystem was designed as an extension of the extended filesystem (**ext**). See *ext2*(5)

ext3 is a journaling version of the **ext2** filesystem. It is easy to switch back and forth between **ext2** and **ext3**. See *ext3*(5)

ext4 is a set of upgrades to **ext3** including substantial performance and reliability enhancements, plus large increases in volume, file, and directory size limits. See *ext4*(5)

hpfs is the High Performance Filesystem, used in OS/2. This filesystem is read-only under Linux due to the lack of available documentation.

iso9660

is a CD-ROM filesystem type conforming to the ISO/IEC 9660 standard.

High Sierra

Linux supports High Sierra, the precursor to the ISO/IEC 9660 standard for CD-ROM filesystems. It is automatically recognized within the **iso9660** filesystem support under Linux.

Rock Ridge

Linux also supports the System Use Sharing Protocol records specified by the Rock Ridge Interchange Protocol. They are used to further describe the files in the **iso9660** filesystem to a UNIX host, and provide information such as long filenames, UID/GID, POSIX permissions, and devices. It is automatically recognized within the **iso9660** filesystem support under Linux.

JFS is a journaling filesystem, developed by IBM, that was integrated into Linux 2.4.24.

minix is the filesystem used in the Minix operating system, the first to run under Linux. It has a number of shortcomings, including a 64 MB partition size limit, short filenames, and a single timestamp. It remains useful for floppies and RAM disks.

msdos is the filesystem used by DOS, Windows, and some OS/2 computers. **msdos** filenames can be no longer than 8 characters, followed by an optional period and 3 character extension.

ncpfs is a network filesystem that supports the NCP protocol, used by Novell NetWare. It was removed from the kernel in Linux 4.17.

To use **ncpfs**, you need special programs, which can be found at .

nfs is the network filesystem used to access disks located on remote computers.

ntfs is the filesystem native to Microsoft Windows NT, supporting features like ACLs, journaling, encryption, and so on.

proc is a pseudo filesystem which is used as an interface to kernel data structures rather than reading and interpreting */dev/kmem*. In particular, its files do not take disk space. See *proc*(5).

Reiserfs
is a journaling filesystem, designed by Hans Reiser, that was integrated into Linux 2.4.1.

smb is a network filesystem that supports the SMB protocol, used by Windows. See .

sysv is an implementation of the System V/Coherent filesystem for Linux. It implements all of Xenix FS, System V/386 FS, and Coherent FS.

umsdos
is an extended DOS filesystem used by Linux. It adds capability for long filenames, UID/GID, POSIX permissions, and special files (devices, named pipes, etc.) under the DOS filesystem, without sacrificing compatibility with DOS.

tmpfs is a filesystem whose contents reside in virtual memory. Since the files on such filesystems typically reside in RAM, file access is extremely fast. See *tmpfs*(5).

vfat is an extended FAT filesystem used by Microsoft Windows95 and Windows NT. **vfat** adds the capability to use long filenames under the MSDOS filesystem.

XFS is a journaling filesystem, developed by SGI, that was integrated into Linux 2.4.20.

xiafs was designed and implemented to be a stable, safe filesystem by extending the Minix filesystem code. It provides the basic most requested features without undue complexity. The **xiafs** filesystem is no longer actively developed or maintained. It was removed from the kernel in Linux 2.1.21.

NAME

ftpusers − list of users that may not log in via the FTP daemon

DESCRIPTION

The text file **ftpusers** contains a list of users that may not log in using the File Transfer Protocol (FTP) server daemon. This file is used not merely for system administration purposes but also for improving security within a TCP/IP networked environment.

The **ftpusers** file will typically contain a list of the users that either have no business using ftp or have too many privileges to be allowed to log in through the FTP server daemon. Such users usually include root, daemon, bin, uucp, and news.

If your FTP server daemon doesn't use **ftpusers**, then it is suggested that you read its documentation to find out how to block access for certain users. Washington University FTP server Daemon (wuftpd) and Professional FTP Daemon (proftpd) are known to make use of **ftpusers**.

Format

The format of **ftpusers** is very simple. There is one account name (or username) per line. Lines starting with a # are ignored.

FILES

/etc/ftpusers

SEE ALSO

passwd(5), *proftpd*(8), *wuftpd*(8)

NAME

gai.conf − getaddrinfo(3) configuration file

DESCRIPTION

A call to *getaddrinfo*(3) might return multiple answers. According to RFC 3484 these answers must be sorted so that the answer with the highest success rate is first in the list. The RFC provides an algorithm for the sorting. The static rules are not always adequate, though. For this reason, the RFC also requires that system administrators should have the possibility to dynamically change the sorting. For the glibc implementation, this can be achieved with the */etc/gai.conf* file.

Each line in the configuration file consists of a keyword and its parameters. White spaces in any place are ignored. Lines starting with '#' are comments and are ignored.

The keywords currently recognized are:

label *netmask precedence*
: The value is added to the label table used in the RFC 3484 sorting. If any **label** definition is present in the configuration file, the default table is not used. All the label definitions of the default table which are to be maintained have to be duplicated. Following the keyword, the line has to contain a network mask and a precedence value.

precedence *netmask precedence*
: This keyword is similar to **label**, but instead the value is added to the precedence table as specified in RFC 3484. Once again, the presence of a single **precedence** line in the configuration file causes the default table to not be used.

reload <**yes**|**no**>
: This keyword controls whether a process checks whether the configuration file has been changed since the last time it was read. If the value is "**yes**", the file is reread. This might cause problems in multithreaded applications and is generally a bad idea. The default is "**no**".

scopev4 *mask value*
: Add another rule to the RFC 3484 scope table for IPv4 address. By default, the scope IDs described in section 3.2 in RFC 3438 are used. Changing these defaults should hardly ever be necessary.

FILES

/etc/gai.conf

VERSIONS

The *gai.conf* file is supported since glibc 2.5.

EXAMPLES

The default table according to RFC 3484 would be specified with the following configuration file:

```
label  ::1/128       0
label  ::/0          1
label  2002::/16     2
label ::/96          3
label ::ffff:0:0/96  4
precedence  ::1/128       50
precedence  ::/0          40
precedence  2002::/16     30
precedence ::/96          20
precedence ::ffff:0:0/96  10
```

SEE ALSO

getaddrinfo(3), RFC 3484

NAME

group − user group file

DESCRIPTION

The */etc/group* file is a text file that defines the groups on the system. There is one entry per line, with the following format:

```
group_name:password:GID:user_list
```

The fields are as follows:

group_name
: the name of the group.

password
: the (encrypted) group password. If this field is empty, no password is needed.

GID
: the numeric group ID.

user_list
: a list of the usernames that are members of this group, separated by commas.

FILES

/etc/group

BUGS

As the 4.2BSD *initgroups*(3) man page says: no one seems to keep */etc/group* up-to-date.

SEE ALSO

NAME

host.conf − resolver configuration file

DESCRIPTION

The file */etc/host.conf* contains configuration information specific to the resolver library. It should contain one configuration keyword per line, followed by appropriate configuration information. The following keywords are recognized:

trim This keyword may be listed more than once. Each time it should be followed by a list of domains, separated by colons (':'), semicolons (';') or commas (','), with the leading dot. When set, the resolver library will automatically trim the given domain name from the end of any hostname resolved via DNS. This is intended for use with local hosts and domains. (Related note: *trim* will not affect hostnames gathered via NIS or the *hosts*(5) file. Care should be taken to ensure that the first hostname for each entry in the hosts file is fully qualified or unqualified, as appropriate for the local installation.)

multi Valid values are *on* and *off*. If set to *on*, the resolver library will return all valid addresses for a host that appears in the */etc/hosts* file, instead of only the first. This is *off* by default, as it may cause a substantial performance loss at sites with large hosts files.

reorder Valid values are *on* and *off*. If set to *on*, the resolver library will attempt to reorder host addresses so that local addresses (i.e., on the same subnet) are listed first when a *gethostbyname*(3) is performed. Reordering is done for all lookup methods. The default value is *off*.

ENVIRONMENT

The following environment variables can be used to allow users to override the behavior which is configured in */etc/host.conf*:

RESOLV_HOST_CONF
If set, this variable points to a file that should be read instead of */etc/host.conf*.

RESOLV_MULTI
Overrides the *multi* command.

RESOLV_REORDER
Overrides the *reorder* command.

RESOLV_ADD_TRIM_DOMAINS
A list of domains, separated by colons (':'), semicolons (';'), or commas (','), with the leading dot, which will be added to the list of domains that should be trimmed.

RESOLV_OVERRIDE_TRIM_DOMAINS
A list of domains, separated by colons (':'), semicolons (';'), or commas (','), with the leading dot, which will replace the list of domains that should be trimmed. Overrides the *trim* command.

FILES

/etc/host.conf
Resolver configuration file

/etc/resolv.conf
Resolver configuration file

/etc/hosts
Local hosts database

NOTES

The following differences exist compared to the original implementation. A new command *spoof* and a new environment variable **RESOLV_SPOOF_CHECK** can take arguments like *off*, *nowarn*, and *warn*. Line comments can appear anywhere and not only at the beginning of a line.

Historical

The *nsswitch.conf*(5) file is the modern way of controlling the order of host lookups.

In glibc 2.4 and earlier, the following keyword is recognized:

order This keyword specifies how host lookups are to be performed. It should be followed by one or more lookup methods, separated by commas. Valid methods are *bind*, *hosts*, and *nis*.

RESOLV_SERV_ORDER
Overrides the *order* command.

Since glibc 2.0.7, and up through glibc 2.24, the following keywords and environment variable have been recognized but never implemented:

nospoof
Valid values are *on* and *off*. If set to *on*, the resolver library will attempt to prevent hostname spoofing to enhance the security of **rlogin** and **rsh**. It works as follows: after performing a host address lookup, the resolver library will perform a hostname lookup for that address. If the two hostnames do not match, the query fails. The default value is *off*.

spoofalert
Valid values are *on* and *off*. If this option is set to *on* and the *nospoof* option is also set, the resolver library will log a warning of the error via the syslog facility. The default value is *off*.

spoof Valid values are *off*, *nowarn*, and *warn*. If this option is set to *off*, spoofed addresses are permitted and no warnings will be emitted via the syslog facility. If this option is set to *warn*, the resolver library will attempt to prevent hostname spoofing to enhance the security and log a warning of the error via the syslog facility. If this option is set to *nowarn*, the resolver library will attempt to prevent hostname spoofing to enhance the security but not emit warnings via the syslog facility. Setting this option to anything else is equal to setting it to *nowarn*.

RESOLV_SPOOF_CHECK
Overrides the *nospoof*, *spoofalert*, and *spoof* commands in the same way as the *spoof* command is parsed. Valid values are *off*, *nowarn*, and *warn*.

NAME

hosts − static table lookup for hostnames

SYNOPSIS

/etc/hosts

DESCRIPTION

This manual page describes the format of the */etc/hosts* file. This file is a simple text file that associates IP addresses with hostnames, one line per IP address. For each host a single line should be present with the following information:

IP_address canonical_hostname [aliases...]

The IP address can conform to either IPv4 or IPv6. Fields of the entry are separated by any number of blanks and/or tab characters. Text from a "#" character until the end of the line is a comment, and is ignored. Host names may contain only alphanumeric characters, minus signs ("−"), and periods (".."). They must begin with an alphabetic character and end with an alphanumeric character. Optional aliases provide for name changes, alternate spellings, shorter hostnames, or generic hostnames (for example, *localhost*). If required, a host may have two separate entries in this file; one for each version of the Internet Protocol (IPv4 and IPv6).

The Berkeley Internet Name Domain (BIND) Server implements the Internet name server for UNIX systems. It augments or replaces the */etc/hosts* file or hostname lookup, and frees a host from relying on */etc/hosts* being up to date and complete.

In modern systems, even though the host table has been superseded by DNS, it is still widely used for:

bootstrapping
: Most systems have a small host table containing the name and address information for important hosts on the local network. This is useful when DNS is not running, for example during system bootup.

NIS
: Sites that use NIS use the host table as input to the NIS host database. Even though NIS can be used with DNS, most NIS sites still use the host table with an entry for all local hosts as a backup.

isolated nodes
: Very small sites that are isolated from the network use the host table instead of DNS. If the local information rarely changes, and the network is not connected to the Internet, DNS offers little advantage.

FILES

/etc/hosts

NOTES

Modifications to this file normally take effect immediately, except in cases where the file is cached by applications.

Historical notes

RFC 952 gave the original format for the host table, though it has since changed.

Before the advent of DNS, the host table was the only way of resolving hostnames on the fledgling Internet. Indeed, this file could be created from the official host data base maintained at the Network Information Control Center (NIC), though local changes were often required to bring it up to date regarding unofficial aliases and/or unknown hosts. The NIC no longer maintains the hosts.txt files, though looking around at the time of writing (circa 2000), there are historical hosts.txt files on the WWW. I just found three, from 92, 94, and 95.

EXAMPLES

```
# The following lines are desirable for IPv4 capable hosts
127.0.0.1       localhost

# 127.0.1.1 is often used for the FQDN of the machine
127.0.1.1       thishost.example.org   thishost
192.168.1.10    foo.example.org        foo
192.168.1.13    bar.example.org        bar
146.82.138.7    master.debian.org      master
```

```
209.237.226.90  www.opensource.org

# The following lines are desirable for IPv6 capable hosts
::1             localhost ip6-localhost ip6-loopback
ff02::1         ip6-allnodes
ff02::2         ip6-allrouters
```

Internet RFC 952

NAME

hosts.equiv − list of hosts and users that are granted "trusted" **r** command access to your system

DESCRIPTION

The file */etc/hosts.equiv* allows or denies hosts and users to use the **r**-commands (e.g., **rlogin**, **rsh**, or **rcp**) without supplying a password.

The file uses the following format:

+|[−]hostname|+@netgroup|−@netgroup [+|[−]username|+@netgroup|−@netgroup]

The *hostname* is the name of a host which is logically equivalent to the local host. Users logged into that host are allowed to access like-named user accounts on the local host without supplying a password. The *hostname* may be (optionally) preceded by a plus (+) sign. If the plus sign is used alone, it allows any host to access your system. You can explicitly deny access to a host by preceding the *hostname* by a minus (−) sign. Users from that host must always supply additional credentials, including possibly a password. For security reasons you should always use the FQDN of the hostname and not the short hostname.

The *username* entry grants a specific user access to all user accounts (except root) without supplying a password. That means the user is NOT restricted to like-named accounts. The *username* may be (optionally) preceded by a plus (+) sign. You can also explicitly deny access to a specific user by preceding the *username* with a minus (−) sign. This says that the user is not trusted no matter what other entries for that host exist.

Netgroups can be specified by preceding the netgroup by an @ sign.

Be extremely careful when using the plus (+) sign. A simple typographical error could result in a standalone plus sign. A standalone plus sign is a wildcard character that means "any host"!

FILES

/etc/hosts.equiv

NOTES

Some systems will honor the contents of this file only when it has owner root and no write permission for anybody else. Some exceptionally paranoid systems even require that there be no other hard links to the file.

Modern systems use the Pluggable Authentication Modules library (PAM). With PAM a standalone plus sign is considered a wildcard character which means "any host" only when the word *promiscuous* is added to the auth component line in your PAM file for the particular service (e.g., **rlogin**).

EXAMPLES

Below are some example */etc/host.equiv* or *~/.rhosts* files.

Allow any user to log in from any host:

```
+
```

Allow any user from *host* with a matching local account to log in:

```
host
```

Note: the use of *+host* is never a valid syntax, including attempting to specify that any user from the host is allowed.

Allow any user from *host* to log in:

```
host +
```

Note: this is distinct from the previous example since it does not require a matching local account.

Allow *user* from *host* to log in as any non-root user:

```
host user
```

Allow all users with matching local accounts from *host* to log in except for *baduser*:

```
host −baduser
host
```

Deny all users from *host*:

```
−host
```

Note: the use of −*host* −*user* is never a valid syntax, including attempting to specify that a particular user from the host is not trusted.

Allow all users with matching local accounts on all hosts in a *netgroup*:

```
+@netgroup
```

Disallow all users on all hosts in a *netgroup*:

```
−@netgroup
```

Allow all users in a *netgroup* to log in from *host* as any non-root user:

```
host +@netgroup
```

Allow all users with matching local accounts on all hosts in a *netgroup* except *baduser*:

```
+@netgroup −baduser
+@netgroup
```

Note: the deny statements must always precede the allow statements because the file is processed sequentially until the first matching rule is found.

SEE ALSO

NAME

issue − prelogin message and identification file

DESCRIPTION

/etc/issue is a text file which contains a message or system identification to be printed before the login prompt. It may contain various **@***char* and *char* sequences, if supported by the **getty**-type program employed on the system.

FILES

/etc/issue

SEE ALSO

motd(5), *agetty*(8), *mingetty*(8)

NAME

locale − describes a locale definition file

DESCRIPTION

The **locale** definition file contains all the information that the *localedef*(1) command needs to convert it into the binary locale database.

The definition files consist of sections which each describe a locale category in detail. See *locale*(7) for additional details for these categories.

Syntax

The locale definition file starts with a header that may consist of the following keywords:

escape_char
: is followed by a character that should be used as the escape-character for the rest of the file to mark characters that should be interpreted in a special way. It defaults to the backslash (\).

comment_char
: is followed by a character that will be used as the comment-character for the rest of the file. It defaults to the number sign (#).

The locale definition has one part for each locale category. Each part can be copied from another existing locale or can be defined from scratch. If the category should be copied, the only valid keyword in the definition is *copy* followed by the name of the locale in double quotes which should be copied. The exceptions for this rule are **LC_COLLATE** and **LC_CTYPE** where a *copy* statement can be followed by locale-specific rules and selected overrides.

When defining a locale or a category from scratch, an existing system- provided locale definition file should be used as a reference to follow common glibc conventions.

Locale category sections

The following category sections are defined by POSIX:

- **LC_CTYPE**
- **LC_COLLATE**
- **LC_MESSAGES**
- **LC_MONETARY**
- **LC_NUMERIC**
- **LC_TIME**

In addition, since glibc 2.2, the GNU C library supports the following nonstandard categories:

- **LC_ADDRESS**
- **LC_IDENTIFICATION**
- **LC_MEASUREMENT**
- **LC_NAME**
- **LC_PAPER**
- **LC_TELEPHONE**

See *locale*(7) for a more detailed description of each category.

LC_ADDRESS

The definition starts with the string *LC_ADDRESS* in the first column.

The following keywords are allowed:

postal_fmt
: followed by a string containing field descriptors that define the format used for postal addresses in the locale. The following field descriptors are recognized:

  %n Person's name, possibly constructed with the **LC_NAME** *name_fmt* keyword (since glibc 2.24).

%a Care of person, or organization.

%f Firm name.

%d Department name.

%b Building name.

%s Street or block (e.g., Japanese) name.

%h House number or designation.

%N
Insert an end-of-line if the previous descriptor's value was not an empty string; otherwise ignore.

%t Insert a space if the previous descriptor's value was not an empty string; otherwise ignore.

%r Room number, door designation.

%e Floor number.

%C Country designation, from the *country_post* keyword.

%l Local township within town or city (since glibc 2.24).

%z Zip number, postal code.

%T Town, city.

%S State, province, or prefecture.

%c Country, as taken from data record.

Each field descriptor may have an 'R' after the '%' to specify that the information is taken from a Romanized version string of the entity.

country_name
followed by the country name in the language of the current document (e.g., "Deutschland" for the **de_DE** locale).

country_post
followed by the abbreviation of the country (see CERT_MAILCODES).

country_ab2
followed by the two-letter abbreviation of the country (ISO 3166).

country_ab3
followed by the three-letter abbreviation of the country (ISO 3166).

country_num
followed by the numeric country code (ISO 3166).

country_car
followed by the international license plate country code.

country_isbn
followed by the ISBN code (for books).

lang_name
followed by the language name in the language of the current document.

lang_ab
followed by the two-letter abbreviation of the language (ISO 639).

lang_term
followed by the three-letter abbreviation of the language (ISO 639-2/T).

lang_lib
followed by the three-letter abbreviation of the language for library use (ISO 639-2/B). Applications should in general prefer *lang_term* over *lang_lib*.

The **LC_ADDRESS** definition ends with the string *END LC_ADDRESS*.

LC_CTYPE

The definition starts with the string *LC_CTYPE* in the first column.

The following keywords are allowed:

upper followed by a list of uppercase letters. The letters **A** through **Z** are included automatically. Characters also specified as **cntrl**, **digit**, **punct**, or **space** are not allowed.

lower followed by a list of lowercase letters. The letters **a** through **z** are included automatically. Characters also specified as **cntrl**, **digit**, **punct**, or **space** are not allowed.

alpha followed by a list of letters. All character specified as either **upper** or **lower** are automatically included. Characters also specified as **cntrl**, **digit**, **punct**, or **space** are not allowed.

digit followed by the characters classified as numeric digits. Only the digits **0** through **9** are allowed. They are included by default in this class.

space followed by a list of characters defined as white-space characters. Characters also specified as **upper**, **lower**, **alpha**, **digit**, **graph**, or **xdigit** are not allowed. The characters **<space>**, **<form-feed>**, **<newline>**, **<carriage-return>**, **<tab>**, and **<vertical-tab>** are automatically included.

cntrl followed by a list of control characters. Characters also specified as **upper**, **lower**, **alpha**, **digit**, **punct**, **graph**, **print**, or **xdigit** are not allowed.

punct followed by a list of punctuation characters. Characters also specified as **upper**, **lower**, **alpha**, **digit**, **cntrl**, **xdigit**, or the **<space>** character are not allowed.

graph followed by a list of printable characters, not including the **<space>** character. The characters defined as **upper**, **lower**, **alpha**, **digit**, **xdigit**, and **punct** are automatically included. Characters also specified as **cntrl** are not allowed.

print followed by a list of printable characters, including the **<space>** character. The characters defined as **upper**, **lower**, **alpha**, **digit**, **xdigit**, **punct**, and the **<space>** character are automatically included. Characters also specified as **cntrl** are not allowed.

xdigit followed by a list of characters classified as hexadecimal digits. The decimal digits must be included followed by one or more set of six characters in ascending order. The following characters are included by default: **0** through **9**, **a** through **f**, **A** through **F**.

blank followed by a list of characters classified as **blank**. The characters **<space>** and **<tab>** are automatically included.

charclass
followed by a list of locale-specific character class names which are then to be defined in the locale.

toupper
followed by a list of mappings from lowercase to uppercase letters. Each mapping is a pair of a lowercase and an uppercase letter separated with a **,** and enclosed in parentheses.

tolower
followed by a list of mappings from uppercase to lowercase letters. If the keyword tolower is not present, the reverse of the toupper list is used.

map totitle
followed by a list of mapping pairs of characters and letters to be used in titles (headings).

class followed by a locale-specific character class definition, starting with the class name followed by the characters belonging to the class.

charconv
followed by a list of locale-specific character mapping names which are then to be defined in the locale.

outdigit
followed by a list of alternate output digits for the locale.

map to_inpunct
followed by a list of mapping pairs of alternate digits and separators for input digits for the locale.

map to_outpunct
followed by a list of mapping pairs of alternate separators for output for the locale.

translit_start
marks the start of the transliteration rules section. The section can contain the *include* keyword in the beginning followed by locale-specific rules and overrides. Any rule specified in the locale file will override any rule copied or included from other files. In case of duplicate rule definitions in the locale file, only the first rule is used.

A transliteration rule consist of a character to be transliterated followed by a list of transliteration targets separated by semicolons. The first target which can be presented in the target character set is used, if none of them can be used the *default_missing* character will be used instead.

include in the transliteration rules section includes a transliteration rule file (and optionally a repertoire map file).

default_missing
in the transliteration rules section defines the default character to be used for transliteration where none of the targets cannot be presented in the target character set.

translit_end
marks the end of the transliteration rules.

The **LC_CTYPE** definition ends with the string *END LC_CTYPE*.

LC_COLLATE

Note that glibc does not support all POSIX-defined options, only the options described below are supported (as of glibc 2.23).

The definition starts with the string *LC_COLLATE* in the first column.

The following keywords are allowed:

coll_weight_max
followed by the number representing used collation levels. This keyword is recognized but ignored by glibc.

collating−element
followed by the definition of a collating-element symbol representing a multicharacter collating element.

collating−symbol
followed by the definition of a collating symbol that can be used in collation order statements.

define followed by **string** to be evaluated in an *ifdef* **string** / *else* / *endif* construct.

reorder−after
followed by a redefinition of a collation rule.

reorder−end
marks the end of the redefinition of a collation rule.

reorder−sections−after
followed by a script name to reorder listed scripts after.

reorder−sections−end
marks the end of the reordering of sections.

script followed by a declaration of a script.

symbol−equivalence
followed by a collating-symbol to be equivalent to another defined collating-symbol.

The collation rule definition starts with a line:

order_start
followed by a list of keywords chosen from **forward**, **backward**, or **position**. The order definition consists of lines that describe the collation order and is terminated with the keyword *order_end*.

The **LC_COLLATE** definition ends with the string *END LC_COLLATE*.

LC_IDENTIFICATION

The definition starts with the string *LC_IDENTIFICATION* in the first column.

The following keywords are allowed:

title followed by the title of the locale document (e.g., "Maori language locale for New Zealand").

source followed by the name of the organization that maintains this document.

address
followed by the address of the organization that maintains this document.

contact followed by the name of the contact person at the organization that maintains this document.

email followed by the email address of the person or organization that maintains this document.

tel followed by the telephone number (in international format) of the organization that maintains this document. As of glibc 2.24, this keyword is deprecated in favor of other contact methods.

fax followed by the fax number (in international format) of the organization that maintains this document. As of glibc 2.24, this keyword is deprecated in favor of other contact methods.

language
followed by the name of the language to which this document applies.

territory
followed by the name of the country/geographic extent to which this document applies.

audience
followed by a description of the audience for which this document is intended.

application
followed by a description of any special application for which this document is intended.

abbreviation
followed by the short name for provider of the source of this document.

revision
followed by the revision number of this document.

date followed by the revision date of this document.

In addition, for each of the categories defined by the document, there should be a line starting with the keyword *category*, followed by:

(1) a string that identifies this locale category definition,

(2) a semicolon, and

(3) one of the **LC_*** identifiers.

The **LC_IDENTIFICATION** definition ends with the string *END LC_IDENTIFICATION*.

LC_MESSAGES

The definition starts with the string *LC_MESSAGES* in the first column.

The following keywords are allowed:

yesexpr
followed by a regular expression that describes possible yes-responses.

noexpr followed by a regular expression that describes possible no-responses.

yesstr followed by the output string corresponding to "yes".

nostr followed by the output string corresponding to "no".

The **LC_MESSAGES** definition ends with the string *END LC_MESSAGES*.

LC_MEASUREMENT

The definition starts with the string *LC_MEASUREMENT* in the first column.

The following keywords are allowed:

measurement
followed by number identifying the standard used for measurement. The following values are recognized:

1 Metric.

2 US customary measurements.

The **LC_MEASUREMENT** definition ends with the string *END LC_MEASUREMENT*.

LC_MONETARY

The definition starts with the string *LC_MONETARY* in the first column.

The following keywords are allowed:

int_curr_symbol
: followed by the international currency symbol. This must be a 4-character string containing the international currency symbol as defined by the ISO 4217 standard (three characters) followed by a separator.

currency_symbol
: followed by the local currency symbol.

mon_decimal_point
: followed by the single-character string that will be used as the decimal delimiter when formatting monetary quantities.

mon_thousands_sep
: followed by the single-character string that will be used as a group separator when formatting monetary quantities.

mon_grouping
: followed by a sequence of integers separated by semicolons that describe the formatting of monetary quantities. See *grouping* below for details.

positive_sign
: followed by a string that is used to indicate a positive sign for monetary quantities.

negative_sign
: followed by a string that is used to indicate a negative sign for monetary quantities.

int_frac_digits
: followed by the number of fractional digits that should be used when formatting with the *int_curr_symbol*.

frac_digits
: followed by the number of fractional digits that should be used when formatting with the *currency_symbol*.

p_cs_precedes
: followed by an integer that indicates the placement of *currency_symbol* for a nonnegative formatted monetary quantity:

  0 the symbol succeeds the value.

  1 the symbol precedes the value.

p_sep_by_space
: followed by an integer that indicates the separation of *currency_symbol*, the sign string, and the value for a nonnegative formatted monetary quantity. The following values are recognized:

  0 No space separates the currency symbol and the value.

  1 If the currency symbol and the sign string are adjacent, a space separates them from the value; otherwise a space separates the currency symbol and the value.

  2 If the currency symbol and the sign string are adjacent, a space separates them from the value; otherwise a space separates the sign string and the value.

n_cs_precedes
: followed by an integer that indicates the placement of *currency_symbol* for a negative formatted monetary quantity. The same values are recognized as for *p_cs_precedes*.

n_sep_by_space
followed by an integer that indicates the separation of *currency_symbol*, the sign string, and the value for a negative formatted monetary quantity. The same values are recognized as for *p_sep_by_space*.

p_sign_posn
followed by an integer that indicates where the *positive_sign* should be placed for a nonnegative monetary quantity:

0 Parentheses enclose the quantity and the *currency_symbol* or *int_curr_symbol*.

1 The sign string precedes the quantity and the *currency_symbol* or the *int_curr_symbol*.

2 The sign string succeeds the quantity and the *currency_symbol* or the *int_curr_symbol*.

3 The sign string precedes the *currency_symbol* or the *int_curr_symbol*.

4 The sign string succeeds the *currency_symbol* or the *int_curr_symbol*.

n_sign_posn
followed by an integer that indicates where the *negative_sign* should be placed for a negative monetary quantity. The same values are recognized as for *p_sign_posn*.

int_p_cs_precedes
followed by an integer that indicates the placement of *int_curr_symbol* for a nonnegative internationally formatted monetary quantity. The same values are recognized as for *p_cs_precedes*.

int_n_cs_precedes
followed by an integer that indicates the placement of *int_curr_symbol* for a negative internationally formatted monetary quantity. The same values are recognized as for *p_cs_precedes*.

int_p_sep_by_space
followed by an integer that indicates the separation of *int_curr_symbol*, the sign string, and the value for a nonnegative internationally formatted monetary quantity. The same values are recognized as for *p_sep_by_space*.

int_n_sep_by_space
followed by an integer that indicates the separation of *int_curr_symbol*, the sign string, and the value for a negative internationally formatted monetary quantity. The same values are recognized as for *p_sep_by_space*.

int_p_sign_posn
followed by an integer that indicates where the *positive_sign* should be placed for a nonnegative internationally formatted monetary quantity. The same values are recognized as for *p_sign_posn*.

int_n_sign_posn
followed by an integer that indicates where the *negative_sign* should be placed for a negative internationally formatted monetary quantity. The same values are recognized as for *p_sign_posn*.

The **LC_MONETARY** definition ends with the string *END LC_MONETARY*.

LC_NAME

The definition starts with the string *LC_NAME* in the first column.

Various keywords are allowed, but only *name_fmt* is mandatory. Other keywords are needed only if there is common convention to use the corresponding salutation in this locale. The allowed keywords are as follows:

name_fmt
followed by a string containing field descriptors that define the format used for names in the locale. The following field descriptors are recognized:

%f Family name(s).

%F Family names in uppercase.

%g First given name.

%G
First given initial.

%l First given name with Latin letters.

%o Other shorter name.

%m
Additional given name(s).

%M
Initials for additional given name(s).

%p Profession.

%s Salutation, such as "Doctor".

%S Abbreviated salutation, such as "Mr." or "Dr.".

%d Salutation, using the FDCC-sets conventions.

%t If the preceding field descriptor resulted in an empty string, then the empty string, otherwise a space character.

name_gen
followed by the general salutation for any gender.

name_mr
followed by the salutation for men.

name_mrs
followed by the salutation for married women.

name_miss
followed by the salutation for unmarried women.

name_ms
followed by the salutation valid for all women.

The **LC_NAME** definition ends with the string *END LC_NAME*.

LC_NUMERIC

The definition starts with the string *LC_NUMERIC* in the first column.

The following keywords are allowed:

decimal_point
followed by the single-character string that will be used as the decimal delimiter when formatting numeric quantities.

thousands_sep
followed by the single-character string that will be used as a group separator when formatting numeric quantities.

grouping
followed by a sequence of integers separated by semicolons that describe the formatting of numeric quantities.

Each integer specifies the number of digits in a group. The first integer defines the size of the group immediately to the left of the decimal delimiter. Subsequent integers define succeeding groups to the left of the previous group. If the last integer is not −1, then the size of the previous group (if any) is repeatedly used for the remainder of the digits. If the last integer is −1, then no further grouping is performed.

The **LC_NUMERIC** definition ends with the string *END LC_NUMERIC*.

LC_PAPER

The definition starts with the string *LC_PAPER* in the first column.

The following keywords are allowed:

height followed by the height, in millimeters, of the standard paper format.

width followed by the width, in millimeters, of the standard paper format.

The **LC_PAPER** definition ends with the string *END LC_PAPER*.

LC_TELEPHONE

The definition starts with the string *LC_TELEPHONE* in the first column.

The following keywords are allowed:

tel_int_fmt
followed by a string that contains field descriptors that identify the format used to dial international numbers. The following field descriptors are recognized:

%a Area code without nationwide prefix (the prefix is often "00").

%A
Area code including nationwide prefix.

%l Local number (within area code).

%e Extension (to local number).

%c Country code.

%C Alternate carrier service code used for dialing abroad.

%t If the preceding field descriptor resulted in an empty string, then the empty string, otherwise a space character.

tel_dom_fmt
followed by a string that contains field descriptors that identify the format used to dial domestic numbers. The recognized field descriptors are the same as for *tel_int_fmt*.

int_select
followed by the prefix used to call international phone numbers.

int_prefix
followed by the prefix used from other countries to dial this country.

The **LC_TELEPHONE** definition ends with the string *END LC_TELEPHONE*.

LC_TIME

The definition starts with the string *LC_TIME* in the first column.

The following keywords are allowed:

abday followed by a list of abbreviated names of the days of the week. The list starts with the first day of the week as specified by *week* (Sunday by default). See NOTES.

day followed by a list of names of the days of the week. The list starts with the first day of the week as specified by *week* (Sunday by default). See NOTES.

abmon followed by a list of abbreviated month names.

mon followed by a list of month names.

d_t_fmt
followed by the appropriate date and time format (for syntax, see *strftime*(3)).

d_fmt followed by the appropriate date format (for syntax, see *strftime*(3)).

t_fmt followed by the appropriate time format (for syntax, see *strftime*(3)).

am_pm followed by the appropriate representation of the **am** and **pm** strings. This should be left empty for locales not using AM/PM convention.

t_fmt_ampm
followed by the appropriate time format (for syntax, see *strftime*(3)) when using 12h clock format. This should be left empty for locales not using AM/PM convention.

era followed by semicolon-separated strings that define how years are counted and displayed for each era in the locale. Each string has the following format:

direction:*offset*:*start_date*:*end_date*:*era_name*:*era_format*

The fields are to be defined as follows:

direction
: Either + or -. + means the years closer to *start_date* have lower numbers than years closer to *end_date*. − means the opposite.

offset
: The number of the year closest to *start_date* in the era, corresponding to the *%Ey* descriptor (see *strptime*(3)).

start_date
: The start of the era in the form of *yyyy/mm/dd*. Years prior AD 1 are represented as negative numbers.

end_date
: The end of the era in the form of *yyyy/mm/dd*, or one of the two special values of **−*** or **+***. **−*** means the ending date is the beginning of time. **+*** means the ending date is the end of time.

era_name
: The name of the era corresponding to the *%EC* descriptor (see *strptime*(3)).

era_format
: The format of the year in the era corresponding to the *%EY* descriptor (see *strptime*(3)).

era_d_fmt
: followed by the format of the date in alternative era notation, corresponding to the *%Ex* descriptor (see *strptime*(3)).

era_t_fmt
: followed by the format of the time in alternative era notation, corresponding to the *%EX* descriptor (see *strptime*(3)).

era_d_t_fmt
: followed by the format of the date and time in alternative era notation, corresponding to the *%Ec* descriptor (see *strptime*(3)).

alt_digits
: followed by the alternative digits used for date and time in the locale.

week
: followed by a list of three values separated by semicolons: The number of days in a week (by default 7), a date of beginning of the week (by default corresponds to Sunday), and the minimal length of the first week in year (by default 4). Regarding the start of the week, **19971130** shall be used for Sunday and **19971201** shall be used for Monday. See NOTES.

first_weekday (since glibc 2.2)
: followed by the number of the day from the *day* list to be shown as the first day of the week in calendar applications. The default value of **1** corresponds to either Sunday or Monday depending on the value of the second *week* list item. See NOTES.

first_workday (since glibc 2.2)
: followed by the number of the first working day from the *day* list. The default value is **2**. See NOTES.

cal_direction
: followed by a number value that indicates the direction for the display of calendar dates, as follows:

  1 Left-right from top.

  2 Top-down from left.

  3 Right-left from top.

date_fmt
: followed by the appropriate date representation for *date*(1) (for syntax, see *strftime*(3)).

The **LC_TIME** definition ends with the string *END LC_TIME*.

FILES

/usr/lib/locale/locale−archive
: Usual default locale archive location.

/usr/share/i18n/locales
: Usual default path for locale definition files.

STANDARDS

POSIX.2.

NOTES

The collective GNU C library community wisdom regarding *abday*, *day*, *week*, *first_weekday*, and *first_workday* states at https://sourceware.org/glibc/wiki/Locales the following:

- The value of the second *week* list item specifies the base of the *abday* and *day* lists.
- *first_weekday* specifies the offset of the first day-of-week in the *abday* and *day* lists.
- For compatibility reasons, all glibc locales should set the value of the second *week* list item to **19971130** (Sunday) and base the *abday* and *day* lists appropriately, and set *first_weekday* and *first_workday* to **1** or **2**, depending on whether the week and work week actually starts on Sunday or Monday for the locale.

NAME

motd − message of the day

DESCRIPTION

The contents of */etc/motd* are displayed by *login*(1) after a successful login but just before it executes the login shell.

The abbreviation "motd" stands for "message of the day", and this file has been traditionally used for exactly that (it requires much less disk space than mail to all users).

FILES

/etc/motd

SEE ALSO

login(1), *issue*(5)

NAME

networks − network name information

DESCRIPTION

The file */etc/networks* is a plain ASCII file that describes known DARPA networks and symbolic names for these networks. Each line represents a network and has the following structure:

name number aliases ...

where the fields are delimited by spaces or tabs. Empty lines are ignored. The hash character (#) indicates the start of a comment: this character, and the remaining characters up to the end of the current line, are ignored by library functions that process the file.

The field descriptions are:

name The symbolic name for the network. Network names can contain any printable characters except white-space characters or the comment character.

number
The official number for this network in numbers-and-dots notation (see *inet*(3)). The trailing ".0" (for the host component of the network address) may be omitted.

aliases Optional aliases for the network.

This file is read by the *route*(8) and *netstat*(8) utilities. Only Class A, B, or C networks are supported, partitioned networks (i.e., network/26 or network/28) are not supported by this file.

FILES

/etc/networks
The networks definition file.

SEE ALSO

getnetbyaddr(3), *getnetbyname*(3), *getnetent*(3), *netstat*(8), *route*(8)

NAME

nologin − prevent unprivileged users from logging into the system

DESCRIPTION

If the file */etc/nologin* exists and is readable, *login*(1) will allow access only to root. Other users will be shown the contents of this file and their logins will be refused. This provides a simple way of temporarily disabling all unprivileged logins.

FILES

/etc/nologin

SEE ALSO

login(1), *shutdown*(8)

NAME

nscd.conf − name service cache daemon configuration file

DESCRIPTION

The file */etc/nscd.conf* is read from *nscd*(8) at startup. Each line specifies either an attribute and a value, or an attribute, service, and a value. Fields are separated either by SPACE or TAB characters. A '#' (number sign) indicates the beginning of a comment; following characters, up to the end of the line, are not interpreted by nscd.

Valid services are *passwd*, *group*, *hosts*, *services*, or *netgroup*.

logfile *debug-file-name*
Specifies name of the file to which debug info should be written.

debug−level *value*
Sets the desired debug level. 0 hides debug info. 1 shows general debug info. 2 additionally shows data in cache dumps. 3 (and above) shows all debug info. The default is 0.

threads *number*
This is the initial number of threads that are started to wait for requests. At least five threads will always be created. The number of threads may increase dynamically up to **max−threads** in response to demand from clients, but never decreases.

max−threads *number*
Specifies the maximum number of threads. The default is 32.

server−user *user*
If this option is set, nscd will run as this user and not as root. If a separate cache for every user is used (−S parameter), this option is ignored.

stat−user *user*
Specifies the user who is allowed to request statistics.

reload−count unlimited | *number*
Sets a limit on the number of times a cached entry gets reloaded without being used before it gets removed. The limit can take values ranging from 0 to 254; values 255 or higher behave the same as **unlimited**. Limit values can be specified in either decimal or hexadecimal with a "0x" prefix. The special value **unlimited** is case-insensitive. The default limit is 5. A limit of 0 turns off the reloading feature. See NOTES below for further discussion of reloading.

paranoia <*yes*|*no*>
Enabling paranoia mode causes nscd to restart itself periodically. The default is no.

restart−interval *time*
Sets the restart interval to *time* seconds if periodic restart is enabled by enabling **paranoia** mode. The default is 3600.

enable−cache *service* <*yes*|*no*>
Enables or disables the specified *service* cache. The default is no.

positive−time−to−live *service value*
Sets the TTL (time-to-live) for positive entries (successful queries) in the specified cache for *service*. *Value* is in seconds. Larger values increase cache hit rates and reduce mean response times, but increase problems with cache coherence. Note that for some name services (including specifically DNS) the TTL returned from the name service is used and this attribute is ignored.

negative−time−to−live *service value*
Sets the TTL (time-to-live) for negative entries (unsuccessful queries) in the specified cache for *service*. *Value* is in seconds. Can result in significant performance improvements if there are several files owned by UIDs (user IDs) not in system databases (for example untarring the Linux kernel sources as root); should be kept small to reduce cache coherency problems.

suggested−size *service value*
This is the internal hash table size, *value* should remain a prime number for optimum efficiency. The default is 211.

check−files *service* <*yes*|*no*>

Enables or disables checking the file belonging to the specified *service* for changes. The files are */etc/passwd*, */etc/group*, */etc/hosts*, */etc/resolv.conf*, */etc/services*, and */etc/netgroup*. The default is yes.

persistent *service* <*yes*|*no*>
Keep the content of the cache for *service* over server restarts; useful when **paranoia** mode is set. The default is no.

shared *service* <*yes*|*no*>
The memory mapping of the nscd databases for *service* is shared with the clients so that they can directly search in them instead of having to ask the daemon over the socket each time a lookup is performed. The default is no. Note that a cache miss will still result in asking the daemon over the socket.

max-db-size *service bytes*
The maximum allowable size, in bytes, of the database files for the *service*. The default is 33554432.

auto-propagate *service* <*yes*|*no*>
When set to *no* for *passwd* or *group* service, then the *.byname* requests are not added to *passwd.byuid* or *group.bygid* cache. This can help with tables containing multiple records for the same ID. The default is yes. This option is valid only for services *passwd* and *group*.

NOTES

The default values stated in this manual page originate from the source code of *nscd*(8) and are used if not overridden in the configuration file. The default values used in the configuration file of your distribution might differ.

Reloading

nscd(8) has a feature called reloading, whose behavior can be surprising.

Reloading is enabled when the **reload-count** attribute has a non-zero value. The default value in the source code enables reloading, although your distribution may differ.

When reloading is enabled, positive cached entries (the results of successful queries) do not simply expire when their TTL is up. Instead, at the expiry time, **nscd** will "reload", i.e., re-issue to the name service the same query that created the cached entry, to get a new value to cache. Depending on */etc/nsswitch.conf* this may mean that a DNS, LDAP, or NIS request is made. If the new query is successful, reloading will repeat when the new value would expire, until **reload-count** reloads have happened for the entry, and only then will it actually be removed from the cache. A request from a client which hits the entry will reset the reload counter on the entry. Purging the cache using *nscd -i* overrides the reload logic and removes the entry.

Reloading has the effect of extending cache entry TTLs without compromising on cache coherency, at the cost of additional load on the backing name service. Whether this is a good idea on your system depends on details of your applications' behavior, your name service, and the effective TTL values of your cache entries. Note that for some name services (for example, DNS), the effective TTL is the value returned from the name service and *not* the value of the **positive-time-to-live** attribute.

Please consider the following advice carefully:

- If your application will make a second request for the same name, after more than 1 TTL but before **reload-count** TTLs, and is sensitive to the latency of a cache miss, then reloading may be a good idea for you.
- If your name service is configured to return very short TTLs, and your applications only make requests rarely under normal circumstances, then reloading may result in additional load on your backing name service without any benefit to applications, which is probably a bad idea for you.
- If your name service capacity is limited, reloading may have the surprising effect of increasing load on your name service instead of reducing it, and may be a bad idea for you.
- Setting **reload-count** to **unlimited** is almost never a good idea, as it will result in a cache that never expires entries and puts never-ending additional load on the backing name service.

Some distributions have an init script for *nscd*(8) with a *reload* command which uses *nscd -i* to purge the cache. That use of the word "reload" is entirely different from the "reloading" described here.

nscd(8)

NAME

nss − Name Service Switch configuration file

DESCRIPTION

Each call to a function which retrieves data from a system database like the password or group database is handled by the Name Service Switch implementation in the GNU C library. The various services provided are implemented by independent modules, each of which naturally varies widely from the other.

The default implementations coming with the GNU C library are by default conservative and do not use unsafe data. This might be very costly in some situations, especially when the databases are large. Some modules allow the system administrator to request taking shortcuts if these are known to be safe. It is then the system administrator's responsibility to ensure the assumption is correct.

There are other modules where the implementation changed over time. If an implementation used to sacrifice speed for memory consumption, it might create problems if the preference is switched.

The */etc/default/nss* file contains a number of variable assignments. Each variable controls the behavior of one or more NSS modules. White spaces are ignored. Lines beginning with '#' are treated as comments.

The variables currently recognized are:

NETID_AUTHORITATIVE = *TRUE*|*FALSE*

If set to TRUE, the NIS backend for the *initgroups*(3) function will accept the information from the *netid.byname* NIS map as authoritative. This can speed up the function significantly if the *group.byname* map is large. The content of the *netid.byname* map is used **as is**. The system administrator has to make sure it is correctly generated.

SERVICES_AUTHORITATIVE = *TRUE*|*FALSE*

If set to TRUE, the NIS backend for the *getservbyname*(3) and *getservbyname_r*(3) functions will assume that the *services.byservicename* NIS map exists and is authoritative, particularly that it contains both keys with /proto and without /proto for both primary service names and service aliases. The system administrator has to make sure it is correctly generated.

SETENT_BATCH_READ = *TRUE*|*FALSE*

If set to TRUE, the NIS backend for the *setpwent*(3) and *setgrent*(3) functions will read the entire database at once and then hand out the requests one by one from memory with every corresponding *getpwent*(3) or *getgrent*(3) call respectively. Otherwise, each *getpwent*(3) or *getgrent*(3) call might result in a network communication with the server to get the next entry.

FILES

/etc/default/nss

EXAMPLES

The default configuration corresponds to the following configuration file:

```
NETID_AUTHORITATIVE=FALSE
SERVICES_AUTHORITATIVE=FALSE
SETENT_BATCH_READ=FALSE
```

SEE ALSO

nsswitch.conf

NAME

nsswitch.conf − Name Service Switch configuration file

DESCRIPTION

The Name Service Switch (NSS) configuration file, */etc/nsswitch.conf*, is used by the GNU C Library and certain other applications to determine the sources from which to obtain name-service information in a range of categories, and in what order. Each category of information is identified by a database name.

The file is plain ASCII text, with columns separated by spaces or tab characters. The first column specifies the database name. The remaining columns describe the order of sources to query and a limited set of actions that can be performed by lookup result.

The following databases are understood by the GNU C Library:

aliases Mail aliases, used by *getaliasent*(3) and related functions.

ethers Ethernet numbers.

group Groups of users, used by *getgrent*(3) and related functions.

hosts Host names and numbers, used by *gethostbyname*(3) and related functions.

initgroups Supplementary group access list, used by *getgrouplist*(3) function.

netgroup Network-wide list of hosts and users, used for access rules. C libraries before glibc 2.1 supported netgroups only over NIS.

networks Network names and numbers, used by *getnetent*(3) and related functions.

passwd User passwords, used by *getpwent*(3) and related functions.

protocols Network protocols, used by *getprotoent*(3) and related functions.

publickey Public and secret keys for Secure_RPC used by NFS and NIS+.

rpc Remote procedure call names and numbers, used by *getrpcbyname*(3) and related functions.

services Network services, used by *getservent*(3) and related functions.

shadow Shadow user passwords, used by *getspnam*(3) and related functions.

The GNU C Library ignores databases with unknown names. Some applications use this to implement special handling for their own databases. For example, *sudo*(8) consults the **sudoers** database. Delegation of subordinate user/group IDs can be configured using the **subid** database. Refer to *subuid*(5) and *subgid*(5) for more details.

Here is an example */etc/nsswitch.conf* file:

```
passwd:         compat
group:          compat
shadow:         compat

hosts:          dns [!UNAVAIL=return] files
networks:       nis [NOTFOUND=return] files
ethers:         nis [NOTFOUND=return] files
protocols:      nis [NOTFOUND=return] files
rpc:            nis [NOTFOUND=return] files
services:       nis [NOTFOUND=return] files
```

The first column is the database name. The remaining columns specify:

- One or more service specifications, for example, "files", "db", or "nis". The order of the services on the line determines the order in which those services will be queried, in turn, until a result is found.
- Optional actions to perform if a particular result is obtained from the preceding service, for example, "[NOTFOUND=return]".

The service specifications supported on your system depend on the presence of shared libraries, and are therefore extensible. Libraries called */lib/libnss_SERVICE.so.***X** will provide the named *SERVICE*. On a standard installation, you can use "files", "db", "nis", and "nisplus". For the **hosts** database, you can

additionally specify "dns". For the **passwd**, **group**, and **shadow** databases, you can additionally specify "compat" (see **Compatibility mode** below). The version number **X** may be 1 for glibc 2.0, or 2 for glibc 2.1 and later. On systems with additional libraries installed, you may have access to further services such as "hesiod", "ldap", "winbind", and "wins".

An action may also be specified following a service specification. The action modifies the behavior following a result obtained from the preceding data source. Action items take the general form:

[*STATUS=ACTION*]
[!*STATUS=ACTION*]

where

STATUS => **success** | **notfound** | **unavail** | **tryagain**
ACTION => **return** | **continue** | **merge**

The ! negates the test, matching all possible results except the one specified. The case of the keywords is not significant.

The *STATUS* value is matched against the result of the lookup function called by the preceding service specification, and can be one of:

success No error occurred and the requested entry is returned. The default action for this condition is "return".

notfound The lookup succeeded, but the requested entry was not found. The default action for this condition is "continue".

unavail The service is permanently unavailable. This can mean either that the required file cannot be read, or, for network services, that the server is not available or does not allow queries. The default action for this condition is "continue".

tryagain The service is temporarily unavailable. This could mean a file is locked or a server currently cannot accept more connections. The default action for this condition is "continue".

The *ACTION* value can be one of:

return Return a result now. Do not call any further lookup functions. However, for compatibility reasons, if this is the selected action for the **group** database and the **notfound** status, and the configuration file does not contain the **initgroups** line, the next lookup function is always called, without affecting the search result.

continue Call the next lookup function.

merge *[SUCCESS=merge]* is used between two database entries. When a group is located in the first of the two group entries, processing will continue on to the next one. If the group is also found in the next entry (and the group name and GID are an exact match), the member list of the second entry will be added to the group object to be returned. Available since glibc 2.24. Note that merging will not be done for *getgrent*(3) nor will duplicate members be pruned when they occur in both entries being merged.

Compatibility mode (compat)

The NSS "compat" service is similar to "files" except that it additionally permits special entries in corresponding files for granting users or members of netgroups access to the system. The following entries are valid in this mode:

For **passwd** and **shadow** databases:

+user Include the specified *user* from the NIS passwd/shadow map.

+@netgroup Include all users in the given *netgroup*.

−user Exclude the specified *user* from the NIS passwd/shadow map.

−@netgroup Exclude all users in the given *netgroup*.

+ Include every user, except previously excluded ones, from the NIS passwd/shadow map.

For **group** database:

+*group* Include the specified *group* from the NIS group map.

−*group* Exclude the specified *group* from the NIS group map.

\+ Include every group, except previously excluded ones, from the NIS group map.

By default, the source is "nis", but this may be overridden by specifying any NSS service except "compat" itself as the source for the pseudo-databases **passwd_compat**, **group_compat**, and **shadow_compat**.

FILES

A service named *SERVICE* is implemented by a shared object library named *libnss_SERVICE.so.***X** that resides in */lib*.

/etc/nsswitch.conf	NSS configuration file.
*/lib/libnss_compat.so.***X**	implements "compat" source.
*/lib/libnss_db.so.***X**	implements "db" source.
*/lib/libnss_dns.so.***X**	implements "dns" source.
*/lib/libnss_files.so.***X**	implements "files" source.
*/lib/libnss_hesiod.so.***X**	implements "hesiod" source.
*/lib/libnss_nis.so.***X**	implements "nis" source.
*/lib/libnss_nisplus.so.***X**	implements "nisplus" source.

The following files are read when "files" source is specified for respective databases:

aliases	*/etc/aliases*
ethers	*/etc/ethers*
group	*/etc/group*
hosts	*/etc/hosts*
initgroups	*/etc/group*
netgroup	*/etc/netgroup*
networks	*/etc/networks*
passwd	*/etc/passwd*
protocols	*/etc/protocols*
publickey	*/etc/publickey*
rpc	*/etc/rpc*
services	*/etc/services*
shadow	*/etc/shadow*

NOTES

Starting with glibc 2.33, **nsswitch.conf** is automatically reloaded if the file is changed. In earlier versions, the entire file was read only once within each process. If the file was later changed, the process would continue using the old configuration.

Traditionally, there was only a single source for service information, often in the form of a single configuration file (e.g., */etc/passwd*). However, as other name services, such as the Network Information Service (NIS) and the Domain Name Service (DNS), became popular, a method was needed that would be more flexible than fixed search orders coded into the C library. The Name Service Switch mechanism, which was based on the mechanism used by Sun Microsystems in the Solaris 2 C library, introduced a cleaner solution to the problem.

NAME

passwd − password file

DESCRIPTION

The */etc/passwd* file is a text file that describes user login accounts for the system. It should have read permission allowed for all users (many utilities, like *ls*(1) use it to map user IDs to usernames), but write access only for the superuser.

In the good old days there was no great problem with this general read permission. Everybody could read the encrypted passwords, but the hardware was too slow to crack a well-chosen password, and moreover the basic assumption used to be that of a friendly user-community. These days many people run some version of the shadow password suite, where */etc/passwd* has an 'x' character in the password field, and the encrypted passwords are in */etc/shadow*, which is readable by the superuser only.

If the encrypted password, whether in */etc/passwd* or in */etc/shadow*, is an empty string, login is allowed without even asking for a password. Note that this functionality may be intentionally disabled in applications, or configurable (for example using the "**nullok**" or "**nonull**" arguments to *pam_unix*(8)).

If the encrypted password in */etc/passwd* is "*NP*" (without the quotes), the shadow record should be obtained from an NIS+ server.

Regardless of whether shadow passwords are used, many system administrators use an asterisk (*) in the encrypted password field to make sure that this user can not authenticate themself using a password. (But see NOTES below.)

If you create a new login, first put an asterisk (*) in the password field, then use *passwd*(1) to set it.

Each line of the file describes a single user, and contains seven colon-separated fields:

```
name:password:UID:GID:GECOS:directory:shell
```

The field are as follows:

name This is the user's login name. It should not contain capital letters.

password This is either the encrypted user password, an asterisk (*), or the letter 'x'. (See *pwconv*(8) for an explanation of 'x'.)

UID The privileged *root* login account (superuser) has the user ID 0.

GID This is the numeric primary group ID for this user. (Additional groups for the user are defined in the system group file; see *group*(5)).

GECOS This field (sometimes called the "comment field") is optional and used only for informational purposes. Usually, it contains the full username. Some programs (for example, *finger*(1)) display information from this field.

GECOS stands for "General Electric Comprehensive Operating System", which was renamed to GCOS when GE's large systems division was sold to Honeywell. Dennis Ritchie has reported: "Sometimes we sent printer output or batch jobs to the GCOS machine. The gcos field in the password file was a place to stash the information for the $IDENTcard. Not elegant."

directory This is the user's home directory: the initial directory where the user is placed after logging in. The value in this field is used to set the **HOME** environment variable.

shell This is the program to run at login (if empty, use */bin/sh*). If set to a nonexistent executable, the user will be unable to login through *login*(1)The value in this field is used to set the **SHELL** environment variable.

FILES

/etc/passwd

NOTES

If you want to create user groups, there must be an entry in */etc/group*, or no group will exist.

If the encrypted password is set to an asterisk (*), the user will be unable to login using *login*(1), but may still login using *rlogin*(1), run existing processes and initiate new ones through *rsh*(1), *cron*(8), *at*(1), or mail filters, etc. Trying to lock an account by simply changing the shell field yields the same result and additionally allows the use of *su*(1)

SEE ALSO

NAME

proc − process information, system information, and sysctl pseudo-filesystem

DESCRIPTION

The **proc** filesystem is a pseudo-filesystem which provides an interface to kernel data structures. It is commonly mounted at */proc*. Typically, it is mounted automatically by the system, but it can also be mounted manually using a command such as:

```
mount -t proc proc /proc
```

Most of the files in the **proc** filesystem are read-only, but some files are writable, allowing kernel variables to be changed.

Mount options

The **proc** filesystem supports the following mount options:

hidepid=*n* (since Linux 3.3)
: This option controls who can access the information in */proc/*pid directories. The argument, *n*, is one of the following values:

  Everybody may access all */proc/*pid directories. This is the traditional behavior, and the default if this mount option is not specified.

  1 Users may not access files and subdirectories inside any */proc/*pid directories but their own (the */proc/*pid directories themselves remain visible). Sensitive files such as */proc/*pid*/cmdline* and */proc/*pid*/status* are now protected against other users. This makes it impossible to learn whether any user is running a specific program (so long as the program doesn't otherwise reveal itself by its behavior).

  2 As for mode 1, but in addition the */proc/*pid directories belonging to other users become invisible. This means that */proc/*pid entries can no longer be used to discover the PIDs on the system. This doesn't hide the fact that a process with a specific PID value exists (it can be learned by other means, for example, by "kill −0 $PID"), but it hides a process's UID and GID, which could otherwise be learned by employing *stat*(2) on a */proc/*pid directory. This greatly complicates an attacker's task of gathering information about running processes (e.g., discovering whether some daemon is running with elevated privileges, whether another user is running some sensitive program, whether other users are running any program at all, and so on).

gid=*gid* (since Linux 3.3)
: Specifies the ID of a group whose members are authorized to learn process information otherwise prohibited by **hidepid** (i.e., users in this group behave as though */proc* was mounted with *hidepid=0*). This group should be used instead of approaches such as putting nonroot users into the *sudoers*(5) file.

Overview

Underneath */proc*, there are the following general groups of files and subdirectories:

*/proc/*pid subdirectories
: Each one of these subdirectories contains files and subdirectories exposing information about the process with the corresponding process ID.

  Underneath each of the */proc/*pid directories, a *task* subdirectory contains subdirectories of the form *task/*tid, which contain corresponding information about each of the threads in the process, where *tid* is the kernel thread ID of the thread.

  The */proc/*pid subdirectories are visible when iterating through */proc* with *getdents*(2) (and thus are visible when one uses *ls*(1) to view the contents of */proc*).

*/proc/*tid subdirectories
: Each one of these subdirectories contains files and subdirectories exposing information about the thread with the corresponding thread ID. The contents of these directories are the same as the corresponding */proc/*pid*/task/*tid directories.

  The */proc/*tid subdirectories are *not* visible when iterating through */proc* with *getdents*(2) (and thus are *not* visible when one uses *ls*(1) to view the contents of */proc*).

/proc/self
: When a process accesses this magic symbolic link, it resolves to the process's own */proc/*pid directory.

/proc/thread-self
: When a thread accesses this magic symbolic link, it resolves to the process's own */proc/self/task/*tid directory.

*/proc/[a-z]**
: Various other files and subdirectories under */proc* expose system-wide information.

All of the above are described in more detail below.

NOTES

Many files contain strings (e.g., the environment and command line) that are in the internal format, with subfields terminated by null bytes ('\0'). When inspecting such files, you may find that the results are more readable if you use a command of the following form to display them:

```
$ cat file | tr '\000' '\n'
```

NAME

/proc/apm − advanced power management

DESCRIPTION

/proc/apm

Advanced power management version and battery information when **CONFIG_APM** is defined at kernel compilation time.

SEE ALSO

proc(5)

NAME

/proc/buddyinfo − memory fragmentation

DESCRIPTION

/proc/buddyinfo

This file contains information which is used for diagnosing memory fragmentation issues. Each line starts with the identification of the node and the name of the zone which together identify a memory region. This is then followed by the count of available chunks of a certain order in which these zones are split. The size in bytes of a certain order is given by the formula:

```
(2^order) * PAGE_SIZE
```

The binary buddy allocator algorithm inside the kernel will split one chunk into two chunks of a smaller order (thus with half the size) or combine two contiguous chunks into one larger chunk of a higher order (thus with double the size) to satisfy allocation requests and to counter memory fragmentation. The order matches the column number, when starting to count at zero.

For example on an x86-64 system:

```
Node 0, zone      DMA      1    1    1    0    2    1    1    0    1    1    3
Node 0, zone    DMA32     65   47    4   81   52   28   13   10    5    1  404
Node 0, zone   Normal    216   55  189  101   84   38   37   27    5    3  587
```

In this example, there is one node containing three zones and there are 11 different chunk sizes. If the page size is 4 kilobytes, then the first zone called *DMA* (on x86 the first 16 megabyte of memory) has 1 chunk of 4 kilobytes (order 0) available and has 3 chunks of 4 megabytes (order 10) available.

If the memory is heavily fragmented, the counters for higher order chunks will be zero and allocation of large contiguous areas will fail.

Further information about the zones can be found in */proc/zoneinfo*.

SEE ALSO

proc(5)

NAME

/proc/bus/ − installed buses

DESCRIPTION

/proc/bus/
: Contains subdirectories for installed buses.

/proc/bus/pccard/
: Subdirectory for PCMCIA devices when **CONFIG_PCMCIA** is set at kernel compilation time.

/proc/bus/pccard/drivers

/proc/bus/pci/
: Contains various bus subdirectories and pseudo-files containing information about PCI buses, installed devices, and device drivers. Some of these files are not ASCII.

/proc/bus/pci/devices
: Information about PCI devices. They may be accessed through *lspci*(8) and *setpci*(8)

SEE ALSO

proc(5)

NAME

/proc/cgroups − control groups

DESCRIPTION

/proc/cgroups (since Linux 2.6.24)

See *cgroups*(7).

SEE ALSO

proc(5)

NAME

/proc/cmdline − kernel boot arguments

DESCRIPTION

/proc/cmdline

Arguments passed to the Linux kernel at boot time. Often done via a boot manager such as *lilo*(8) or *grub*(8)Any arguments embedded in the kernel image or initramfs via **CONFIG_BOOT_CONFIG** will also be displayed.

SEE ALSO

proc(5)

NAME

/proc/config.gz − kernel build configuration

DESCRIPTION

/proc/config.gz (since Linux 2.6)

This file exposes the configuration options that were used to build the currently running kernel, in the same format as they would be shown in the *.config* file that resulted when configuring the kernel (using *make xconfig*, *make config*, or similar). The file contents are compressed; view or search them using *zcat*(1) and *zgrep*(1)As long as no changes have been made to the following file, the contents of */proc/config.gz* are the same as those provided by:

```
cat /lib/modules/$(uname -r)/build/.config
```

/proc/config.gz is provided only if the kernel is configured with **CONFIG_IKCONFIG_PROC**.

SEE ALSO

proc(5)

NAME

/proc/cpuinfo − CPU and system architecture information

DESCRIPTION

/proc/cpuinfo

This is a collection of CPU and system architecture dependent items, for each supported architecture a different list. Two common entries are *processor* which gives CPU number and *bogomips*; a system constant that is calculated during kernel initialization. SMP machines have information for each CPU. The *lscpu*(1) command gathers its information from this file.

SEE ALSO

proc(5)

NAME

/proc/crypto − ciphers provided by kernel crypto API

DESCRIPTION

/proc/crypto

A list of the ciphers provided by the kernel crypto API. For details, see the kernel *Linux Kernel Crypto API* documentation available under the kernel source directory *Documentation/crypto/* (or *Documentation/DocBook* before Linux 4.10; the documentation can be built using a command such as *make htmldocs* in the root directory of the kernel source tree).

SEE ALSO

proc(5)

NAME

/proc/devices − major numbers and device groups

DESCRIPTION

/proc/devices

Text listing of major numbers and device groups. This can be used by MAKEDEV scripts for consistency with the kernel.

SEE ALSO

proc(5)

NAME

/proc/diskstats − disk I/O statistics

DESCRIPTION

/proc/diskstats (since Linux 2.5.69)

This file contains disk I/O statistics for each disk device. See the Linux kernel source file *Documentation/admin−guide/iostats.rst* (or *Documentation/iostats.txt* before Linux 5.3) for further information.

SEE ALSO

proc(5)

NAME

/proc/dma − ISA DMA channels

DESCRIPTION

/proc/dma

This is a list of the registered *ISA* DMA (direct memory access) channels in use.

SEE ALSO

proc(5)

NAME

/proc/driver/ − empty dir

DESCRIPTION

/proc/driver/

Empty subdirectory.

SEE ALSO

proc(5)

NAME

/proc/execdomains − ABI personalities (obsolete)

DESCRIPTION

/proc/execdomains

Used to list ABI personalities before Linux 4.1; now contains a constant string for userspace compatibility.

SEE ALSO

proc(5)

NAME

/proc/fb − frame buffer

DESCRIPTION

/proc/fb

Frame buffer information when **CONFIG_FB** is defined during kernel compilation.

SEE ALSO

proc(5)

NAME

/proc/filesystems − supported filesystems

DESCRIPTION

/proc/filesystems

A text listing of the filesystems which are supported by the kernel, namely filesystems which were compiled into the kernel or whose kernel modules are currently loaded. (See also *filesystems*(5).) If a filesystem is marked with "nodev", this means that it does not require a block device to be mounted (e.g., virtual filesystem, network filesystem).

Incidentally, this file may be used by *mount*(8) when no filesystem is specified and it didn't manage to determine the filesystem type. Then filesystems contained in this file are tried (excepted those that are marked with "nodev").

SEE ALSO

proc(5)

NAME

/proc/fs/ − mounted filesystems

DESCRIPTION

/proc/fs/

Contains subdirectories that in turn contain files with information about (certain) mounted filesystems.

SEE ALSO

proc(5)

NAME

/proc/ide/ − IDE channels and attached devices

DESCRIPTION

/proc/ide

This directory exists on systems with the IDE bus. There are directories for each IDE channel and attached device. Files include:

```
cache              buffer size in KB
capacity           number of sectors
driver             driver version
geometry           physical and logical geometry
identify           in hexadecimal
media              media type
model              manufacturer's model number
settings           drive settings
smart_thresholds   IDE disk management thresholds (in hex)
smart_values       IDE disk management values (in hex)
```

The *hdparm*(8) utility provides access to this information in a friendly format.

SEE ALSO

proc(5)

NAME

/proc/interrupts − number of interrupts

DESCRIPTION

/proc/interrupts

This is used to record the number of interrupts per CPU per IO device. Since Linux 2.6.24, for the i386 and x86-64 architectures, at least, this also includes interrupts internal to the system (that is, not associated with a device as such), such as NMI (nonmaskable interrupt), LOC (local timer interrupt), and for SMP systems, TLB (TLB flush interrupt), RES (rescheduling interrupt), CAL (remote function call interrupt), and possibly others. Very easy to read formatting, done in ASCII.

SEE ALSO

proc(5)

NAME

/proc/iomem − I/O memory map

DESCRIPTION

/proc/iomem

I/O memory map in Linux 2.4.

SEE ALSO

proc(5)

NAME

/proc/ioports − I/O port regions

DESCRIPTION

/proc/ioports

This is a list of currently registered Input-Output port regions that are in use.

SEE ALSO

proc(5)

NAME

/proc/kallsyms − kernel exported symbols

DESCRIPTION

/proc/kallsyms (since Linux 2.5.71)

This holds the kernel exported symbol definitions used by the *modules*(X) tools to dynamically link and bind loadable modules. In Linux 2.5.47 and earlier, a similar file with slightly different syntax was named *ksyms*.

HISTORY

/proc/ksyms (Linux 1.1.23–2.5.47)

See */proc/kallsyms*.

SEE ALSO

proc(5)

NAME

/proc/kcore − physical memory

DESCRIPTION

/proc/kcore

This file represents the physical memory of the system and is stored in the ELF core file format. With this pseudo-file, and an unstripped kernel (*/usr/src/linux/vmlinux*) binary, GDB can be used to examine the current state of any kernel data structures.

The total length of the file is the size of physical memory (RAM) plus 4 KiB.

SEE ALSO

proc(5)

NAME

/proc/keys, /proc/key−users − in-kernel key management

DESCRIPTION

/proc/keys (since Linux 2.6.10)
See *keyrings*(7).

/proc/key−users (since Linux 2.6.10)
See *keyrings*(7).

SEE ALSO

proc(5)

NAME

/proc/kmsg − kernel messages

DESCRIPTION

/proc/kmsg

This file can be used instead of the *syslog*(2) system call to read kernel messages. A process must have superuser privileges to read this file, and only one process should read this file. This file should not be read if a syslog process is running which uses the *syslog*(2) system call facility to log kernel messages.

Information in this file is retrieved with the *dmesg*(1) program.

SEE ALSO

proc(5)

NAME

/proc/kpagecgroup − memory cgroups

DESCRIPTION

/proc/kpagecgroup (since Linux 4.3)

This file contains a 64-bit inode number of the memory cgroup each page is charged to, indexed by page frame number (see the discussion of */proc/*pid*/pagemap*).

The */proc/kpagecgroup* file is present only if the **CONFIG_MEMCG** kernel configuration option is enabled.

SEE ALSO

proc(5)

NAME

/proc/kpagecount − count of mappings of physical pages

DESCRIPTION

/proc/kpagecount (since Linux 2.6.25)

This file contains a 64-bit count of the number of times each physical page frame is mapped, indexed by page frame number (see the discussion of */proc/*pid*/pagemap*).

The */proc/kpagecount* file is present only if the **CONFIG_PROC_PAGE_MONITOR** kernel configuration option is enabled.

SEE ALSO

proc(5)

NAME

/proc/kpageflags − physical pages frame masks

DESCRIPTION

/proc/kpageflags (since Linux 2.6.25)

This file contains 64-bit masks corresponding to each physical page frame; it is indexed by page frame number (see the discussion of */proc/*pid*/pagemap*). The bits are as follows:

0	-	KPF_LOCKED	
1	-	KPF_ERROR	
2	-	KPF_REFERENCED	
3	-	KPF_UPTODATE	
4	-	KPF_DIRTY	
5	-	KPF_LRU	
6	-	KPF_ACTIVE	
7	-	KPF_SLAB	
8	-	KPF_WRITEBACK	
9	-	KPF_RECLAIM	
10	-	KPF_BUDDY	
11	-	KPF_MMAP	(since Linux 2.6.31)
12	-	KPF_ANON	(since Linux 2.6.31)
13	-	KPF_SWAPCACHE	(since Linux 2.6.31)
14	-	KPF_SWAPBACKED	(since Linux 2.6.31)
15	-	KPF_COMPOUND_HEAD	(since Linux 2.6.31)
16	-	KPF_COMPOUND_TAIL	(since Linux 2.6.31)
17	-	KPF_HUGE	(since Linux 2.6.31)
18	-	KPF_UNEVICTABLE	(since Linux 2.6.31)
19	-	KPF_HWPOISON	(since Linux 2.6.31)
20	-	KPF_NOPAGE	(since Linux 2.6.31)
21	-	KPF_KSM	(since Linux 2.6.32)
22	-	KPF_THP	(since Linux 3.4)
23	-	KPF_BALLOON	(since Linux 3.18)
24	-	KPF_ZERO_PAGE	(since Linux 4.0)
25	-	KPF_IDLE	(since Linux 4.3)
26	-	KPF_PGTABLE	(since Linux 4.18)

For further details on the meanings of these bits, see the kernel source file *Documentation/admin−guide/mm/pagemap.rst*. Before Linux 2.6.29, **KPF_WRITEBACK**, **KPF_RECLAIM**, **KPF_BUDDY**, and **KPF_LOCKED** did not report correctly.

The */proc/kpageflags* file is present only if the **CONFIG_PROC_PAGE_MONITOR** kernel configuration option is enabled.

SEE ALSO

proc(5)

NAME

/proc/loadavg − load average

DESCRIPTION

/proc/loadavg

The first three fields in this file are load average figures giving the number of jobs in the run queue (state R) or waiting for disk I/O (state D) averaged over 1, 5, and 15 minutes. They are the same as the load average numbers given by *uptime*(1) and other programs. The fourth field consists of two numbers separated by a slash (/). The first of these is the number of currently runnable kernel scheduling entities (processes, threads). The value after the slash is the number of kernel scheduling entities that currently exist on the system. The fifth field is the PID of the process that was most recently created on the system.

SEE ALSO

proc(5)

NAME

/proc/locks − current file locks and leases

DESCRIPTION

/proc/locks

This file shows current file locks (*flock*(2) and *fcntl*(2)) and leases (*fcntl*(2)).

An example of the content shown in this file is the following:

```
1: POSIX  ADVISORY  READ  5433 08:01:7864448 128 128
2: FLOCK  ADVISORY  WRITE 2001 08:01:7864554 0 EOF
3: FLOCK  ADVISORY  WRITE 1568 00:2f:32388 0 EOF
4: POSIX  ADVISORY  WRITE 699 00:16:28457 0 EOF
5: POSIX  ADVISORY  WRITE 764 00:16:21448 0 0
6: POSIX  ADVISORY  READ  3548 08:01:7867240 1 1
7: POSIX  ADVISORY  READ  3548 08:01:7865567 1826 2335
8: OFDLCK ADVISORY  WRITE -1 08:01:8713209 128 191
```

The fields shown in each line are as follows:

[1] The ordinal position of the lock in the list.

[2] The lock type. Values that may appear here include:

FLOCK
This is a BSD file lock created using *flock*(2).

OFDLCK
This is an open file description (OFD) lock created using *fcntl*(2).

POSIX This is a POSIX byte-range lock created using *fcntl*(2).

[3] Among the strings that can appear here are the following:

ADVISORY
This is an advisory lock.

MANDATORY
This is a mandatory lock.

[4] The type of lock. Values that can appear here are:

READ This is a POSIX or OFD read lock, or a BSD shared lock.

WRITE
This is a POSIX or OFD write lock, or a BSD exclusive lock.

[5] The PID of the process that owns the lock.

Because OFD locks are not owned by a single process (since multiple processes may have file descriptors that refer to the same open file description), the value −1 is displayed in this field for OFD locks. (Before Linux 4.14, a bug meant that the PID of the process that initially acquired the lock was displayed instead of the value −1.)

[6] Three colon-separated subfields that identify the major and minor device ID of the device containing the filesystem where the locked file resides, followed by the inode number of the locked file.

[7] The byte offset of the first byte of the lock. For BSD locks, this value is always 0.

[8] The byte offset of the last byte of the lock. **EOF** in this field means that the lock extends to the end of the file. For BSD locks, the value shown is always *EOF*.

Since Linux 4.9, the list of locks shown in */proc/locks* is filtered to show just the locks for the processes in the PID namespace (see *pid_namespaces*(7)) for which the */proc* filesystem was mounted. (In the initial PID namespace, there is no filtering of the records shown in this file.)

The *lslocks*(8) command provides a bit more information about each lock.

SEE ALSO

proc(5)

NAME

/proc/malloc − debug malloc (obsolete)

DESCRIPTION

/proc/malloc (only up to and including Linux 2.2)

This file is present only if **CONFIG_DEBUG_MALLOC** was defined during compilation.

SEE ALSO

proc(5)

NAME

/proc/meminfo − memory usage

DESCRIPTION

/proc/meminfo

This file reports statistics about memory usage on the system. It is used by *free*(1) to report the amount of free and used memory (both physical and swap) on the system as well as the shared memory and buffers used by the kernel. Each line of the file consists of a parameter name, followed by a colon, the value of the parameter, and an option unit of measurement (e.g., "kB"). The list below describes the parameter names and the format specifier required to read the field value. Except as noted below, all of the fields have been present since at least Linux 2.6.0. Some fields are displayed only if the kernel was configured with various options; those dependencies are noted in the list.

MemTotal %lu
: Total usable RAM (i.e., physical RAM minus a few reserved bits and the kernel binary code).

MemFree %lu
: The sum of *LowFree+HighFree*.

MemAvailable %lu (since Linux 3.14)
: An estimate of how much memory is available for starting new applications, without swapping.

Buffers %lu
: Relatively temporary storage for raw disk blocks that shouldn't get tremendously large (20 MB or so).

Cached %lu
: In-memory cache for files read from the disk (the page cache). Doesn't include *SwapCached*.

SwapCached %lu
: Memory that once was swapped out, is swapped back in but still also is in the swap file. (If memory pressure is high, these pages don't need to be swapped out again because they are already in the swap file. This saves I/O.)

Active %lu
: Memory that has been used more recently and usually not reclaimed unless absolutely necessary.

Inactive %lu
: Memory which has been less recently used. It is more eligible to be reclaimed for other purposes.

Active(anon) %lu (since Linux 2.6.28)
: [To be documented.]

Inactive(anon) %lu (since Linux 2.6.28)
: [To be documented.]

Active(file) %lu (since Linux 2.6.28)
: [To be documented.]

Inactive(file) %lu (since Linux 2.6.28)
: [To be documented.]

Unevictable %lu (since Linux 2.6.28)
: (From Linux 2.6.28 to Linux 2.6.30, **CONFIG_UNEVICTABLE_LRU** was required.) [To be documented.]

Mlocked %lu (since Linux 2.6.28)
: (From Linux 2.6.28 to Linux 2.6.30, **CONFIG_UNEVICTABLE_LRU** was required.) [To be documented.]

HighTotal %lu
(Starting with Linux 2.6.19, **CONFIG_HIGHMEM** is required.) Total amount of highmem. Highmem is all memory above ~860 MB of physical memory. Highmem areas are for use by user-space programs, or for the page cache. The kernel must use tricks to access this memory, making it slower to access than lowmem.

HighFree %lu
(Starting with Linux 2.6.19, **CONFIG_HIGHMEM** is required.) Amount of free highmem.

LowTotal %lu
(Starting with Linux 2.6.19, **CONFIG_HIGHMEM** is required.) Total amount of lowmem. Lowmem is memory which can be used for everything that highmem can be used for, but it is also available for the kernel's use for its own data structures. Among many other things, it is where everything from *Slab* is allocated. Bad things happen when you're out of lowmem.

LowFree %lu
(Starting with Linux 2.6.19, **CONFIG_HIGHMEM** is required.) Amount of free lowmem.

MmapCopy %lu (since Linux 2.6.29)
(**CONFIG_MMU** is required.) [To be documented.]

SwapTotal %lu
Total amount of swap space available.

SwapFree %lu
Amount of swap space that is currently unused.

Dirty %lu
Memory which is waiting to get written back to the disk.

Writeback %lu
Memory which is actively being written back to the disk.

AnonPages %lu (since Linux 2.6.18)
Non-file backed pages mapped into user-space page tables.

Mapped %lu
Files which have been mapped into memory (with *mmap*(2)), such as libraries.

Shmem %lu (since Linux 2.6.32)
Amount of memory consumed in *tmpfs*(5) filesystems.

KReclaimable %lu (since Linux 4.20)
Kernel allocations that the kernel will attempt to reclaim under memory pressure. Includes *SReclaimable* (below), and other direct allocations with a shrinker.

Slab %lu
In-kernel data structures cache. (See *slabinfo*(5).)

SReclaimable %lu (since Linux 2.6.19)
Part of *Slab*, that might be reclaimed, such as caches.

SUnreclaim %lu (since Linux 2.6.19)
Part of *Slab*, that cannot be reclaimed on memory pressure.

KernelStack %lu (since Linux 2.6.32)
Amount of memory allocated to kernel stacks.

PageTables %lu (since Linux 2.6.18)
Amount of memory dedicated to the lowest level of page tables.

Quicklists %lu (since Linux 2.6.27)
(**CONFIG_QUICKLIST** is required.) [To be documented.]

NFS_Unstable %lu (since Linux 2.6.18)
NFS pages sent to the server, but not yet committed to stable storage.

Bounce %lu (since Linux 2.6.18)
Memory used for block device "bounce buffers".

WritebackTmp %lu (since Linux 2.6.26)
Memory used by FUSE for temporary writeback buffers.

CommitLimit %lu (since Linux 2.6.10)
This is the total amount of memory currently available to be allocated on the system, expressed in kilobytes. This limit is adhered to only if strict overcommit accounting is enabled (mode 2 in */proc/sys/vm/overcommit_memory*). The limit is calculated according to the formula described under */proc/sys/vm/overcommit_memory*. For further details, see the kernel source file *Documentation/vm/overcommit−accounting.rst*.

Committed_AS %lu
The amount of memory presently allocated on the system. The committed memory is a sum of all of the memory which has been allocated by processes, even if it has not been "used" by them as of yet. A process which allocates 1 GB of memory (using *malloc*(3) or similar), but touches only 300 MB of that memory will show up as using only 300 MB of memory even if it has the address space allocated for the entire 1 GB.

This 1 GB is memory which has been "committed" to by the VM and can be used at any time by the allocating application. With strict overcommit enabled on the system (mode 2 in */proc/sys/vm/overcommit_memory*), allocations which would exceed the *CommitLimit* will not be permitted. This is useful if one needs to guarantee that processes will not fail due to lack of memory once that memory has been successfully allocated.

VmallocTotal %lu
Total size of vmalloc memory area.

VmallocUsed %lu
Amount of vmalloc area which is used. Since Linux 4.4, this field is no longer calculated, and is hard coded as 0. See */proc/vmallocinfo*.

VmallocChunk %lu
Largest contiguous block of vmalloc area which is free. Since Linux 4.4, this field is no longer calculated and is hard coded as 0. See */proc/vmallocinfo*.

HardwareCorrupted %lu (since Linux 2.6.32)
(**CONFIG_MEMORY_FAILURE** is required.) [To be documented.]

LazyFree %lu (since Linux 4.12)
Shows the amount of memory marked by *madvise*(2) **MADV_FREE**.

AnonHugePages %lu (since Linux 2.6.38)
(**CONFIG_TRANSPARENT_HUGEPAGE** is required.) Non-file backed huge pages mapped into user-space page tables.

ShmemHugePages %lu (since Linux 4.8)
(**CONFIG_TRANSPARENT_HUGEPAGE** is required.) Memory used by shared memory (shmem) and *tmpfs*(5) allocated with huge pages.

ShmemPmdMapped %lu (since Linux 4.8)
(**CONFIG_TRANSPARENT_HUGEPAGE** is required.) Shared memory mapped into user space with huge pages.

CmaTotal %lu (since Linux 3.1)
Total CMA (Contiguous Memory Allocator) pages. (**CONFIG_CMA** is required.)

CmaFree %lu (since Linux 3.1)
Free CMA (Contiguous Memory Allocator) pages. (**CONFIG_CMA** is required.)

HugePages_Total %lu
(**CONFIG_HUGETLB_PAGE** is required.) The size of the pool of huge pages.

HugePages_Free %lu
(**CONFIG_HUGETLB_PAGE** is required.) The number of huge pages in the pool that are not yet allocated.

HugePages_Rsvd %lu (since Linux 2.6.17)
(**CONFIG_HUGETLB_PAGE** is required.) This is the number of huge pages for which a commitment to allocate from the pool has been made, but no allocation has yet been made. These reserved huge pages guarantee that an application will be able to allocate a huge page from the pool of huge pages at fault time.

HugePages_Surp %lu (since Linux 2.6.24)
(**CONFIG_HUGETLB_PAGE** is required.) This is the number of huge pages in the pool above the value in */proc/sys/vm/nr_hugepages*. The maximum number of surplus huge pages is controlled by */proc/sys/vm/nr_overcommit_hugepages*.

Hugepagesize %lu
(**CONFIG_HUGETLB_PAGE** is required.) The size of huge pages.

DirectMap4k %lu (since Linux 2.6.27)
Number of bytes of RAM linearly mapped by kernel in 4 kB pages. (x86.)

DirectMap4M %lu (since Linux 2.6.27)
Number of bytes of RAM linearly mapped by kernel in 4 MB pages. (x86 with **CONFIG_X86_64** or **CONFIG_X86_PAE** enabled.)

DirectMap2M %lu (since Linux 2.6.27)
Number of bytes of RAM linearly mapped by kernel in 2 MB pages. (x86 with neither **CONFIG_X86_64** nor **CONFIG_X86_PAE** enabled.)

DirectMap1G %lu (since Linux 2.6.27)
(x86 with **CONFIG_X86_64** and **CONFIG_X86_DIRECT_GBPAGES** enabled.)

DESCRIPTION

/proc/partitions

Contains the major and minor numbers of each partition as well as the number of 1024-byte blocks and the partition name.

SEE ALSO

proc(5)

NAME

/proc/pci − PCI devices

DESCRIPTION

/proc/pci

This is a listing of all PCI devices found during kernel initialization and their configuration.

This file has been deprecated in favor of a new */proc* interface for PCI (*/proc/bus/pci*). It became optional in Linux 2.2 (available with **CONFIG_PCI_OLD_PROC** set at kernel compilation). It became once more nonoptionally enabled in Linux 2.4. Next, it was deprecated in Linux 2.6 (still available with **CONFIG_PCI_LEGACY_PROC** set), and finally removed altogether since Linux 2.6.17.

SEE ALSO

proc(5)

NAME

/proc/pid/, /proc/self/ − process information

DESCRIPTION

*/proc/*pid/

There is a numerical subdirectory for each running process; the subdirectory is named by the process ID. Each */proc/*pid subdirectory contains the pseudo-files and directories described below.

The files inside each */proc/*pid directory are normally owned by the effective user and effective group ID of the process. However, as a security measure, the ownership is made *root:root* if the process's "dumpable" attribute is set to a value other than 1.

Before Linux 4.11, *root:root* meant the "global" root user ID and group ID (i.e., UID 0 and GID 0 in the initial user namespace). Since Linux 4.11, if the process is in a noninitial user namespace that has a valid mapping for user (group) ID 0 inside the namespace, then the user (group) ownership of the files under */proc/*pid is instead made the same as the root user (group) ID of the namespace. This means that inside a container, things work as expected for the container "root" user.

The process's "dumpable" attribute may change for the following reasons:

- The attribute was explicitly set via the *prctl*(2) **PR_SET_DUMPABLE** operation.
- The attribute was reset to the value in the file */proc/sys/fs/suid_dumpable* (described below), for the reasons described in *prctl*(2).

Resetting the "dumpable" attribute to 1 reverts the ownership of the */proc/*pid/* files to the process's effective UID and GID. Note, however, that if the effective UID or GID is subsequently modified, then the "dumpable" attribute may be reset, as described in *prctl*(2). Therefore, it may be desirable to reset the "dumpable" attribute *after* making any desired changes to the process's effective UID or GID.

/proc/self/

This directory refers to the process accessing the */proc* filesystem, and is identical to the */proc* directory named by the process ID of the same process.

SEE ALSO

proc(5)

NAME

/proc/pid/attr/ − security-related attributes

DESCRIPTION

*/proc/*pid*/attr/*

The files in this directory provide an API for security modules. The contents of this directory are files that can be read and written in order to set security-related attributes. This directory was added to support SELinux, but the intention was that the API be general enough to support other security modules. For the purpose of explanation, examples of how SELinux uses these files are provided below.

This directory is present only if the kernel was configured with **CONFIG_SECURITY**.

*/proc/*pid*/attr/current* (since Linux 2.6.0)

The contents of this file represent the current security attributes of the process.

In SELinux, this file is used to get the security context of a process. Prior to Linux 2.6.11, this file could not be used to set the security context (a write was always denied), since SELinux limited process security transitions to *execve*(2) (see the description of */proc/*pid*/attr/exec*, below). Since Linux 2.6.11, SELinux lifted this restriction and began supporting "set" operations via writes to this node if authorized by policy, although use of this operation is only suitable for applications that are trusted to maintain any desired separation between the old and new security contexts.

Prior to Linux 2.6.28, SELinux did not allow threads within a multithreaded process to set their security context via this node as it would yield an inconsistency among the security contexts of the threads sharing the same memory space. Since Linux 2.6.28, SELinux lifted this restriction and began supporting "set" operations for threads within a multithreaded process if the new security context is bounded by the old security context, where the bounded relation is defined in policy and guarantees that the new security context has a subset of the permissions of the old security context.

Other security modules may choose to support "set" operations via writes to this node.

*/proc/*pid*/attr/exec* (since Linux 2.6.0)

This file represents the attributes to assign to the process upon a subsequent *execve*(2).

In SELinux, this is needed to support role/domain transitions, and *execve*(2) is the preferred point to make such transitions because it offers better control over the initialization of the process in the new security label and the inheritance of state. In SELinux, this attribute is reset on *execve*(2) so that the new program reverts to the default behavior for any *execve*(2) calls that it may make. In SELinux, a process can set only its own */proc/*pid*/attr/exec* attribute.

*/proc/*pid*/attr/fscreate* (since Linux 2.6.0)

This file represents the attributes to assign to files created by subsequent calls to *open*(2), *mkdir*(2), *symlink*(2), and *mknod*(2)

SELinux employs this file to support creation of a file (using the aforementioned system calls) in a secure state, so that there is no risk of inappropriate access being obtained between the time of creation and the time that attributes are set. In SELinux, this attribute is reset on *execve*(2), so that the new program reverts to the default behavior for any file creation calls it may make, but the attribute will persist across multiple file creation calls within a program unless it is explicitly reset. In SELinux, a process can set only its own */proc/*pid*/attr/fscreate* attribute.

*/proc/*pid*/attr/keycreate* (since Linux 2.6.18)

If a process writes a security context into this file, all subsequently created keys (**add_key**(2)) will be labeled with this context. For further information, see the kernel source file *Documentation/security/keys/core.rst* (or file *Documentation/security/keys.txt* between Linux 3.0 and Linux 4.13, or *Documentation/keys.txt* before Linux 3.0).

*/proc/*pid*/attr/prev* (since Linux 2.6.0)

This file contains the security context of the process before the last *execve*(2); that is, the previous value of */proc/*pid*/attr/current*.

*/proc/*pid*/attr/socketcreate* (since Linux 2.6.18)
If a process writes a security context into this file, all subsequently created sockets will be labeled with this context.

SEE ALSO

proc(5)

NAME

/proc/pid/clear_refs − reset the PG_Referenced and ACCESSED/YOUNG bits

DESCRIPTION

*/proc/*pid*/clear_refs* (since Linux 2.6.22)

This is a write-only file, writable only by owner of the process.

The following values may be written to the file:

1 (since Linux 2.6.22)
: Reset the PG_Referenced and ACCESSED/YOUNG bits for all the pages associated with the process. (Before Linux 2.6.32, writing any nonzero value to this file had this effect.)

2 (since Linux 2.6.32)
: Reset the PG_Referenced and ACCESSED/YOUNG bits for all anonymous pages associated with the process.

3 (since Linux 2.6.32)
: Reset the PG_Referenced and ACCESSED/YOUNG bits for all file-mapped pages associated with the process.

Clearing the PG_Referenced and ACCESSED/YOUNG bits provides a method to measure approximately how much memory a process is using. One first inspects the values in the "Referenced" fields for the VMAs shown in */proc/*pid*/smaps* to get an idea of the memory footprint of the process. One then clears the PG_Referenced and ACCESSED/YOUNG bits and, after some measured time interval, once again inspects the values in the "Referenced" fields to get an idea of the change in memory footprint of the process during the measured interval. If one is interested only in inspecting the selected mapping types, then the value 2 or 3 can be used instead of 1.

Further values can be written to affect different properties:

4 (since Linux 3.11)
: Clear the soft-dirty bit for all the pages associated with the process. This is used (in conjunction with */proc/*pid*/pagemap*) by the check-point restore system to discover which pages of a process have been dirtied since the file */proc/*pid*/clear_refs* was written to.

5 (since Linux 4.0)
: Reset the peak resident set size ("high water mark") to the process's current resident set size value.

Writing any value to */proc/*pid*/clear_refs* other than those listed above has no effect.

The */proc/*pid*/clear_refs* file is present only if the **CONFIG_PROC_PAGE_MONITOR** kernel configuration option is enabled.

SEE ALSO

proc(5)

NAME

/proc/pid/cmdline − command line

DESCRIPTION

*/proc/*pid*/cmdline*

This read-only file holds the complete command line for the process, unless the process is a zombie. In the latter case, there is nothing in this file: that is, a read on this file will return 0 characters.

For processes which are still running, the command-line arguments appear in this file in the same layout as they do in process memory: If the process is well-behaved, it is a set of strings separated by null bytes ('\0'), with a further null byte after the last string.

This is the common case, but processes have the freedom to override the memory region and break assumptions about the contents or format of the */proc/*pid*/cmdline* file.

If, after an *execve*(2), the process modifies its *argv* strings, those changes will show up here. This is not the same thing as modifying the *argv* array.

Furthermore, a process may change the memory location that this file refers via *prctl*(2) operations such as **PR_SET_MM_ARG_START**.

Think of this file as the command line that the process wants you to see.

SEE ALSO

proc(5)

NAME

/proc/pid/comm − command name

DESCRIPTION

*/proc/*pid*/comm* (since Linux 2.6.33)

This file exposes the process's *comm* value—that is, the command name associated with the process. Different threads in the same process may have different *comm* values, accessible via */proc/*pid*/task/*tid*/comm*. A thread may modify its *comm* value, or that of any of other thread in the same thread group (see the discussion of **CLONE_THREAD** in *clone*(2)), by writing to the file */proc/self/task/*tid*/comm*. Strings longer than **TASK_COMM_LEN** (16) characters (including the terminating null byte) are silently truncated.

This file provides a superset of the *prctl*(2) **PR_SET_NAME** and **PR_GET_NAME** operations, and is employed by *pthread_setname_np*(3) when used to rename threads other than the caller. The value in this file is used for the *%e* specifier in */proc/sys/kernel/core_pattern*; see *core*(5).

DESCRIPTION

*/proc/*pid*/cpuset* (since Linux 2.6.12)

See *cpuset*(7).

SEE ALSO

proc(5)

NAME

/proc/pid/cwd − symbolic link to current working directory

DESCRIPTION

*/proc/*pid*/cwd*

This is a symbolic link to the current working directory of the process. To find out the current working directory of process 20, for instance, you can do this:

```
$ cd /proc/20/cwd; pwd -P
```

In a multithreaded process, the contents of this symbolic link are not available if the main thread has already terminated (typically by calling *pthread_exit*(3)).

Permission to dereference or read (**readlink**(2)) this symbolic link is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

SEE ALSO

proc(5)

NAME

/proc/pid/environ − initial environment

DESCRIPTION

*/proc/*pid*/environ*

This file contains the initial environment that was set when the currently executing program was started via *execve*(2). The entries are separated by null bytes ('\0'), and there may be a null byte at the end. Thus, to print out the environment of process 1, you would do:

```
$ cat /proc/1/environ | tr '\000' '\n'
```

If, after an *execve*(2), the process modifies its environment (e.g., by calling functions such as *putenv*(3) or modifying the *environ*(7) variable directly), this file will *not* reflect those changes.

Furthermore, a process may change the memory location that this file refers via *prctl*(2) operations such as **PR_SET_MM_ENV_START**.

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

SEE ALSO

proc(5)

NAME

/proc/pid/exe − symbolic link to program pathname

DESCRIPTION

*/proc/*pid*/exe*

Under Linux 2.2 and later, this file is a symbolic link containing the actual pathname of the executed command. This symbolic link can be dereferenced normally; attempting to open it will open the executable. You can even type */proc/*pid*/exe* to run another copy of the same executable that is being run by process *pid*. If the pathname has been unlinked, the symbolic link will contain the string ' (deleted)' appended to the original pathname. In a multithreaded process, the contents of this symbolic link are not available if the main thread has already terminated (typically by calling *pthread_exit*(3)).

Permission to dereference or read (**readlink**(2)) this symbolic link is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

Under Linux 2.0 and earlier, */proc/*pid*/exe* is a pointer to the binary which was executed, and appears as a symbolic link. A *readlink*(2) call on this file under Linux 2.0 returns a string in the format:

```
[device]:inode
```

For example, [0301]:1502 would be inode 1502 on device major 03 (IDE, MFM, etc. drives) minor 01 (first partition on the first drive).

find(1) with the *−inum* option can be used to locate the file.

SEE ALSO

proc(5)

NAME

/proc/pid/fd/ − file descriptors

DESCRIPTION

*/proc/*pid*/fd/*

This is a subdirectory containing one entry for each file which the process has open, named by its file descriptor, and which is a symbolic link to the actual file. Thus, 0 is standard input, 1 standard output, 2 standard error, and so on.

For file descriptors for pipes and sockets, the entries will be symbolic links whose content is the file type with the inode. A *readlink*(2) call on this file returns a string in the format:

```
type:[inode]
```

For example, *socket:[2248868]* will be a socket and its inode is 2248868. For sockets, that inode can be used to find more information in one of the files under */proc/net/*.

For file descriptors that have no corresponding inode (e.g., file descriptors produced by *bpf*(2), *epoll_create*(2), *eventfd*(2), *inotify_init*(2), *perf_event_open*(2), *signalfd*(2), *timerfd_create*(2), and *userfaultfd*(2)), the entry will be a symbolic link with contents of the form

```
anon_inode:file-type
```

In many cases (but not all), the *file-type* is surrounded by square brackets.

For example, an epoll file descriptor will have a symbolic link whose content is the string *anon_inode:[eventpoll]*.

In a multithreaded process, the contents of this directory are not available if the main thread has already terminated (typically by calling *pthread_exit*(3)).

Programs that take a filename as a command-line argument, but don't take input from standard input if no argument is supplied, and programs that write to a file named as a command-line argument, but don't send their output to standard output if no argument is supplied, can nevertheless be made to use standard input or standard output by using */proc/*pid*/fd* files as command-line arguments. For example, assuming that *−i* is the flag designating an input file and *−o* is the flag designating an output file:

```
$ foobar −i /proc/self/fd/0 −o /proc/self/fd/1 ...
```

and you have a working filter.

/proc/self/fd/N is approximately the same as */dev/fd/N* in some UNIX and UNIX-like systems. Most Linux MAKEDEV scripts symbolically link */dev/fd* to */proc/self/fd*, in fact.

Most systems provide symbolic links */dev/stdin*, */dev/stdout*, and */dev/stderr*, which respectively link to the files *0*, *1*, and *2* in */proc/self/fd*. Thus the example command above could be written as:

```
$ foobar −i /dev/stdin −o /dev/stdout ...
```

Permission to dereference or read (**readlink**(2)) the symbolic links in this directory is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

Note that for file descriptors referring to inodes (pipes and sockets, see above), those inodes still have permission bits and ownership information distinct from those of the */proc/*pid*/fd* entry, and that the owner may differ from the user and group IDs of the process. An unprivileged process may lack permissions to open them, as in this example:

```
$ echo test | sudo −u nobody cat
test
$ echo test | sudo −u nobody cat /proc/self/fd/0
cat: /proc/self/fd/0: Permission denied
```

File descriptor 0 refers to the pipe created by the shell and owned by that shell's user, which is not *nobody*, so **cat** does not have permission to create a new file descriptor to read from that inode, even though it can still read from its existing file descriptor 0.

SEE ALSO

proc(5)

NAME

/proc/pid/fdinfo/ − information about file descriptors

DESCRIPTION

*/proc/*pid*/fdinfo/* (since Linux 2.6.22)

This is a subdirectory containing one entry for each file which the process has open, named by its file descriptor. The files in this directory are readable only by the owner of the process. The contents of each file can be read to obtain information about the corresponding file descriptor. The content depends on the type of file referred to by the corresponding file descriptor.

For regular files and directories, we see something like:

```
$ cat /proc/12015/fdinfo/4
pos:    1000
flags:  01002002
mnt_id: 21
```

The fields are as follows:

pos This is a decimal number showing the file offset.

flags This is an octal number that displays the file access mode and file status flags (see *open*(2)). If the close-on-exec file descriptor flag is set, then *flags* will also include the value **O_CLOEXEC**.

Before Linux 3.1, this field incorrectly displayed the setting of **O_CLOEXEC** at the time the file was opened, rather than the current setting of the close-on-exec flag.

mnt_id This field, present since Linux 3.15, is the ID of the mount containing this file. See the description of */proc/*pid*/mountinfo*.

For eventfd file descriptors (see *eventfd*(2)), we see (since Linux 3.8) the following fields:

```
pos:  0
flags:      02
mnt_id:     10
eventfd-count:               40
```

eventfd-count is the current value of the eventfd counter, in hexadecimal.

For epoll file descriptors (see *epoll*(7)), we see (since Linux 3.8) the following fields:

```
pos:  0
flags:      02
mnt_id:     10
tfd:        9 events:       19 data: 74253d2500000009
tfd:        7 events:       19 data: 74253d2500000007
```

Each of the lines beginning *tfd* describes one of the file descriptors being monitored via the epoll file descriptor (see *epoll_ctl*(2) for some details). The *tfd* field is the number of the file descriptor. The *events* field is a hexadecimal mask of the events being monitored for this file descriptor. The *data* field is the data value associated with this file descriptor.

For signalfd file descriptors (see *signalfd*(2)), we see (since Linux 3.8) the following fields:

```
pos:  0
flags:      02
mnt_id:     10
sigmask:    0000000000000006
```

sigmask is the hexadecimal mask of signals that are accepted via this signalfd file descriptor. (In this example, bits 2 and 3 are set, corresponding to the signals **SIGINT** and **SIGQUIT**; see *signal*(7).)

For inotify file descriptors (see *inotify*(7)), we see (since Linux 3.8) the following fields:

```
pos:  0
flags:      00
mnt_id:     11
```

```
inotify wd:2 ino:7ef82a sdev:800001 mask:800afff ignored_mask:0 fhandle-byt
inotify wd:1 ino:192627 sdev:800001 mask:800afff ignored_mask:0 fhandle-byt
```

Each of the lines beginning with "inotify" displays information about one file or directory that is being monitored. The fields in this line are as follows:

wd A watch descriptor number (in decimal).

ino The inode number of the target file (in hexadecimal).

sdev The ID of the device where the target file resides (in hexadecimal).

mask The mask of events being monitored for the target file (in hexadecimal).

If the kernel was built with exportfs support, the path to the target file is exposed as a file handle, via three hexadecimal fields: *fhandle-bytes*, *fhandle-type*, and *f_handle*.

For fanotify file descriptors (see *fanotify*(7)), we see (since Linux 3.8) the following fields:

```
pos:  0
flags:      02
mnt_id:     11
fanotify flags:0 event-flags:88002
fanotify ino:19264f sdev:800001 mflags:0 mask:1 ignored_mask:0 fhandle-byte
```

The fourth line displays information defined when the fanotify group was created via *fanotify_init*(2):

flags The *flags* argument given to *fanotify_init*(2) (expressed in hexadecimal).

event-flags
The *event_f_flags* argument given to *fanotify_init*(2) (expressed in hexadecimal).

Each additional line shown in the file contains information about one of the marks in the fanotify group. Most of these fields are as for inotify, except:

mflags The flags associated with the mark (expressed in hexadecimal).

mask The events mask for this mark (expressed in hexadecimal).

ignored_mask
The mask of events that are ignored for this mark (expressed in hexadecimal).

For details on these fields, see *fanotify_mark*(2).

For timerfd file descriptors (see *timerfd*(2)), we see (since Linux 3.17) the following fields:

```
pos:    0
flags:  02004002
mnt_id: 13
clockid: 0
ticks: 0
settime flags: 03
it_value: (7695568592, 640020877)
it_interval: (0, 0)
```

clockid This is the numeric value of the clock ID (corresponding to one of the **CLOCK_*** constants defined via <*time.h*>) that is used to mark the progress of the timer (in this example, 0 is **CLOCK_REALTIME**).

ticks This is the number of timer expirations that have occurred, (i.e., the value that *read*(2) on it would return).

settime flags
This field lists the flags with which the timerfd was last armed (see *timerfd_settime*(2)), in octal (in this example, both **TFD_TIMER_ABSTIME** and **TFD_TIMER_CANCEL_ON_SET** are set).

it_value
This field contains the amount of time until the timer will next expire, expressed in seconds and nanoseconds. This is always expressed as a relative value, regardless of whether the timer was created using the **TFD_TIMER_ABSTIME** flag.

it_interval
This field contains the interval of the timer, in seconds and nanoseconds. (The *it_value* and *it_interval* fields contain the values that *timerfd_gettime*(2) on this file descriptor would return.)

SEE ALSO

proc(5)

NAME

/proc/pid/io − I/O statistics

DESCRIPTION

*/proc/*pid*/io* (since Linux 2.6.20)

This file contains I/O statistics for the process and its waited-for children, for example:

```
# cat /proc/3828/io
rchar: 323934931
wchar: 323929600
syscr: 632687
syscw: 632675
read_bytes: 0
write_bytes: 323932160
cancelled_write_bytes: 0
```

The fields are as follows:

rchar: characters read

The number of bytes returned by successful *read*(2) and similar system calls.

wchar: characters written

The number of bytes returned by successful *write*(2) and similar system calls.

syscr: read syscalls

The number of "file read" system calls—those from the *read*(2) family, *sendfile*(2), *copy_file_range*(2), and *ioctl*(2) **BTRFS_IOC_ENCODED_READ**[**_32**] (including when invoked by the kernel as part of other syscalls).

syscw: write syscalls

The number of "file write" system calls—those from the *write*(2) family, *sendfile*(2), *copy_file_range*(2), and *ioctl*(2) **BTRFS_IOC_ENCODED_WRITE**[**_32**] (including when invoked by the kernel as part of other syscalls).

read_bytes: bytes read

The number of bytes really fetched from the storage layer. This is accurate for block-backed filesystems.

write_bytes: bytes written

The number of bytes really sent to the storage layer.

cancelled_write_bytes:

The above statistics fail to account for truncation: if a process writes 1 MB to a regular file and then removes it, said 1 MB will not be written, but *will* have nevertheless been accounted as a 1 MB write. This field represents the number of bytes "saved" from I/O writeback. This can yield to having done negative I/O if caches dirtied by another process are truncated. *cancelled_write_bytes* applies to I/O already accounted-for in *write_bytes*.

Permission to access this file is governed by *ptrace*(2) access mode **PTRACE_MODE_READ_FSCREDS**.

CAVEATS

These counters are not atomic: on systems where 64-bit integer operations may tear, a counter could be updated simultaneously with a read, yielding an incorrect intermediate value.

SEE ALSO

getrusage(2), *proc*(5)

NAME

/proc/pid/limits − resource limits

DESCRIPTION

*/proc/*pid*/limits* (since Linux 2.6.24)

This file displays the soft limit, hard limit, and units of measurement for each of the process's resource limits (see *getrlimit*(2)). Up to and including Linux 2.6.35, this file is protected to allow reading only by the real UID of the process. Since Linux 2.6.36, this file is readable by all users on the system.

SEE ALSO

proc(5)

NAME

/proc/pid/map_files/ − memory-mapped files

DESCRIPTION

*/proc/*pid*/map_files/* (since Linux 3.3)

This subdirectory contains entries corresponding to memory-mapped files (see *mmap*(2)). Entries are named by memory region start and end address pair (expressed as hexadecimal numbers), and are symbolic links to the mapped files themselves. Here is an example, with the output wrapped and reformatted to fit on an 80-column display:

```
# ls -l /proc/self/map_files/
lr--------. 1 root root 64 Apr 16 21:31
            3252e00000-3252e20000 -> /usr/lib64/ld-2.15.so
...
```

Although these entries are present for memory regions that were mapped with the **MAP_FILE** flag, the way anonymous shared memory (regions created with the **MAP_ANON | MAP_SHARED** flags) is implemented in Linux means that such regions also appear on this directory. Here is an example where the target file is the deleted */dev/zero* one:

```
lrw-------. 1 root root 64 Apr 16 21:33
            7fc075d2f000-7fc075e6f000 -> /dev/zero (deleted)
```

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

Until Linux 4.3, this directory appeared only if the **CONFIG_CHECKPOINT_RESTORE** kernel configuration option was enabled.

Capabilities are required to read the contents of the symbolic links in this directory: before Linux 5.9, the reading process requires **CAP_SYS_ADMIN** in the initial user namespace; since Linux 5.9, the reading process must have either **CAP_SYS_ADMIN** or **CAP_CHECKPOINT_RESTORE** in the initial (i.e. root) user namespace.

SEE ALSO

proc(5)

NAME

/proc/pid/maps − mapped memory regions

DESCRIPTION

*/proc/*pid*/maps*

A file containing the currently mapped memory regions and their access permissions. See *mmap*(2) for some further information about memory mappings.

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

The format of the file is:

```
address           perms offset  dev   inode       pathname
00400000-00452000 r-xp 00000000 08:02 173521      /usr/bin/dbus-daemon
00651000-00652000 r--p 00051000 08:02 173521      /usr/bin/dbus-daemon
00652000-00655000 rw-p 00052000 08:02 173521      /usr/bin/dbus-daemon
00e03000-00e24000 rw-p 00000000 00:00 0           [heap]
00e24000-011f7000 rw-p 00000000 00:00 0           [heap]
...
35b1800000-35b1820000 r-xp 00000000 08:02 135522  /usr/lib64/ld-2.15.so
35b1a1f000-35b1a20000 r--p 0001f000 08:02 135522  /usr/lib64/ld-2.15.so
35b1a20000-35b1a21000 rw-p 00020000 08:02 135522  /usr/lib64/ld-2.15.so
35b1a21000-35b1a22000 rw-p 00000000 00:00 0
35b1c00000-35b1dac000 r-xp 00000000 08:02 135870  /usr/lib64/libc-2.15.so
35b1dac000-35b1fac000 ---p 001ac000 08:02 135870  /usr/lib64/libc-2.15.so
35b1fac000-35b1fb0000 r--p 001ac000 08:02 135870  /usr/lib64/libc-2.15.so
35b1fb0000-35b1fb2000 rw-p 001b0000 08:02 135870  /usr/lib64/libc-2.15.so
...
f2c6ff8c000-7f2c7078c000 rw-p 00000000 00:00 0    [stack:986]
...
7fffb2c0d000-7fffb2c2e000 rw-p 00000000 00:00 0   [stack]
7fffb2d48000-7fffb2d49000 r-xp 00000000 00:00 0   [vdso]
```

The *address* field is the address space in the process that the mapping occupies. The *perms* field is a set of permissions:

```
r = read
w = write
x = execute
s = shared
p = private (copy on write)
```

The *offset* field is the offset into the file/whatever; *dev* is the device (major:minor); *inode* is the inode on that device. 0 indicates that no inode is associated with the memory region, as would be the case with BSS (uninitialized data).

The *pathname* field will usually be the file that is backing the mapping. For ELF files, you can easily coordinate with the *offset* field by looking at the Offset field in the ELF program headers (*readelf −l*).

There are additional helpful pseudo-paths:

[stack] The initial process's (also known as the main thread's) stack.

*[stack:*tid*]* (from Linux 3.4 to Linux 4.4)
A thread's stack (where the *tid* is a thread ID). It corresponds to the */proc/*pid*/task/*tid*/* path. This field was removed in Linux 4.5, since providing this information for a process with large numbers of threads is expensive.

[vdso] The virtual dynamically linked shared object. See *vdso*(7).

[heap] The process's heap.

*[anon:*name*]* (since Linux 5.17)
A named private anonymous mapping. Set with *prctl*(2) **PR_SET_VMA_ANON_NAME**.

*[anon_shmem:*name*]* (since Linux 6.2)
A named shared anonymous mapping. Set with *prctl*(2) **PR_SET_VMA_ANON_NAME**.

If the *pathname* field is blank, this is an anonymous mapping as obtained via *mmap*(2). There is no easy way to coordinate this back to a process's source, short of running it through *gdb*(1), *strace*(1), or similar.

pathname is shown unescaped except for newline characters, which are replaced with an octal escape sequence. As a result, it is not possible to determine whether the original pathname contained a newline character or the literal *\012* character sequence.

If the mapping is file-backed and the file has been deleted, the string " (deleted)" is appended to the pathname. Note that this is ambiguous too.

Under Linux 2.0, there is no field giving pathname.

proc(5)

NAME

/proc/pid/mem − memory

DESCRIPTION

*/proc/*pid*/mem*

This file can be used to access the pages of a process's memory through *open*(2), *read*(2), and *lseek*(2).

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_ATTACH_FSCREDS** check; see *ptrace*(2).

SEE ALSO

proc(5)

NAME

/proc/pid/mountinfo − mount information

DESCRIPTION

*/proc/*pid*/mountinfo* (since Linux 2.6.26)

This file contains information about mounts in the process's mount namespace (see *mount_namespaces*(7)). It supplies various information (e.g., propagation state, root of mount for bind mounts, identifier for each mount and its parent) that is missing from the (older) */proc/*pid*/mounts* file, and fixes various other problems with that file (e.g., nonextensibility, failure to distinguish per-mount versus per-superblock options).

The file contains lines of the form:

```
36 35 98:0 /mnt1 /mnt2 rw,noatime master:1 - ext3 /dev/root rw,errors=continue
(1)(2)(3)   (4)   (5)      (6)      (7)   (8) (9)   (10)         (11)
```

The numbers in parentheses are labels for the descriptions below:

(1) mount ID: a unique ID for the mount (may be reused after *umount*(2)).

(2) parent ID: the ID of the parent mount (or of self for the root of this mount namespace's mount tree).

If a new mount is stacked on top of a previous existing mount (so that it hides the existing mount) at pathname P, then the parent of the new mount is the previous mount at that location. Thus, when looking at all the mounts stacked at a particular location, the top-most mount is the one that is not the parent of any other mount at the same location. (Note, however, that this top-most mount will be accessible only if the longest path subprefix of P that is a mount point is not itself hidden by a stacked mount.)

If the parent mount lies outside the process's root directory (see *chroot*(2)), the ID shown here won't have a corresponding record in *mountinfo* whose mount ID (field 1) matches this parent mount ID (because mounts that lie outside the process's root directory are not shown in *mountinfo*). As a special case of this point, the process's root mount may have a parent mount (for the initramfs filesystem) that lies outside the process's root directory, and an entry for that mount will not appear in *mountinfo*.

(3) major:minor: the value of *st_dev* for files on this filesystem (see *stat*(2)).

(4) root: the pathname of the directory in the filesystem which forms the root of this mount.

(5) mount point: the pathname of the mount point relative to the process's root directory.

(6) mount options: per-mount options (see *mount*(2)).

(7) optional fields: zero or more fields of the form "tag[:value]"; see below.

(8) separator: the end of the optional fields is marked by a single hyphen.

(9) filesystem type: the filesystem type in the form "type[.subtype]".

(10) mount source: filesystem-specific information or "none".

(11) super options: per-superblock options (see *mount*(2)).

Currently, the possible optional fields are *shared*, *master*, *propagate_from*, and *unbindable*. See *mount_namespaces*(7) for a description of these fields. Parsers should ignore all unrecognized optional fields.

For more information on mount propagation see *Documentation/filesystems/sharedsubtree.rst* (or *Documentation/filesystems/sharedsubtree.txt* before Linux 5.8) in the Linux kernel source tree.

SEE ALSO

proc(5)

NAME

/proc/pid/mounts − mounted filesystems

DESCRIPTION

*/proc/*pid*/mounts* (since Linux 2.4.19)

This file lists all the filesystems currently mounted in the process's mount namespace (see *mount_namespaces*(7)). The format of this file is documented in *fstab*(5)

Since Linux 2.6.15, this file is pollable: after opening the file for reading, a change in this file (i.e., a filesystem mount or unmount) causes *select*(2) to mark the file descriptor as having an exceptional condition, and *poll*(2) and *epoll_wait*(2) mark the file as having a priority event (**POLLPRI**). (Before Linux 2.6.30, a change in this file was indicated by the file descriptor being marked as readable for *select*(2), and being marked as having an error condition for *poll*(2) and *epoll_wait*(2).)

/proc/mounts

Before Linux 2.4.19, this file was a list of all the filesystems currently mounted on the system. With the introduction of per-process mount namespaces in Linux 2.4.19 (see *mount_namespaces*(7)), this file became a link to */proc/self/mounts*, which lists the mounts of the process's own mount namespace. The format of this file is documented in *fstab*(5)

SEE ALSO

proc(5)

NAME

/proc/pid/mountstats − mount statistics

DESCRIPTION

*/proc/*pid*/mountstats* (since Linux 2.6.17)

This file exports information (statistics, configuration information) about the mounts in the process's mount namespace (see *mount_namespaces*(7)). Lines in this file have the form:

```
device /dev/sda7 mounted on /home with fstype ext3 [stats]
(       1      )            ( 2 )             (3 ) (  4  )
```

The fields in each line are:

(1) The name of the mounted device (or "nodevice" if there is no corresponding device).

(2) The mount point within the filesystem tree.

(3) The filesystem type.

(4) Optional statistics and configuration information. Currently (as at Linux 2.6.26), only NFS filesystems export information via this field.

This file is readable only by the owner of the process.

SEE ALSO

proc(5)

NAME

/proc/pid/net/, /proc/net/ − network layer information

DESCRIPTION

*/proc/*pid*/net/* (since Linux 2.6.25)
See the description of */proc/net*.

/proc/net/
This directory contains various files and subdirectories containing information about the networking layer. The files contain ASCII structures and are, therefore, readable with *cat*(1)However, the standard *netstat*(8) suite provides much cleaner access to these files.

With the advent of network namespaces, various information relating to the network stack is virtualized (see *network_namespaces*(7)). Thus, since Linux 2.6.25, */proc/net* is a symbolic link to the directory */proc/self/net*, which contains the same files and directories as listed below. However, these files and directories now expose information for the network namespace of which the process is a member.

/proc/net/arp
This holds an ASCII readable dump of the kernel ARP table used for address resolutions. It will show both dynamically learned and preprogrammed ARP entries. The format is:

```
IP address      HW type   Flags      HW address           Mask   Device
192.168.0.50    0x1       0x2        00:50:BF:25:68:F3    *      eth0
192.168.0.250   0x1       0xc        00:00:00:00:00:00    *      eth0
```

Here "IP address" is the IPv4 address of the machine and the "HW type" is the hardware type of the address from RFC 826. The flags are the internal flags of the ARP structure (as defined in */usr/include/linux/if_arp.h*) and the "HW address" is the data link layer mapping for that IP address if it is known.

/proc/net/dev
The dev pseudo-file contains network device status information. This gives the number of received and sent packets, the number of errors and collisions and other basic statistics. These are used by the *ifconfig*(8) program to report device status. The format is:

```
Inter−|   Receive                                                |  Transmit
 face |bytes    packets errs drop fifo frame compressed multicast|bytes    pac
    lo: 2776770   11307    0    0    0     0          0         0  2776770   1
  eth0: 1215645    2751    0    0    0     0          0         0  1782404
  ppp0: 1622270    5552    1    0    0     0          0         0   354130
  tap0:    7714      81    0    0    0     0          0         0     7714
```

/proc/net/dev_mcast
Defined in */usr/src/linux/net/core/dev_mcast.c*:

```
indx interface_name  dmi_u dmi_g dmi_address
2    eth0            1     0     01005e000001
3    eth1            1     0     01005e000001
4    eth2            1     0     01005e000001
```

/proc/net/igmp
Internet Group Management Protocol. Defined in */usr/src/linux/net/core/igmp.c*.

/proc/net/rarp
This file uses the same format as the *arp* file and contains the current reverse mapping database used to provide *rarp*(8) reverse address lookup services. If RARP is not configured into the kernel, this file will not be present.

/proc/net/raw
Holds a dump of the RAW socket table. Much of the information is not of use apart from debugging. The "sl" value is the kernel hash slot for the socket, the "local_address" is the local address and protocol number pair. "St" is the internal status of the socket. The "tx_queue" and "rx_queue" are the outgoing and incoming data queue in terms of kernel memory usage. The "tr", "tm−>when", and "rexmits" fields are not used by RAW. The "uid" field holds the effective UID of the creator of the socket.

/proc/net/snmp
This file holds the ASCII data needed for the IP, ICMP, TCP, and UDP management information bases for an SNMP agent.

/proc/net/tcp
Holds a dump of the TCP socket table. Much of the information is not of use apart from debugging. The "sl" value is the kernel hash slot for the socket, the "local_address" is the local address and port number pair. The "rem_address" is the remote address and port number pair (if connected). "St" is the internal status of the socket. The "tx_queue" and "rx_queue" are the outgoing and incoming data queue in terms of kernel memory usage. The "tr", "tm−>when", and "rexmits" fields hold internal information of the kernel socket state and are useful only for debugging. The "uid" field holds the effective UID of the creator of the socket.

/proc/net/udp
Holds a dump of the UDP socket table. Much of the information is not of use apart from debugging. The "sl" value is the kernel hash slot for the socket, the "local_address" is the local address and port number pair. The "rem_address" is the remote address and port number pair (if connected). "St" is the internal status of the socket. The "tx_queue" and "rx_queue" are the outgoing and incoming data queue in terms of kernel memory usage. The "tr", "tm−>when", and "rexmits" fields are not used by UDP. The "uid" field holds the effective UID of the creator of the socket. The format is:

```
sl  local_address rem_address   st tx_queue rx_queue tr rexmits  tm->when uid
 1: 01642C89:0201 0C642C89:03FF 01 00000000:00000001 01:000071BA 00000000 0
 1: 00000000:0801 00000000:0000 0A 00000000:00000000 00:00000000 6F000100 0
 1: 00000000:0201 00000000:0000 0A 00000000:00000000 00:00000000 00000000 0
```

/proc/net/unix
Lists the UNIX domain sockets present within the system and their status. The format is:

```
Num RefCount Protocol Flags    Type St Inode Path
 0: 00000002 00000000 00000000 0001 03    42
 1: 00000001 00000000 00010000 0001 01  1948 /dev/printer
```

The fields are as follows:

Num: the kernel table slot number.

RefCount: the number of users of the socket.

Protocol: currently always 0.

Flags: the internal kernel flags holding the status of the socket.

Type: the socket type. For **SOCK_STREAM** sockets, this is 0001; for **SOCK_DGRAM** sockets, it is 0002; and for **SOCK_SEQPACKET** sockets, it is 0005.

St: the internal state of the socket.

Inode: the inode number of the socket.

Path: the bound pathname (if any) of the socket. Sockets in the abstract namespace are included in the list, and are shown with a *Path* that commences with the character '@'.

/proc/net/netfilter/nfnetlink_queue
This file contains information about netfilter user-space queueing, if used. Each line represents a queue. Queues that have not been subscribed to by user space are not shown.

```
  1   4207     0  2 65535     0     0        0  1
(1)   (2)    (3)(4)  (5)    (6)   (7)      (8)
```

The fields in each line are:

(1) The ID of the queue. This matches what is specified in the **−−queue−num** or **−−queue−balance** options to the *iptables*(8) NFQUEUE target. See *iptables-extensions*(8) for more information.

(2) The netlink port ID subscribed to the queue.

(3) The number of packets currently queued and waiting to be processed by the application.

(4) The copy mode of the queue. It is either 1 (metadata only) or 2 (also copy payload data to user space).

(5) Copy range; that is, how many bytes of packet payload should be copied to user space at most.

(6) queue dropped. Number of packets that had to be dropped by the kernel because too many packets are already waiting for user space to send back the mandatory accept/drop verdicts.

(7) queue user dropped. Number of packets that were dropped within the netlink subsystem. Such drops usually happen when the corresponding socket buffer is full; that is, user space is not able to read messages fast enough.

(8) sequence number. Every queued packet is associated with a (32-bit) monotonically increasing sequence number. This shows the ID of the most recent packet queued.

The last number exists only for compatibility reasons and is always 1.

proc(5)

NAME

/proc/pid/oom_score − OOM-killer score

DESCRIPTION

*/proc/*pid*/oom_score* (since Linux 2.6.11)

This file displays the current score that the kernel gives to this process for the purpose of selecting a process for the OOM-killer. A higher score means that the process is more likely to be selected by the OOM-killer. The basis for this score is the amount of memory used by the process, with increases (+) or decreases (−) for factors including:

- whether the process is privileged (−).

Before Linux 2.6.36 the following factors were also used in the calculation of oom_score:

- whether the process creates a lot of children using *fork*(2) (+);
- whether the process has been running a long time, or has used a lot of CPU time (−);
- whether the process has a low nice value (i.e., > 0) (+); and
- whether the process is making direct hardware access (−).

The *oom_score* also reflects the adjustment specified by the *oom_score_adj* or *oom_adj* setting for the process.

SEE ALSO

proc(5), *proc_pid_oom_score_adj*(5)

NAME

/proc/pid/oom_score_adj − OOM-killer score adjustment

DESCRIPTION

*/proc/*pid*/oom_score_adj* (since Linux 2.6.36)

This file can be used to adjust the badness heuristic used to select which process gets killed in out-of-memory conditions.

The badness heuristic assigns a value to each candidate task ranging from 0 (never kill) to 1000 (always kill) to determine which process is targeted. The units are roughly a proportion along that range of allowed memory the process may allocate from, based on an estimation of its current memory and swap use. For example, if a task is using all allowed memory, its badness score will be 1000. If it is using half of its allowed memory, its score will be 500.

There is an additional factor included in the badness score: root processes are given 3% extra memory over other tasks.

The amount of "allowed" memory depends on the context in which the OOM-killer was called. If it is due to the memory assigned to the allocating task's cpuset being exhausted, the allowed memory represents the set of mems assigned to that cpuset (see *cpuset*(7)). If it is due to a mempolicy's node(s) being exhausted, the allowed memory represents the set of mempolicy nodes. If it is due to a memory limit (or swap limit) being reached, the allowed memory is that configured limit. Finally, if it is due to the entire system being out of memory, the allowed memory represents all allocatable resources.

The value of *oom_score_adj* is added to the badness score before it is used to determine which task to kill. Acceptable values range from −1000 (OOM_SCORE_ADJ_MIN) to +1000 (OOM_SCORE_ADJ_MAX). This allows user space to control the preference for OOM-killing, ranging from always preferring a certain task or completely disabling it from OOM-killing. The lowest possible value, −1000, is equivalent to disabling OOM-killing entirely for that task, since it will always report a badness score of 0.

Consequently, it is very simple for user space to define the amount of memory to consider for each task. Setting an *oom_score_adj* value of +500, for example, is roughly equivalent to allowing the remainder of tasks sharing the same system, cpuset, mempolicy, or memory controller resources to use at least 50% more memory. A value of −500, on the other hand, would be roughly equivalent to discounting 50% of the task's allowed memory from being considered as scoring against the task.

For backward compatibility with previous kernels, */proc/*pid*/oom_adj* can still be used to tune the badness score. Its value is scaled linearly with *oom_score_adj*.

Writing to */proc/*pid*/oom_score_adj* or */proc/*pid*/oom_adj* will change the other with its scaled value.

The *choom*(1) program provides a command-line interface for adjusting the *oom_score_adj* value of a running process or a newly executed command.

HISTORY

*/proc/*pid*/oom_adj* (since Linux 2.6.11)

This file can be used to adjust the score used to select which process should be killed in an out-of-memory (OOM) situation. The kernel uses this value for a bit-shift operation of the process's *oom_score* value: valid values are in the range −16 to +15, plus the special value −17, which disables OOM-killing altogether for this process. A positive score increases the likelihood of this process being killed by the OOM-killer; a negative score decreases the likelihood.

The default value for this file is 0; a new process inherits its parent's *oom_adj* setting. A process must be privileged (**CAP_SYS_RESOURCE**) to update this file, although a process can always increase its own *oom_adj* setting (since Linux 2.6.20).

Since Linux 2.6.36, use of this file is deprecated in favor of */proc/*pid*/oom_score_adj*, and finally removed in Linux 3.7.

NAME

/proc/pid/pagemap − mapping of virtual pages

DESCRIPTION

*/proc/*pid*/pagemap* (since Linux 2.6.25)

This file shows the mapping of each of the process's virtual pages into physical page frames or swap area. It contains one 64-bit value for each virtual page, with the bits set as follows:

63 If set, the page is present in RAM.

62 If set, the page is in swap space

61 (since Linux 3.5)
The page is a file-mapped page or a shared anonymous page.

60–58 (since Linux 3.11)
Zero

57 (since Linux 5.14)
If set, the page is write-protected through *userfaultfd*(2).

56 (since Linux 4.2)
The page is exclusively mapped.

55 (since Linux 3.11)
PTE is soft-dirty (see the kernel source file *Documentation/admin−guide/mm/soft−dirty.rst*).

54–0 If the page is present in RAM (bit 63), then these bits provide the page frame number, which can be used to index */proc/kpageflags* and */proc/kpagecount*. If the page is present in swap (bit 62), then bits 4–0 give the swap type, and bits 54–5 encode the swap offset.

Before Linux 3.11, bits 60–55 were used to encode the base-2 log of the page size.

To employ */proc/*pid*/pagemap* efficiently, use */proc/*pid*/maps* to determine which areas of memory are actually mapped and seek to skip over unmapped regions.

The */proc/*pid*/pagemap* file is present only if the **CONFIG_PROC_PAGE_MONITOR** kernel configuration option is enabled.

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

NAME

/proc/pid/projid_map − project ID mappings

DESCRIPTION

*/proc/*pid*/projid_map* (since Linux 3.7)

See *user_namespaces*(7).

SEE ALSO

proc(5)

NAME

/proc/pid/root/ − symbolic link to root directory

DESCRIPTION

*/proc/*pid*/root/*

UNIX and Linux support the idea of a per-process root of the filesystem, set by the *chroot*(2) system call. This file is a symbolic link that points to the process's root directory, and behaves in the same way as *exe*, and *fd/**.

Note however that this file is not merely a symbolic link. It provides the same view of the filesystem (including namespaces and the set of per-process mounts) as the process itself. An example illustrates this point. In one terminal, we start a shell in new user and mount namespaces, and in that shell we create some new mounts:

```
$ PS1='sh1# ' unshare -Urnm
sh1# mount -t tmpfs tmpfs /etc  # Mount empty tmpfs at /etc
sh1# mount --bind /usr /dev     # Mount /usr at /dev
sh1# echo $$
27123
```

In a second terminal window, in the initial mount namespace, we look at the contents of the corresponding mounts in the initial and new namespaces:

```
$ PS1='sh2# ' sudo sh
sh2# ls /etc | wc -l                  # In initial NS
309
sh2# ls /proc/27123/root/etc | wc -l  # /etc in other NS
0                                     # The empty tmpfs dir
sh2# ls /dev | wc -l                  # In initial NS
205
sh2# ls /proc/27123/root/dev | wc -l  # /dev in other NS
11                                    # Actually bind
                                      # mounted to /usr
sh2# ls /usr | wc -l                  # /usr in initial NS
11
```

In a multithreaded process, the contents of the */proc/*pid*/root* symbolic link are not available if the main thread has already terminated (typically by calling *pthread_exit*(3)).

Permission to dereference or read (**readlink**(2)) this symbolic link is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

SEE ALSO

proc(5)

NAME

/proc/pid/seccomp − secure computing mode

DESCRIPTION

*/proc/*pid*/seccomp* (Linux 2.6.12 to Linux 2.6.22)

This file can be used to read and change the process's secure computing (seccomp) mode setting. It contains the value 0 if the process is not in seccomp mode, and 1 if the process is in strict seccomp mode (see *seccomp*(2)). Writing 1 to this file places the process irreversibly in strict seccomp mode. (Further attempts to write to the file fail with the **EPERM** error.)

In Linux 2.6.23, this file went away, to be replaced by the *prctl*(2) **PR_GET_SECCOMP** and **PR_SET_SECCOMP** operations (and later by *seccomp*(2) and the *Seccomp* field in */proc/*pid*/status*).

SEE ALSO

proc(5)

SEE ALSO

proc(5)

NAME

/proc/pid/smaps − XXX: What does ’s’ in "smaps" stand for?

DESCRIPTION

*/proc/*pid*/smaps* (since Linux 2.6.14)

This file shows memory consumption for each of the process’s mappings. (The *pmap*(1) command displays similar information, in a form that may be easier for parsing.) For each mapping there is a series of lines such as the following:

```
00400000-0048a000 r-xp 00000000 fd:03 960637       /bin/bash
Size:                552 kB
Rss:                 460 kB
Pss:                 100 kB
Shared_Clean:        452 kB
Shared_Dirty:          0 kB
Private_Clean:         8 kB
Private_Dirty:         0 kB
Referenced:          460 kB
Anonymous:             0 kB
AnonHugePages:         0 kB
ShmemHugePages:        0 kB
ShmemPmdMapped:        0 kB
Swap:                  0 kB
KernelPageSize:        4 kB
MMUPageSize:           4 kB
Locked:                0 kB
ProtectionKey:         0
VmFlags: rd ex mr mw me dw
```

The first of these lines shows the same information as is displayed for the mapping in */proc/*pid*/maps*. The following lines show the size of the mapping, the amount of the mapping that is currently resident in RAM ("Rss"), the process’s proportional share of this mapping ("Pss"), the number of clean and dirty shared pages in the mapping, and the number of clean and dirty private pages in the mapping. "Referenced" indicates the amount of memory currently marked as referenced or accessed. "Anonymous" shows the amount of memory that does not belong to any file. "Swap" shows how much would-be-anonymous memory is also used, but out on swap.

The "KernelPageSize" line (available since Linux 2.6.29) is the page size used by the kernel to back the virtual memory area. This matches the size used by the MMU in the majority of cases. However, one counter-example occurs on PPC64 kernels whereby a kernel using 64 kB as a base page size may still use 4 kB pages for the MMU on older processors. To distinguish the two attributes, the "MMUPageSize" line (also available since Linux 2.6.29) reports the page size used by the MMU.

The "Locked" indicates whether the mapping is locked in memory or not.

The "ProtectionKey" line (available since Linux 4.9, on x86 only) contains the memory protection key (see *pkeys*(7)) associated with the virtual memory area. This entry is present only if the kernel was built with the **CONFIG_X86_INTEL_MEMORY_PROTECTION_KEYS** configuration option (since Linux 4.6).

The "VmFlags" line (available since Linux 3.8) represents the kernel flags associated with the virtual memory area, encoded using the following two-letter codes:

rd	-	readable
wr	-	writable
ex	-	executable
sh	-	shared
mr	-	may read
mw	-	may write
me	-	may execute

ms	-	may share
gd	-	stack segment grows down
pf	-	pure PFN range
dw	-	disabled write to the mapped file
lo	-	pages are locked in memory
io	-	memory mapped I/O area
sr	-	sequential read advise provided
rr	-	random read advise provided
dc	-	do not copy area on fork
de	-	do not expand area on remapping
ac	-	area is accountable
nr	-	swap space is not reserved for the area
ht	-	area uses huge tlb pages
sf	-	perform synchronous page faults (since Linux 4.15)
nl	-	non-linear mapping (removed in Linux 4.0)
ar	-	architecture specific flag
wf	-	wipe on fork (since Linux 4.14)
dd	-	do not include area into core dump
sd	-	soft-dirty flag (since Linux 3.13)
mm	-	mixed map area
hg	-	huge page advise flag
nh	-	no-huge page advise flag
mg	-	mergeable advise flag
um	-	userfaultfd missing pages tracking (since Linux 4.3)
uw	-	userfaultfd wprotect pages tracking (since Linux 4.3)

The */proc/*pid*/smaps* file is present only if the **CONFIG_PROC_PAGE_MONITOR** kernel configuration option is enabled.

proc(5)

NAME

/proc/pid/stack − kernel stack

DESCRIPTION

*/proc/*pid*/stack* (since Linux 2.6.29)

This file provides a symbolic trace of the function calls in this process's kernel stack. This file is provided only if the kernel was built with the **CONFIG_STACKTRACE** configuration option.

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_ATTACH_FSCREDS** check; see *ptrace*(2).

SEE ALSO

proc(5)

NAME

/proc/pid/stat − status information

DESCRIPTION

*/proc/*pid*/stat*

Status information about the process. This is used by *ps*(1)It is defined in the kernel source file *fs/proc/array.c*.

The fields, in order, with their proper *scanf*(3) format specifiers, are listed below. Whether or not certain of these fields display valid information is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** | **PTRACE_MODE_NOAUDIT** check (refer to *ptrace*(2)). If the check denies access, then the field value is displayed as 0. The affected fields are indicated with the marking [PT].

(1) *pid* %d
The process ID.

(2) *comm* %s
The filename of the executable, in parentheses. Strings longer than **TASK_COMM_LEN** (16) characters (including the terminating null byte) are silently truncated. This is visible whether or not the executable is swapped out.

(3) *state* %c
One of the following characters, indicating process state:

R	Running
S	Sleeping in an interruptible wait
D	Waiting in uninterruptible disk sleep
Z	Zombie
T	Stopped (on a signal) or (before Linux 2.6.33) trace stopped
t	Tracing stop (Linux 2.6.33 onward)
W	Paging (only before Linux 2.6.0)
X	Dead (from Linux 2.6.0 onward)
x	Dead (Linux 2.6.33 to 3.13 only)
K	Wakekill (Linux 2.6.33 to 3.13 only)
W	Waking (Linux 2.6.33 to 3.13 only)
P	Parked (Linux 3.9 to 3.13 only)
I	Idle (Linux 4.14 onward)

(4) *ppid* %d
The PID of the parent of this process.

(5) *pgrp* %d
The process group ID of the process.

(6) *session* %d
The session ID of the process.

(7) *tty_nr* %d
The controlling terminal of the process. (The minor device number is contained in the combination of bits 31 to 20 and 7 to 0; the major device number is in bits 15 to 8.)

(8) *tpgid* %d
The ID of the foreground process group of the controlling terminal of the process.

(9) *flags* %u
The kernel flags word of the process. For bit meanings, see the PF_* defines in the Linux kernel source file *include/linux/sched.h*. Details depend on the kernel version.

The format for this field was %lu before Linux 2.6.

(10) *minflt* %lu
The number of minor faults the process has made which have not required loading a memory page from disk.

(11) *cminflt* %lu
The number of minor faults that the process's waited-for children have made.

(12) *majflt* %lu
The number of major faults the process has made which have required loading a memory page from disk.

(13) *cmajflt* %lu
The number of major faults that the process's waited-for children have made.

(14) *utime* %lu
Amount of time that this process has been scheduled in user mode, measured in clock ticks (divide by *sysconf(_SC_CLK_TCK)*). This includes guest time, *guest_time* (time spent running a virtual CPU, see below), so that applications that are not aware of the guest time field do not lose that time from their calculations.

(15) *stime* %lu
Amount of time that this process has been scheduled in kernel mode, measured in clock ticks (divide by *sysconf(_SC_CLK_TCK)*).

(16) *cutime* %ld
Amount of time that this process's waited-for children have been scheduled in user mode, measured in clock ticks (divide by *sysconf(_SC_CLK_TCK)*). (See also *times*(2).) This includes guest time, *cguest_time* (time spent running a virtual CPU, see below).

(17) *cstime* %ld
Amount of time that this process's waited-for children have been scheduled in kernel mode, measured in clock ticks (divide by *sysconf(_SC_CLK_TCK)*).

(18) *priority* %ld
(Explanation for Linux 2.6) For processes running a real-time scheduling policy (*policy* below; see *sched_setscheduler*(2)), this is the negated scheduling priority, minus one; that is, a number in the range −2 to −100, corresponding to real-time priorities 1 to 99. For processes running under a non-real-time scheduling policy, this is the raw nice value (**setpriority**(2)) as represented in the kernel. The kernel stores nice values as numbers in the range 0 (high) to 39 (low), corresponding to the user-visible nice range of −20 to 19.

Before Linux 2.6, this was a scaled value based on the scheduler weighting given to this process.

(19) *nice* %ld
The nice value (see *setpriority*(2)), a value in the range 19 (low priority) to −20 (high priority).

(20) *num_threads* %ld
Number of threads in this process (since Linux 2.6). Before Linux 2.6, this field was hard coded to 0 as a placeholder for an earlier removed field.

(21) *itrealvalue* %ld
The time in jiffies before the next **SIGALRM** is sent to the process due to an interval timer. Since Linux 2.6.17, this field is no longer maintained, and is hard coded as 0.

(22) *starttime* %llu
The time the process started after system boot. Before Linux 2.6, this value was expressed in jiffies. Since Linux 2.6, the value is expressed in clock ticks (divide by *sysconf(_SC_CLK_TCK)*).

The format for this field was %lu before Linux 2.6.

(23) *vsize* %lu
Virtual memory size in bytes.

(24) *rss* %ld
Resident Set Size: number of pages the process has in real memory. This is just the pages which count toward text, data, or stack space. This does not include pages which have not been demand-loaded in, or which are swapped out. This value is inaccurate; see */proc/*pid*/statm* below.

(25) *rsslim* %lu
Current soft limit in bytes on the rss of the process; see the description of **RLIMIT_RSS** in *getrlimit*(2).

(26) *startcode* %lu [PT]
The address above which program text can run.

(27) *endcode* %lu [PT]
The address below which program text can run.

(28) *startstack* %lu [PT]
The address of the start (i.e., bottom) of the stack.

(29) *kstkesp* %lu [PT]
The current value of ESP (stack pointer), as found in the kernel stack page for the process.

(30) *kstkeip* %lu [PT]
The current EIP (instruction pointer).

(31) *signal* %lu
The bitmap of pending signals, displayed as a decimal number. Obsolete, because it does not provide information on real-time signals; use */proc/*pid*/status* instead.

(32) *blocked* %lu
The bitmap of blocked signals, displayed as a decimal number. Obsolete, because it does not provide information on real-time signals; use */proc/*pid*/status* instead.

(33) *sigignore* %lu
The bitmap of ignored signals, displayed as a decimal number. Obsolete, because it does not provide information on real-time signals; use */proc/*pid*/status* instead.

(34) *sigcatch* %lu
The bitmap of caught signals, displayed as a decimal number. Obsolete, because it does not provide information on real-time signals; use */proc/*pid*/status* instead.

(35) *wchan* %lu [PT]
This is the "channel" in which the process is waiting. It is the address of a location in the kernel where the process is sleeping. The corresponding symbolic name can be found in */proc/*pid*/wchan*.

(36) *nswap* %lu
Number of pages swapped (not maintained).

(37) *cnswap* %lu
Cumulative *nswap* for child processes (not maintained).

(38) *exit_signal* %d (since Linux 2.1.22)
Signal to be sent to parent when we die.

(39) *processor* %d (since Linux 2.2.8)
CPU number last executed on.

(40) *rt_priority* %u (since Linux 2.5.19)
Real-time scheduling priority, a number in the range 1 to 99 for processes scheduled under a real-time policy, or 0, for non-real-time processes (see *sched_setscheduler*(2)).

(41) *policy* %u (since Linux 2.5.19)
Scheduling policy (see *sched_setscheduler*(2)). Decode using the SCHED_* constants in *linux/sched.h*.

The format for this field was %lu before Linux 2.6.22.

(42) *delayacct_blkio_ticks* %llu (since Linux 2.6.18)
Aggregated block I/O delays, measured in clock ticks (centiseconds).

(43) *guest_time* %lu (since Linux 2.6.24)
Guest time of the process (time spent running a virtual CPU for a guest operating system), measured in clock ticks (divide by *sysconf(_SC_CLK_TCK)*).

(44) *cguest_time* %ld (since Linux 2.6.24)
Guest time of the process's children, measured in clock ticks (divide by *sysconf(_SC_CLK_TCK)*).

(45) *start_data* %lu (since Linux 3.3) [PT]
Address above which program initialized and uninitialized (BSS) data are placed.

(46) *end_data* %lu (since Linux 3.3) [PT]
Address below which program initialized and uninitialized (BSS) data are placed.

(47) *start_brk* %lu (since Linux 3.3) [PT]
Address above which program heap can be expanded with *brk*(2).

(48) *arg_start* %lu (since Linux 3.5) [PT]
Address above which program command-line arguments (*argv*) are placed.

(49) *arg_end* %lu (since Linux 3.5) [PT]
Address below program command-line arguments (*argv*) are placed.

(50) *env_start* %lu (since Linux 3.5) [PT]
Address above which program environment is placed.

(51) *env_end* %lu (since Linux 3.5) [PT]
Address below which program environment is placed.

(52) *exit_code* %d (since Linux 3.5) [PT]
The thread's exit status in the form reported by *waitpid*(2).

SEE ALSO

proc(5), *proc_pid_status*(5)

NAME

/proc/pid/statm − memory usage information

DESCRIPTION

*/proc/*pid*/statm*

Provides information about memory usage, measured in pages. The columns are:

```
size       (1) total program size
           (same as VmSize in /proc/pid/status)
resident   (2) resident set size
           (inaccurate; same as VmRSS in /proc/pid/status)
shared     (3) number of resident shared pages
           (i.e., backed by a file)
           (inaccurate; same as RssFile+RssShmem in
           /proc/pid/status)
text       (4) text (code)
lib        (5) library (unused since Linux 2.6; always 0)
data       (6) data + stack
dt         (7) dirty pages (unused since Linux 2.6; always 0)
```

Some of these values are inaccurate because of a kernel-internal scalability optimization. If accurate values are required, use */proc/*pid*/smaps* or */proc/*pid*/smaps_rollup* instead, which are much slower but provide accurate, detailed information.

NAME

/proc/pid/status − memory usage and status information

DESCRIPTION

*/proc/*pid*/status*

Provides much of the information in */proc/*pid*/stat* and */proc/*pid*/statm* in a format that's easier for humans to parse. Here's an example:

```
$ cat /proc/$$/status
Name:   bash
Umask:  0022
State:  S (sleeping)
Tgid:   17248
Ngid:   0
Pid:    17248
PPid:   17200
TracerPid:      0
Uid:    1000    1000    1000    1000
Gid:    100     100     100     100
FDSize: 256
Groups: 16 33 100
NStgid: 17248
NSpid:  17248
NSpgid: 17248
NSsid:  17200
VmPeak:       131168 kB
VmSize:       131168 kB
VmLck:             0 kB

Mems_allowed_list:      0
voluntary_ctxt_switches:        150
nonvoluntary_ctxt_switches:     545
```

The fields are as follows:

Name Command run by this process. Strings longer than **TASK_COMM_LEN** (16) characters (including the terminating null byte) are silently truncated.

Umask Process umask, expressed in octal with a leading zero; see *umask*(2). (Since Linux 4.7.)

State Current state of the process. One of "R (running)", "S (sleeping)", "D (disk sleep)", "T (stopped)", "t (tracing stop)", "Z (zombie)", or "X (dead)".

Tgid Thread group ID (i.e., Process ID).

Ngid NUMA group ID (0 if none; since Linux 3.13).

Pid Thread ID (see *gettid*(2)).

PPid PID of parent process.

TracerPid
PID of process tracing this process (0 if not being traced).

Uid
Gid Real, effective, saved set, and filesystem UIDs (GIDs).

FDSize Number of file descriptor slots currently allocated.

Groups Supplementary group list.

NStgid Thread group ID (i.e., PID) in each of the PID namespaces of which *pid* is a member. The leftmost entry shows the value with respect to the PID namespace of the process that mounted this procfs (or the root namespace if mounted by the kernel), followed by the value in successively nested inner namespaces. (Since Linux 4.1.)

NSpid Thread ID in each of the PID namespaces of which *pid* is a member. The fields are ordered as for *NStgid*. (Since Linux 4.1.)

NSpgid Process group ID in each of the PID namespaces of which *pid* is a member. The fields are ordered as for *NStgid*. (Since Linux 4.1.)

NSsid descendant namespace session ID hierarchy Session ID in each of the PID namespaces of which *pid* is a member. The fields are ordered as for *NStgid*. (Since Linux 4.1.)

VmPeak
Peak virtual memory size.

VmSize Virtual memory size.

VmLck Locked memory size (see *mlock*(2)).

VmPin Pinned memory size (since Linux 3.2). These are pages that can't be moved because something needs to directly access physical memory.

VmHWM
Peak resident set size ("high water mark"). This value is inaccurate; see */proc/*pid*/statm* above.

VmRSS Resident set size. Note that the value here is the sum of *RssAnon*, *RssFile*, and *RssShmem*. This value is inaccurate; see */proc/*pid*/statm* above.

RssAnon
Size of resident anonymous memory. (since Linux 4.5). This value is inaccurate; see */proc/*pid*/statm* above.

RssFile Size of resident file mappings. (since Linux 4.5). This value is inaccurate; see */proc/*pid*/statm* above.

RssShmem
Size of resident shared memory (includes System V shared memory, mappings from *tmpfs*(5), and shared anonymous mappings). (since Linux 4.5).

VmData
VmStk
VmExe Size of data, stack, and text segments. This value is inaccurate; see */proc/*pid*/statm* above.

VmLib Shared library code size.

VmPTE
Page table entries size (since Linux 2.6.10).

VmPMD
Size of second-level page tables (added in Linux 4.0; removed in Linux 4.15).

VmSwap
Swapped-out virtual memory size by anonymous private pages; shmem swap usage is not included (since Linux 2.6.34). This value is inaccurate; see */proc/*pid*/statm* above.

HugetlbPages
Size of hugetlb memory portions (since Linux 4.4).

CoreDumping
Contains the value 1 if the process is currently dumping core, and 0 if it is not (since Linux 4.15). This information can be used by a monitoring process to avoid killing a process that is currently dumping core, which could result in a corrupted core dump file.

Threads
Number of threads in process containing this thread.

SigQ This field contains two slash-separated numbers that relate to queued signals for the real user ID of this process. The first of these is the number of currently queued signals for this real user ID, and the second is the resource limit on the number of queued signals for this process (see the description of **RLIMIT_SIGPENDING** in *getrlimit*(2)).

SigPnd
ShdPnd
Mask (expressed in hexadecimal) of signals pending for thread and for process as a whole (see *pthreads*(7) and *signal*(7)).

SigBlk
SigIgn
SigCgt Masks (expressed in hexadecimal) indicating signals being blocked, ignored, and caught (see *signal*(7)).

CapInh
CapPrm
CapEff Masks (expressed in hexadecimal) of capabilities enabled in inheritable, permitted, and effective sets (see *capabilities*(7)).

CapBnd
Capability bounding set, expressed in hexadecimal (since Linux 2.6.26, see *capabilities*(7)).

CapAmb
Ambient capability set, expressed in hexadecimal (since Linux 4.3, see *capabilities*(7)).

NoNewPrivs
: Value of the *no_new_privs* bit (since Linux 4.10, see *prctl*(2)).

Seccomp
: Seccomp mode of the process (since Linux 3.8, see *seccomp*(2)). 0 means **SECCOMP_MODE_DISABLED**; 1 means **SECCOMP_MODE_STRICT**; 2 means **SECCOMP_MODE_FILTER**. This field is provided only if the kernel was built with the **CONFIG_SECCOMP** kernel configuration option enabled.

Seccomp_filters
: Number of seccomp filters attached to the process (since Linux 5.9, see *seccomp*(2)).

Speculation_Store_Bypass
: Speculation flaw mitigation state (since Linux 4.17, see *prctl*(2)).

Cpus_allowed
: Hexadecimal mask of CPUs on which this process may run (since Linux 2.6.24, see *cpuset*(7)).

Cpus_allowed_list
: Same as previous, but in "list format" (since Linux 2.6.26, see *cpuset*(7)).

Mems_allowed
: Mask of memory nodes allowed to this process (since Linux 2.6.24, see *cpuset*(7)).

Mems_allowed_list
: Same as previous, but in "list format" (since Linux 2.6.26, see *cpuset*(7)).

voluntary_ctxt_switches
nonvoluntary_ctxt_switches
: Number of voluntary and involuntary context switches (since Linux 2.6.23).

SEE ALSO

proc(5)

NAME

/proc/pid/syscall − currently executed system call

DESCRIPTION

*/proc/*pid*/syscall* (since Linux 2.6.27)

This file exposes the system call number and argument registers for the system call currently being executed by the process, followed by the values of the stack pointer and program counter registers. The values of all six argument registers are exposed, although most system calls use fewer registers.

If the process is blocked, but not in a system call, then the file displays −1 in place of the system call number, followed by just the values of the stack pointer and program counter. If process is not blocked, then the file contains just the string "running".

This file is present only if the kernel was configured with **CONFIG_HAVE_ARCH_TRACEHOOK**.

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_ATTACH_FSCREDS** check; see *ptrace*(2).

SEE ALSO

proc(5)

NAME

/proc/pid/task/, /proc/tid/, /proc/thread−self/ − thread information

DESCRIPTION

*/proc/*pid*/task/* (since Linux 2.6.0)

This is a directory that contains one subdirectory for each thread in the process. The name of each subdirectory is the numerical thread ID (*tid*) of the thread (see *gettid*(2)).

Within each of these subdirectories, there is a set of files with the same names and contents as under the */proc/*pid directories. For attributes that are shared by all threads, the contents for each of the files under the *task/*tid subdirectories will be the same as in the corresponding file in the parent */proc/*pid directory (e.g., in a multithreaded process, all of the *task/*tid*/cwd* files will have the same value as the */proc/*pid*/cwd* file in the parent directory, since all of the threads in a process share a working directory). For attributes that are distinct for each thread, the corresponding files under *task/*tid may have different values (e.g., various fields in each of the *task/*tid*/status* files may be different for each thread), or they might not exist in */proc/*pid at all.

In a multithreaded process, the contents of the */proc/*pid*/task* directory are not available if the main thread has already terminated (typically by calling *pthread_exit*(3)).

*/proc/*tid/

There is a numerical subdirectory for each running thread that is not a thread group leader (i.e., a thread whose thread ID is not the same as its process ID); the subdirectory is named by the thread ID. Each one of these subdirectories contains files and subdirectories exposing information about the thread with the thread ID *tid*. The contents of these directories are the same as the corresponding */proc/*pid*/task/*tid directories.

The */proc/*tid subdirectories are *not* visible when iterating through */proc* with *getdents*(2) (and thus are *not* visible when one uses *ls*(1) to view the contents of */proc*). However, the pathnames of these directories are visible to (i.e., usable as arguments in) system calls that operate on pathnames.

/proc/thread−self/ (since Linux 3.17)

This directory refers to the thread accessing the */proc* filesystem, and is identical to the */proc/self/task/*tid directory named by the process thread ID (*tid*) of the same thread.

SEE ALSO

proc(5)

NAME

/proc/pid/timers − POSIX timers

DESCRIPTION

*/proc/*pid*/timers* (since Linux 3.10)

A list of the POSIX timers for this process. Each timer is listed with a line that starts with the string "ID:". For example:

```
ID: 1
signal: 60/00007fff86e452a8
notify: signal/pid.2634
ClockID: 0
ID: 0
signal: 60/00007fff86e452a8
notify: signal/pid.2634
ClockID: 1
```

The lines shown for each timer have the following meanings:

ID The ID for this timer. This is not the same as the timer ID returned by *timer_create*(2); rather, it is the same kernel-internal ID that is available via the *si_timerid* field of the *siginfo_t* structure (see *sigaction*(2)).

signal This is the signal number that this timer uses to deliver notifications followed by a slash, and then the *sigev_value* value supplied to the signal handler. Valid only for timers that notify via a signal.

notify The part before the slash specifies the mechanism that this timer uses to deliver notifications, and is one of "thread", "signal", or "none". Immediately following the slash is either the string "tid" for timers with **SIGEV_THREAD_ID** notification, or "pid" for timers that notify by other mechanisms. Following the "." is the PID of the process (or the kernel thread ID of the thread) that will be delivered a signal if the timer delivers notifications via a signal.

ClockID

This field identifies the clock that the timer uses for measuring time. For most clocks, this is a number that matches one of the user-space **CLOCK_*** constants exposed via <*time.h*>. **CLOCK_PROCESS_CPUTIME_ID** timers display with a value of −6 in this field. **CLOCK_THREAD_CPUTIME_ID** timers display with a value of −2 in this field.

This file is available only when the kernel was configured with **CONFIG_CHECKPOINT_RESTORE**.

SEE ALSO

proc(5)

NAME

/proc/pid/timerslack_ns − timer slack in nanoseconds

DESCRIPTION

*/proc/*pid*/timerslack_ns* (since Linux 4.6)

This file exposes the process's "current" timer slack value, expressed in nanoseconds. The file is writable, allowing the process's timer slack value to be changed. Writing 0 to this file resets the "current" timer slack to the "default" timer slack value. For further details, see the discussion of **PR_SET_TIMERSLACK** in *prctl*(2).

Initially, permission to access this file was governed by a ptrace access mode **PTRACE_MODE_ATTACH_FSCREDS** check (see *ptrace*(2)). However, this was subsequently deemed too strict a requirement (and had the side effect that requiring a process to have the **CAP_SYS_PTRACE** capability would also allow it to view and change any process's memory). Therefore, since Linux 4.9, only the (weaker) **CAP_SYS_NICE** capability is required to access this file.

SEE ALSO

proc(5)

NAME

/proc/pid/gid_map, /proc/pid/uid_map − user and group ID mappings

DESCRIPTION

*/proc/*pid*/gid_map* (since Linux 3.5)
See *user_namespaces*(7).

*/proc/*pid*/uid_map* (since Linux 3.5)
See *user_namespaces*(7).

SEE ALSO

proc(5)

NAME

/proc/pid/wchan − wait channel

DESCRIPTION

*/proc/*pid*/wchan* (since Linux 2.6.0)

The symbolic name corresponding to the location in the kernel where the process is sleeping.

Permission to access this file is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

SEE ALSO

proc(5)

NAME

/proc/profile − kernel profiling

DESCRIPTION

/proc/profile (since Linux 2.4)

This file is present only if the kernel was booted with the *profile=1* command-line option. It exposes kernel profiling information in a binary format for use by *readprofile*(1)Writing (e.g., an empty string) to this file resets the profiling counters; on some architectures, writing a binary integer "profiling multiplier" of size *sizeof(int)* sets the profiling interrupt frequency.

SEE ALSO

proc(5)

NAME

/proc/scsi/ − SCSI

DESCRIPTION

/proc/scsi/

A directory with the *scsi* mid-level pseudo-file and various SCSI low-level driver directories, which contain a file for each SCSI host in this system, all of which give the status of some part of the SCSI IO subsystem. These files contain ASCII structures and are, therefore, readable with *cat*(1)

You can also write to some of the files to reconfigure the subsystem or switch certain features on or off.

/proc/scsi/scsi

This is a listing of all SCSI devices known to the kernel. The listing is similar to the one seen during bootup. scsi currently supports only the *add−single−device* command which allows root to add a hotplugged device to the list of known devices.

The command

```
echo 'scsi add−single−device 1 0 5 0' > /proc/scsi/scsi
```

will cause host scsi1 to scan on SCSI channel 0 for a device on ID 5 LUN 0. If there is already a device known on this address or the address is invalid, an error will be returned.

*/proc/scsi/*drivername*/*

drivername can currently be NCR53c7xx, aha152x, aha1542, aha1740, aic7xxx, buslogic, eata_dma, eata_pio, fdomain, in2000, pas16, qlogic, scsi_debug, seagate, t128, u15−24f, ultrastore, or wd7000. These directories show up for all drivers that registered at least one SCSI HBA. Every directory contains one file per registered host. Every host-file is named after the number the host was assigned during initialization.

Reading these files will usually show driver and host configuration, statistics, and so on.

Writing to these files allows different things on different hosts. For example, with the *latency* and *nolatency* commands, root can switch on and off command latency measurement code in the eata_dma driver. With the *lockup* and *unlock* commands, root can control bus lockups simulated by the scsi_debug driver.

SEE ALSO

proc(5)

NAME

/proc/slabinfo − kernel caches

DESCRIPTION

/proc/slabinfo

Information about kernel caches. See *slabinfo*(5) for details.

SEE ALSO

proc(5)

NAME

/proc/stat − kernel system statistics

DESCRIPTION

/proc/stat

kernel/system statistics. Varies with architecture. Common entries include:

cpu 10132153 290696 3084719 46828483 16683 0 25195 0 175628 0
cpu0 1393280 32966 572056 13343292 6130 0 17875 0 23933 0

The amount of time, measured in units of USER_HZ (1/100ths of a second on most architectures, use *sysconf(_SC_CLK_TCK)* to obtain the right value), that the system ("cpu" line) or the specific CPU ("cpu*N*" line) spent in various states:

user (1) Time spent in user mode.

nice (2) Time spent in user mode with low priority (nice).

system (3) Time spent in system mode.

idle (4) Time spent in the idle task. This value should be USER_HZ times the second entry in the */proc/uptime* pseudo-file.

iowait (since Linux 2.5.41)
(5) Time waiting for I/O to complete. This value is not reliable, for the following reasons:

- The CPU will not wait for I/O to complete; iowait is the time that a task is waiting for I/O to complete. When a CPU goes into idle state for outstanding task I/O, another task will be scheduled on this CPU.
- On a multi-core CPU, the task waiting for I/O to complete is not running on any CPU, so the iowait of each CPU is difficult to calculate.
- The value in this field may *decrease* in certain conditions.

irq (since Linux 2.6.0)
(6) Time servicing interrupts.

softirq (since Linux 2.6.0)
(7) Time servicing softirqs.

steal (since Linux 2.6.11)
(8) Stolen time, which is the time spent in other operating systems when running in a virtualized environment

guest (since Linux 2.6.24)
(9) Time spent running a virtual CPU for guest operating systems under the control of the Linux kernel.

guest_nice (since Linux 2.6.33)
(10) Time spent running a niced guest (virtual CPU for guest operating systems under the control of the Linux kernel).

page 5741 1808
The number of pages the system paged in and the number that were paged out (from disk).

swap 1 0
The number of swap pages that have been brought in and out.

intr 1462898
This line shows counts of interrupts serviced since boot time, for each of the possible system interrupts. The first column is the total of all interrupts serviced including unnumbered architecture specific interrupts; each subsequent column is the total for that particular numbered interrupt. Unnumbered interrupts are not shown, only summed into the total.

disk_io: (2,0):(31,30,5764,1,2) (3,0):...
(major,disk_idx):(noinfo, read_io_ops, blks_read, write_io_ops, blks_written)
(Linux 2.4 only)

ctxt 115315
The number of context switches that the system underwent.

btime 769041601
boot time, in seconds since the Epoch, 1970-01-01 00:00:00 +0000 (UTC).

processes 86031
Number of forks since boot.

procs_running 6
Number of processes in runnable state. (Linux 2.5.45 onward.)

procs_blocked 2
Number of processes blocked waiting for I/O to complete. (Linux 2.5.45 onward.)

softirq 229245889 94 60001584 13619 5175704 2471304 28 51212741 59130143 0 51240672
This line shows the number of softirq for all CPUs. The first column is the total of all softirqs and each subsequent column is the total for particular softirq. (Linux 2.6.31 onward.)

SEE ALSO

proc(5)

NAME

/proc/swaps − swap areas

DESCRIPTION

/proc/swaps

Swap areas in use. See also *swapon*(8)

SEE ALSO

proc(5)

NAME

/proc/sys/ − system information, and sysctl pseudo-filesystem

DESCRIPTION

/proc/sys/

This directory (present since Linux 1.3.57) contains a number of files and subdirectories corresponding to kernel variables. These variables can be read and in some cases modified using the */proc* filesystem, and the (deprecated) *sysctl*(2) system call.

String values may be terminated by either '\0' or '\n'.

Integer and long values may be written either in decimal or in hexadecimal notation (e.g., 0x3FFF). When writing multiple integer or long values, these may be separated by any of the following whitespace characters: ' ', '\t', or '\n'. Using other separators leads to the error **EINVAL**.

SEE ALSO

proc(5)

NAME

/proc/sys/abi/ − application binary information

DESCRIPTION

/proc/sys/abi/ (since Linux 2.4.10)

This directory may contain files with application binary information. See the Linux kernel source file *Documentation/sysctl/abi.rst* (or *Documentation/sysctl/abi.txt* before Linux 5.3) for more information.

SEE ALSO

proc(5), *proc_sys*(5)

NAME

/proc/sys/debug/ − debug

DESCRIPTION

/proc/sys/debug/

This directory may be empty.

SEE ALSO

proc(5), *proc_sys*(5)

NAME

/proc/sys/dev/ − device-specific information

DESCRIPTION

/proc/sys/dev/

This directory contains device-specific information (e.g., *dev/cdrom/info*). On some systems, it may be empty.

SEE ALSO

proc(5), *proc_sys*(5)

NAME

/proc/sys/fs/ − kernel variables related to filesystems

DESCRIPTION

/proc/sys/fs/

This directory contains the files and subdirectories for kernel variables related to filesystems.

/proc/sys/fs/aio−max−nr and */proc/sys/fs/aio−nr* (since Linux 2.6.4)

aio−nr is the running total of the number of events specified by *io_setup*(2) calls for all currently active AIO contexts. If *aio−nr* reaches *aio−max−nr*, then *io_setup*(2) will fail with the error **EAGAIN**. Raising *aio−max−nr* does not result in the preallocation or resizing of any kernel data structures.

/proc/sys/fs/binfmt_misc

Documentation for files in this directory can be found in the Linux kernel source in the file *Documentation/admin−guide/binfmt−misc.rst* (or in *Documentation/binfmt_misc.txt* on older kernels).

/proc/sys/fs/dentry−state (since Linux 2.2)

This file contains information about the status of the directory cache (dcache). The file contains six numbers, *nr_dentry*, *nr_unused*, *age_limit* (age in seconds), *want_pages* (pages requested by system) and two dummy values.

- *nr_dentry* is the number of allocated dentries (dcache entries). This field is unused in Linux 2.2.
- *nr_unused* is the number of unused dentries.
- *age_limit* is the age in seconds after which dcache entries can be reclaimed when memory is short.
- *want_pages* is nonzero when the kernel has called shrink_dcache_pages() and the dcache isn't pruned yet.

/proc/sys/fs/dir−notify−enable

This file can be used to disable or enable the *dnotify* interface described in *fcntl*(2) on a system-wide basis. A value of 0 in this file disables the interface, and a value of 1 enables it.

/proc/sys/fs/dquot−max

This file shows the maximum number of cached disk quota entries. On some (2.4) systems, it is not present. If the number of free cached disk quota entries is very low and you have some awesome number of simultaneous system users, you might want to raise the limit.

/proc/sys/fs/dquot−nr

This file shows the number of allocated disk quota entries and the number of free disk quota entries.

/proc/sys/fs/epoll/ (since Linux 2.6.28)

This directory contains the file *max_user_watches*, which can be used to limit the amount of kernel memory consumed by the *epoll* interface. For further details, see *epoll*(7).

/proc/sys/fs/file−max

This file defines a system-wide limit on the number of open files for all processes. System calls that fail when encountering this limit fail with the error **ENFILE**. (See also *setrlimit*(2), which can be used by a process to set the per-process limit, **RLIMIT_NOFILE**, on the number of files it may open.) If you get lots of error messages in the kernel log about running out of file handles (open file descriptions) (look for "VFS: file−max limit <number> reached"), try increasing this value:

```
echo 100000 > /proc/sys/fs/file−max
```

Privileged processes (**CAP_SYS_ADMIN**) can override the *file−max* limit.

/proc/sys/fs/file−nr

This (read-only) file contains three numbers: the number of allocated file handles (i.e., the number of open file descriptions; see *open*(2)); the number of free file handles; and the maximum number of file handles (i.e., the same value as */proc/sys/fs/file−max*). If the number of allocated file handles is close to the maximum, you should consider increasing the maximum.

Before Linux 2.6, the kernel allocated file handles dynamically, but it didn't free them again. Instead the free file handles were kept in a list for reallocation; the "free file handles" value indicates the size of that list. A large number of free file handles indicates that there was a past peak in the usage of open file handles. Since Linux 2.6, the kernel does deallocate freed file handles, and the "free file handles" value is always zero.

/proc/sys/fs/inode−max (only present until Linux 2.2)
This file contains the maximum number of in-memory inodes. This value should be 3–4 times larger than the value in *file−max*, since *stdin*, *stdout* and network sockets also need an inode to handle them. When you regularly run out of inodes, you need to increase this value.

Starting with Linux 2.4, there is no longer a static limit on the number of inodes, and this file is removed.

/proc/sys/fs/inode−nr
This file contains the first two values from *inode−state*.

/proc/sys/fs/inode−state
This file contains seven numbers: *nr_inodes*, *nr_free_inodes*, *preshrink*, and four dummy values (always zero).

nr_inodes is the number of inodes the system has allocated. *nr_free_inodes* represents the number of free inodes.

preshrink is nonzero when the *nr_inodes* > *inode−max* and the system needs to prune the inode list instead of allocating more; since Linux 2.4, this field is a dummy value (always zero).

/proc/sys/fs/inotify/ (since Linux 2.6.13)
This directory contains files *max_queued_events*, *max_user_instances*, and *max_user_watches*, that can be used to limit the amount of kernel memory consumed by the *inotify* interface. For further details, see *inotify*(7).

/proc/sys/fs/lease−break−time
This file specifies the grace period that the kernel grants to a process holding a file lease (**fcntl**(2)) after it has sent a signal to that process notifying it that another process is waiting to open the file. If the lease holder does not remove or downgrade the lease within this grace period, the kernel forcibly breaks the lease.

/proc/sys/fs/leases−enable
This file can be used to enable or disable file leases (**fcntl**(2)) on a system-wide basis. If this file contains the value 0, leases are disabled. A nonzero value enables leases.

/proc/sys/fs/mount−max (since Linux 4.9)
The value in this file specifies the maximum number of mounts that may exist in a mount namespace. The default value in this file is 100,000.

/proc/sys/fs/mqueue/ (since Linux 2.6.6)
This directory contains files *msg_max*, *msgsize_max*, and *queues_max*, controlling the resources used by POSIX message queues. See *mq_overview*(7) for details.

/proc/sys/fs/nr_open (since Linux 2.6.25)
This file imposes a ceiling on the value to which the **RLIMIT_NOFILE** resource limit can be raised (see *getrlimit*(2)). This ceiling is enforced for both unprivileged and privileged process. The default value in this file is 1048576. (Before Linux 2.6.25, the ceiling for **RLIMIT_NOFILE** was hard-coded to the same value.)

/proc/sys/fs/overflowgid and */proc/sys/fs/overflowuid*
These files allow you to change the value of the fixed UID and GID. The default is 65534. Some filesystems support only 16-bit UIDs and GIDs, although in Linux UIDs and GIDs are 32 bits. When one of these filesystems is mounted with writes enabled, any UID or GID that would exceed 65535 is translated to the overflow value before being written to disk.

/proc/sys/fs/pipe−max−size (since Linux 2.6.35)
See *pipe*(7).

/proc/sys/fs/pipe−user−pages−hard (since Linux 4.5)
See *pipe*(7).

/proc/sys/fs/pipe-user-pages-soft (since Linux 4.5)
See *pipe*(7).

/proc/sys/fs/protected_fifos (since Linux 4.19)
The value in this file is/can be set to one of the following:

Writing to FIFOs is unrestricted.

1 Don't allow **O_CREAT** *open*(2) on FIFOs that the caller doesn't own in world-writable sticky directories, unless the FIFO is owned by the owner of the directory.

2 As for the value 1, but the restriction also applies to group-writable sticky directories.

The intent of the above protections is to avoid unintentional writes to an attacker-controlled FIFO when a program expected to create a regular file.

/proc/sys/fs/protected_hardlinks (since Linux 3.6)
When the value in this file is 0, no restrictions are placed on the creation of hard links (i.e., this is the historical behavior before Linux 3.6). When the value in this file is 1, a hard link can be created to a target file only if one of the following conditions is true:

- The calling process has the **CAP_FOWNER** capability in its user namespace and the file UID has a mapping in the namespace.
- The filesystem UID of the process creating the link matches the owner (UID) of the target file (as described in *credentials*(7), a process's filesystem UID is normally the same as its effective UID).
- All of the following conditions are true:
  - the target is a regular file;
  - the target file does not have its set-user-ID mode bit enabled;
  - the target file does not have both its set-group-ID and group-executable mode bits enabled; and
  - the caller has permission to read and write the target file (either via the file's permissions mask or because it has suitable capabilities).

The default value in this file is 0. Setting the value to 1 prevents a longstanding class of security issues caused by hard-link-based time-of-check, time-of-use races, most commonly seen in world-writable directories such as */tmp*. The common method of exploiting this flaw is to cross privilege boundaries when following a given hard link (i.e., a root process follows a hard link created by another user). Additionally, on systems without separated partitions, this stops unauthorized users from "pinning" vulnerable set-user-ID and set-group-ID files against being upgraded by the administrator, or linking to special files.

/proc/sys/fs/protected_regular (since Linux 4.19)
The value in this file is/can be set to one of the following:

Writing to regular files is unrestricted.

1 Don't allow **O_CREAT** *open*(2) on regular files that the caller doesn't own in world-writable sticky directories, unless the regular file is owned by the owner of the directory.

2 As for the value 1, but the restriction also applies to group-writable sticky directories.

The intent of the above protections is similar to *protected_fifos*, but allows an application to avoid writes to an attacker-controlled regular file, where the application expected to create one.

/proc/sys/fs/protected_symlinks (since Linux 3.6)
When the value in this file is 0, no restrictions are placed on following symbolic links (i.e., this is the historical behavior before Linux 3.6). When the value in this file is 1, symbolic links are followed only in the following circumstances:

- the filesystem UID of the process following the link matches the owner (UID) of the symbolic link (as described in *credentials*(7), a process's filesystem UID is normally the same as its effective UID);

- the link is not in a sticky world-writable directory; or
- the symbolic link and its parent directory have the same owner (UID)

A system call that fails to follow a symbolic link because of the above restrictions returns the error **EACCES** in *errno*.

The default value in this file is 0. Setting the value to 1 avoids a longstanding class of security issues based on time-of-check, time-of-use races when accessing symbolic links.

/proc/sys/fs/suid_dumpable (since Linux 2.6.13)
The value in this file is assigned to a process's "dumpable" flag in the circumstances described in *prctl*(2). In effect, the value in this file determines whether core dump files are produced for set-user-ID or otherwise protected/tainted binaries. The "dumpable" setting also affects the ownership of files in a process's */proc/*pid directory, as described above.

Three different integer values can be specified:

0 (default)
This provides the traditional (pre-Linux 2.6.13) behavior. A core dump will not be produced for a process which has changed credentials (by calling *seteuid*(2), *setgid*(2), or similar, or by executing a set-user-ID or set-group-ID program) or whose binary does not have read permission enabled.

1 ("debug")
All processes dump core when possible. (Reasons why a process might nevertheless not dump core are described in *core*(5).) The core dump is owned by the filesystem user ID of the dumping process and no security is applied. This is intended for system debugging situations only: this mode is insecure because it allows unprivileged users to examine the memory contents of privileged processes.

2 ("suidsafe")
Any binary which normally would not be dumped (see "0" above) is dumped readable by root only. This allows the user to remove the core dump file but not to read it. For security reasons core dumps in this mode will not overwrite one another or other files. This mode is appropriate when administrators are attempting to debug problems in a normal environment.

Additionally, since Linux 3.6, */proc/sys/kernel/core_pattern* must either be an absolute pathname or a pipe command, as detailed in *core*(5). Warnings will be written to the kernel log if *core_pattern* does not follow these rules, and no core dump will be produced.

For details of the effect of a process's "dumpable" setting on ptrace access mode checking, see *ptrace*(2).

/proc/sys/fs/super−max
This file controls the maximum number of superblocks, and thus the maximum number of mounted filesystems the kernel can have. You need increase only *super−max* if you need to mount more filesystems than the current value in *super−max* allows you to.

/proc/sys/fs/super−nr
This file contains the number of filesystems currently mounted.

proc(5), *proc_sys*(5)

NAME

/proc/sys/kernel/ − control a range of kernel parameters

DESCRIPTION

/proc/sys/kernel/

This directory contains files controlling a range of kernel parameters, as described below.

/proc/sys/kernel/acct

This file contains three numbers: *highwater*, *lowwater*, and *frequency*. If BSD-style process accounting is enabled, these values control its behavior. If free space on filesystem where the log lives goes below *lowwater* percent, accounting suspends. If free space gets above *highwater* percent, accounting resumes. *frequency* determines how often the kernel checks the amount of free space (value is in seconds). Default values are 4, 2, and 30. That is, suspend accounting if 2% or less space is free; resume it if 4% or more space is free; consider information about amount of free space valid for 30 seconds.

/proc/sys/kernel/auto_msgmni (Linux 2.6.27 to Linux 3.18)

From Linux 2.6.27 to Linux 3.18, this file was used to control recomputing of the value in */proc/sys/kernel/msgmni* upon the addition or removal of memory or upon IPC namespace creation/removal. Echoing "1" into this file enabled *msgmni* automatic recomputing (and triggered a recomputation of *msgmni* based on the current amount of available memory and number of IPC namespaces). Echoing "0" disabled automatic recomputing. (Automatic recomputing was also disabled if a value was explicitly assigned to */proc/sys/kernel/msgmni*.) The default value in *auto_msgmni* was 1.

Since Linux 3.19, the content of this file has no effect (because *msgmni* defaults to near the maximum value possible), and reads from this file always return the value "0".

/proc/sys/kernel/cap_last_cap (since Linux 3.2)

See *capabilities*(7).

/proc/sys/kernel/cap−bound (from Linux 2.2 to Linux 2.6.24)

This file holds the value of the kernel *capability bounding set* (expressed as a signed decimal number). This set is ANDed against the capabilities permitted to a process during *execve*(2). Starting with Linux 2.6.25, the system-wide capability bounding set disappeared, and was replaced by a per-thread bounding set; see *capabilities*(7).

/proc/sys/kernel/core_pattern

See *core*(5).

/proc/sys/kernel/core_pipe_limit

See *core*(5).

/proc/sys/kernel/core_uses_pid

See *core*(5).

/proc/sys/kernel/ctrl−alt−del

This file controls the handling of Ctrl-Alt-Del from the keyboard. When the value in this file is 0, Ctrl-Alt-Del is trapped and sent to the *init*(1) program to handle a graceful restart. When the value is greater than zero, Linux's reaction to a Vulcan Nerve Pinch (tm) will be an immediate reboot, without even syncing its dirty buffers. Note: when a program (like dosemu) has the keyboard in "raw" mode, the Ctrl-Alt-Del is intercepted by the program before it ever reaches the kernel tty layer, and it's up to the program to decide what to do with it.

/proc/sys/kernel/dmesg_restrict (since Linux 2.6.37)

The value in this file determines who can see kernel syslog contents. A value of 0 in this file imposes no restrictions. If the value is 1, only privileged users can read the kernel syslog. (See *syslog*(2) for more details.) Since Linux 3.4, only users with the **CAP_SYS_ADMIN** capability may change the value in this file.

/proc/sys/kernel/domainname and */proc/sys/kernel/hostname*

can be used to set the NIS/YP domainname and the hostname of your box in exactly the same way as the commands *domainname*(1) and *hostname*(1), that is:

```
# echo 'darkstar' > /proc/sys/kernel/hostname
# echo 'mydomain' > /proc/sys/kernel/domainname
```

has the same effect as

```
# hostname 'darkstar'
# domainname 'mydomain'
```

Note, however, that the classic darkstar.frop.org has the hostname "darkstar" and DNS (Internet Domain Name Server) domainname "frop.org", not to be confused with the NIS (Network Information Service) or YP (Yellow Pages) domainname. These two domain names are in general different. For a detailed discussion see the *hostname*(1) man page.

/proc/sys/kernel/hotplug
This file contains the pathname for the hotplug policy agent. The default value in this file is */sbin/hotplug*.

/proc/sys/kernel/htab−reclaim (before Linux 2.4.9.2)
(PowerPC only) If this file is set to a nonzero value, the PowerPC htab (see kernel file *Documentation/powerpc/ppc_htab.txt*) is pruned each time the system hits the idle loop.

/proc/sys/kernel/keys/
This directory contains various files that define parameters and limits for the key-management facility. These files are described in *keyrings*(7).

/proc/sys/kernel/kptr_restrict (since Linux 2.6.38)
The value in this file determines whether kernel addresses are exposed via */proc* files and other interfaces. A value of 0 in this file imposes no restrictions. If the value is 1, kernel pointers printed using the *%pK* format specifier will be replaced with zeros unless the user has the **CAP_SYSLOG** capability. If the value is 2, kernel pointers printed using the *%pK* format specifier will be replaced with zeros regardless of the user's capabilities. The initial default value for this file was 1, but the default was changed to 0 in Linux 2.6.39. Since Linux 3.4, only users with the **CAP_SYS_ADMIN** capability can change the value in this file.

/proc/sys/kernel/l2cr
(PowerPC only) This file contains a flag that controls the L2 cache of G3 processor boards. If 0, the cache is disabled. Enabled if nonzero.

/proc/sys/kernel/modprobe
This file contains the pathname for the kernel module loader. The default value is */sbin/modprobe*. The file is present only if the kernel is built with the **CONFIG_MODULES** (**CONFIG_KMOD** in Linux 2.6.26 and earlier) option enabled. It is described by the Linux kernel source file *Documentation/kmod.txt* (present only in Linux 2.4 and earlier).

/proc/sys/kernel/modules_disabled (since Linux 2.6.31)
A toggle value indicating if modules are allowed to be loaded in an otherwise modular kernel. This toggle defaults to off (0), but can be set true (1). Once true, modules can be neither loaded nor unloaded, and the toggle cannot be set back to false. The file is present only if the kernel is built with the **CONFIG_MODULES** option enabled.

/proc/sys/kernel/msgmax (since Linux 2.2)
This file defines a system-wide limit specifying the maximum number of bytes in a single message written on a System V message queue.

/proc/sys/kernel/msgmni (since Linux 2.4)
This file defines the system-wide limit on the number of message queue identifiers. See also */proc/sys/kernel/auto_msgmni*.

/proc/sys/kernel/msgmnb (since Linux 2.2)
This file defines a system-wide parameter used to initialize the *msg_qbytes* setting for subsequently created message queues. The *msg_qbytes* setting specifies the maximum number of bytes that may be written to the message queue.

/proc/sys/kernel/ngroups_max (since Linux 2.6.4)
This is a read-only file that displays the upper limit on the number of a process's group memberships.

/proc/sys/kernel/ns_last_pid (since Linux 3.3)
See *pid_namespaces*(7).

/proc/sys/kernel/ostype and */proc/sys/kernel/osrelease*
These files give substrings of */proc/version*.

/proc/sys/kernel/overflowgid and */proc/sys/kernel/overflowuid*
These files duplicate the files */proc/sys/fs/overflowgid* and */proc/sys/fs/overflowuid*.

/proc/sys/kernel/panic
This file gives read/write access to the kernel variable *panic_timeout*. If this is zero, the kernel will loop on a panic; if nonzero, it indicates that the kernel should autoreboot after this number of seconds. When you use the software watchdog device driver, the recommended setting is 60.

/proc/sys/kernel/panic_on_oops (since Linux 2.5.68)
This file controls the kernel's behavior when an oops or BUG is encountered. If this file contains 0, then the system tries to continue operation. If it contains 1, then the system delays a few seconds (to give klogd time to record the oops output) and then panics. If the */proc/sys/kernel/panic* file is also nonzero, then the machine will be rebooted.

/proc/sys/kernel/pid_max (since Linux 2.5.34)
This file specifies the value at which PIDs wrap around (i.e., the value in this file is one greater than the maximum PID). PIDs greater than this value are not allocated; thus, the value in this file also acts as a system-wide limit on the total number of processes and threads. The default value for this file, 32768, results in the same range of PIDs as on earlier kernels. On 32-bit platforms, 32768 is the maximum value for *pid_max*. On 64-bit systems, *pid_max* can be set to any value up to 2^22 (**PID_MAX_LIMIT**, approximately 4 million).

/proc/sys/kernel/powersave−nap (PowerPC only)
This file contains a flag. If set, Linux-PPC will use the "nap" mode of powersaving, otherwise the "doze" mode will be used.

/proc/sys/kernel/printk
See *syslog*(2).

/proc/sys/kernel/pty (since Linux 2.6.4)
This directory contains two files relating to the number of UNIX 98 pseudoterminals (see *pts*(4)) on the system.

/proc/sys/kernel/pty/max
This file defines the maximum number of pseudoterminals.

/proc/sys/kernel/pty/nr
This read-only file indicates how many pseudoterminals are currently in use.

/proc/sys/kernel/random/
This directory contains various parameters controlling the operation of the file */dev/random*. See *random*(4) for further information.

/proc/sys/kernel/random/uuid (since Linux 2.4)
Each read from this read-only file returns a randomly generated 128-bit UUID, as a string in the standard UUID format.

/proc/sys/kernel/randomize_va_space (since Linux 2.6.12)
Select the address space layout randomization (ASLR) policy for the system (on architectures that support ASLR). Three values are supported for this file:

0 Turn ASLR off. This is the default for architectures that don't support ASLR, and when the kernel is booted with the *norandmaps* parameter.

1 Make the addresses of *mmap*(2) allocations, the stack, and the VDSO page randomized. Among other things, this means that shared libraries will be loaded at randomized addresses. The text segment of PIE-linked binaries will also be loaded at a randomized address. This value is the default if the kernel was configured with **CONFIG_COMPAT_BRK**.

2 (Since Linux 2.6.25) Also support heap randomization. This value is the default if the kernel was not configured with **CONFIG_COMPAT_BRK**.

/proc/sys/kernel/real−root−dev
This file is documented in the Linux kernel source file *Documentation/admin−guide/initrd.rst* (or *Documentation/initrd.txt* before Linux 4.10).

/proc/sys/kernel/reboot−cmd (Sparc only)
This file seems to be a way to give an argument to the SPARC ROM/Flash boot loader. Maybe to tell it what to do after rebooting?

/proc/sys/kernel/rtsig−max
(Up to and including Linux 2.6.7; see *setrlimit*(2)) This file can be used to tune the maximum number of POSIX real-time (queued) signals that can be outstanding in the system.

/proc/sys/kernel/rtsig−nr
(Up to and including Linux 2.6.7.) This file shows the number of POSIX real-time signals currently queued.

*/proc/*pid*/sched_autogroup_enabled* (since Linux 2.6.38)
See *sched*(7).

/proc/sys/kernel/sched_child_runs_first (since Linux 2.6.23)
If this file contains the value zero, then, after a *fork*(2), the parent is first scheduled on the CPU. If the file contains a nonzero value, then the child is scheduled first on the CPU. (Of course, on a multiprocessor system, the parent and the child might both immediately be scheduled on a CPU.)

/proc/sys/kernel/sched_rr_timeslice_ms (since Linux 3.9)
See *sched_rr_get_interval*(2).

/proc/sys/kernel/sched_rt_period_us (since Linux 2.6.25)
See *sched*(7).

/proc/sys/kernel/sched_rt_runtime_us (since Linux 2.6.25)
See *sched*(7).

/proc/sys/kernel/seccomp/ (since Linux 4.14)
This directory provides additional seccomp information and configuration. See *seccomp*(2) for further details.

/proc/sys/kernel/sem (since Linux 2.4)
This file contains 4 numbers defining limits for System V IPC semaphores. These fields are, in order:

SEMMSL
The maximum semaphores per semaphore set.

SEMMNS
A system-wide limit on the number of semaphores in all semaphore sets.

SEMOPM
The maximum number of operations that may be specified in a *semop*(2) call.

SEMMNI
A system-wide limit on the maximum number of semaphore identifiers.

/proc/sys/kernel/sg−big−buff
This file shows the size of the generic SCSI device (sg) buffer. You can't tune it just yet, but you could change it at compile time by editing *include/scsi/sg.h* and changing the value of **SG_BIG_BUFF**. However, there shouldn't be any reason to change this value.

/proc/sys/kernel/shm_rmid_forced (since Linux 3.1)
If this file is set to 1, all System V shared memory segments will be marked for destruction as soon as the number of attached processes falls to zero; in other words, it is no longer possible to create shared memory segments that exist independently of any attached process.

The effect is as though a *shmctl*(2) **IPC_RMID** is performed on all existing segments as well as all segments created in the future (until this file is reset to 0). Note that existing segments that are attached to no process will be immediately destroyed when this file is set to 1. Setting this option will also destroy segments that were created, but never attached, upon termination of the process that created the segment with *shmget*(2).

Setting this file to 1 provides a way of ensuring that all System V shared memory segments are counted against the resource usage and resource limits (see the description of **RLIMIT_AS** in *getrlimit*(2)) of at least one process.

Because setting this file to 1 produces behavior that is nonstandard and could also break existing applications, the default value in this file is 0. Set this file to 1 only if you have a good understanding of the semantics of the applications using System V shared memory on your system.

/proc/sys/kernel/shmall (since Linux 2.2)
This file contains the system-wide limit on the total number of pages of System V shared memory.

/proc/sys/kernel/shmmax (since Linux 2.2)
This file can be used to query and set the run-time limit on the maximum (System V IPC) shared memory segment size that can be created. Shared memory segments up to 1 GB are now supported in the kernel. This value defaults to **SHMMAX**.

/proc/sys/kernel/shmmni (since Linux 2.4)
This file specifies the system-wide maximum number of System V shared memory segments that can be created.

/proc/sys/kernel/sysctl_writes_strict (since Linux 3.16)
The value in this file determines how the file offset affects the behavior of updating entries in files under */proc/sys*. The file has three possible values:

−1 This provides legacy handling, with no printk warnings. Each *write*(2) must fully contain the value to be written, and multiple writes on the same file descriptor will overwrite the entire value, regardless of the file position.

(default) This provides the same behavior as for −1,
but printk warnings are written for processes that perform writes when the file offset is not 0.

1 Respect the file offset when writing strings into */proc/sys* files. Multiple writes will *append* to the value buffer. Anything written beyond the maximum length of the value buffer will be ignored. Writes to numeric */proc/sys* entries must always be at file offset 0 and the value must be fully contained in the buffer provided to *write*(2).

/proc/sys/kernel/sysrq
This file controls the functions allowed to be invoked by the SysRq key. By default, the file contains 1 meaning that every possible SysRq request is allowed (in older kernel versions, SysRq was disabled by default, and you were required to specifically enable it at run-time, but this is not the case any more). Possible values in this file are:

Disable sysrq completely

1 Enable all functions of sysrq

> 1 Bit mask of allowed sysrq functions, as follows:
2 Enable control of console logging level
4 Enable control of keyboard (SAK, unraw)
8 Enable debugging dumps of processes etc.
16 Enable sync command
32 Enable remount read-only
64 Enable signaling of processes (term, kill, oom-kill)
128 Allow reboot/poweroff
256 Allow nicing of all real-time tasks

This file is present only if the **CONFIG_MAGIC_SYSRQ** kernel configuration option is enabled. For further details see the Linux kernel source file *Documentation/admin−guide/sysrq.rst* (or *Documentation/sysrq.txt* before Linux 4.10).

/proc/sys/kernel/version
This file contains a string such as:

```
#5 Wed Feb 25 21:49:24 MET 1998
```

The "#5" means that this is the fifth kernel built from this source base and the date following it indicates the time the kernel was built.

/proc/sys/kernel/threads-max (since Linux 2.3.11)
This file specifies the system-wide limit on the number of threads (tasks) that can be created on the system.

Since Linux 4.1, the value that can be written to *threads-max* is bounded. The minimum value that can be written is 20. The maximum value that can be written is given by the constant **FUTEX_TID_MASK** (0x3fffffff). If a value outside of this range is written to *threads-max*, the error **EINVAL** occurs.

The value written is checked against the available RAM pages. If the thread structures would occupy too much (more than 1/8th) of the available RAM pages, *threads-max* is reduced accordingly.

/proc/sys/kernel/yama/ptrace_scope (since Linux 3.5)
See *ptrace*(2).

/proc/sys/kernel/zero-paged (PowerPC only)
This file contains a flag. When enabled (nonzero), Linux-PPC will pre-zero pages in the idle loop, possibly speeding up get_free_pages.

proc(5), *proc_sys*(5)

NAME

/proc/sys/vm/ − virtual memory subsystem

DESCRIPTION

/proc/sys/vm/

This directory contains files for memory management tuning, buffer, and cache management.

/proc/sys/vm/admin_reserve_kbytes (since Linux 3.10)

This file defines the amount of free memory (in KiB) on the system that should be reserved for users with the capability **CAP_SYS_ADMIN**.

The default value in this file is the minimum of [3% of free pages, 8MiB] expressed as KiB. The default is intended to provide enough for the superuser to log in and kill a process, if necessary, under the default overcommit 'guess' mode (i.e., 0 in */proc/sys/vm/overcommit_memory*).

Systems running in "overcommit never" mode (i.e., 2 in */proc/sys/vm/overcommit_memory*) should increase the value in this file to account for the full virtual memory size of the programs used to recover (e.g., *login*(1) *ssh*(1), and *top*(1)) Otherwise, the superuser may not be able to log in to recover the system. For example, on x86-64 a suitable value is 131072 (128MiB reserved).

Changing the value in this file takes effect whenever an application requests memory.

/proc/sys/vm/compact_memory (since Linux 2.6.35)

When 1 is written to this file, all zones are compacted such that free memory is available in contiguous blocks where possible. The effect of this action can be seen by examining */proc/buddyinfo*.

Present only if the kernel was configured with **CONFIG_COMPACTION**.

/proc/sys/vm/drop_caches (since Linux 2.6.16)

Writing to this file causes the kernel to drop clean caches, dentries, and inodes from memory, causing that memory to become free. This can be useful for memory management testing and performing reproducible filesystem benchmarks. Because writing to this file causes the benefits of caching to be lost, it can degrade overall system performance.

To free pagecache, use:

```
echo 1 > /proc/sys/vm/drop_caches
```

To free dentries and inodes, use:

```
echo 2 > /proc/sys/vm/drop_caches
```

To free pagecache, dentries, and inodes, use:

```
echo 3 > /proc/sys/vm/drop_caches
```

Because writing to this file is a nondestructive operation and dirty objects are not freeable, the user should run *sync*(1) first.

/proc/sys/vm/sysctl_hugetlb_shm_group (since Linux 2.6.7)

This writable file contains a group ID that is allowed to allocate memory using huge pages. If a process has a filesystem group ID or any supplementary group ID that matches this group ID, then it can make huge-page allocations without holding the **CAP_IPC_LOCK** capability; see *memfd_create*(2), *mmap*(2), and *shmget*(2).

/proc/sys/vm/legacy_va_layout (since Linux 2.6.9)

If nonzero, this disables the new 32-bit memory-mapping layout; the kernel will use the legacy (2.4) layout for all processes.

/proc/sys/vm/memory_failure_early_kill (since Linux 2.6.32)

Control how to kill processes when an uncorrected memory error (typically a 2-bit error in a memory module) that cannot be handled by the kernel is detected in the background by hardware. In some cases (like the page still having a valid copy on disk), the kernel will handle the failure transparently without affecting any applications. But if there is no other up-to-date copy of the data, it will kill processes to prevent any data corruptions from propagating.

The file has one of the following values:

1 Kill all processes that have the corrupted-and-not-reloadable page mapped as soon as the corruption is detected. Note that this is not supported for a few types of pages, such as kernel internally allocated data or the swap cache, but works for the majority of user pages.

0 Unmap the corrupted page from all processes and kill a process only if it tries to access the page.

The kill is performed using a **SIGBUS** signal with *si_code* set to **BUS_MCEERR_AO**. Processes can handle this if they want to; see *sigaction*(2) for more details.

This feature is active only on architectures/platforms with advanced machine check handling and depends on the hardware capabilities.

Applications can override the *memory_failure_early_kill* setting individually with the *prctl*(2) **PR_MCE_KILL** operation.

Present only if the kernel was configured with **CONFIG_MEMORY_FAILURE**.

/proc/sys/vm/memory_failure_recovery (since Linux 2.6.32)
Enable memory failure recovery (when supported by the platform).

1 Attempt recovery.

0 Always panic on a memory failure.

Present only if the kernel was configured with **CONFIG_MEMORY_FAILURE**.

/proc/sys/vm/oom_dump_tasks (since Linux 2.6.25)
Enables a system-wide task dump (excluding kernel threads) to be produced when the kernel performs an OOM-killing. The dump includes the following information for each task (thread, process): thread ID, real user ID, thread group ID (process ID), virtual memory size, resident set size, the CPU that the task is scheduled on, oom_adj score (see the description of */proc/*pid*/oom_adj*), and command name. This is helpful to determine why the OOM-killer was invoked and to identify the rogue task that caused it.

If this contains the value zero, this information is suppressed. On very large systems with thousands of tasks, it may not be feasible to dump the memory state information for each one. Such systems should not be forced to incur a performance penalty in OOM situations when the information may not be desired.

If this is set to nonzero, this information is shown whenever the OOM-killer actually kills a memory-hogging task.

The default value is 0.

/proc/sys/vm/oom_kill_allocating_task (since Linux 2.6.24)
This enables or disables killing the OOM-triggering task in out-of-memory situations.

If this is set to zero, the OOM-killer will scan through the entire tasklist and select a task based on heuristics to kill. This normally selects a rogue memory-hogging task that frees up a large amount of memory when killed.

If this is set to nonzero, the OOM-killer simply kills the task that triggered the out-of-memory condition. This avoids a possibly expensive tasklist scan.

If */proc/sys/vm/panic_on_oom* is nonzero, it takes precedence over whatever value is used in */proc/sys/vm/oom_kill_allocating_task*.

The default value is 0.

/proc/sys/vm/overcommit_kbytes (since Linux 3.14)
This writable file provides an alternative to */proc/sys/vm/overcommit_ratio* for controlling the *CommitLimit* when */proc/sys/vm/overcommit_memory* has the value 2. It allows the amount of memory overcommitting to be specified as an absolute value (in kB), rather than as a percentage, as is done with *overcommit_ratio*. This allows for finer-grained control of *CommitLimit* on systems with extremely large memory sizes.

Only one of *overcommit_kbytes* or *overcommit_ratio* can have an effect: if *overcommit_kbytes* has a nonzero value, then it is used to calculate *CommitLimit*, otherwise *overcommit_ratio* is used. Writing a value to either of these files causes the value in the other file to be set to zero.

/proc/sys/vm/overcommit_memory

This file contains the kernel virtual memory accounting mode. Values are:

0: heuristic overcommit (this is the default)
1: always overcommit, never check
2: always check, never overcommit

In mode 0, calls of *mmap*(2) with **MAP_NORESERVE** are not checked, and the default check is very weak, leading to the risk of getting a process "OOM-killed".

In mode 1, the kernel pretends there is always enough memory, until memory actually runs out. One use case for this mode is scientific computing applications that employ large sparse arrays. Before Linux 2.6.0, any nonzero value implies mode 1.

In mode 2 (available since Linux 2.6), the total virtual address space that can be allocated (*CommitLimit* in */proc/meminfo*) is calculated as

```
CommitLimit = (total_RAM − total_huge_TLB) *
              overcommit_ratio / 100 + total_swap
```

where:

- *total_RAM* is the total amount of RAM on the system;
- *total_huge_TLB* is the amount of memory set aside for huge pages;
- *overcommit_ratio* is the value in */proc/sys/vm/overcommit_ratio*; and
- *total_swap* is the amount of swap space.

For example, on a system with 16 GB of physical RAM, 16 GB of swap, no space dedicated to huge pages, and an *overcommit_ratio* of 50, this formula yields a *CommitLimit* of 24 GB.

Since Linux 3.14, if the value in */proc/sys/vm/overcommit_kbytes* is nonzero, then *CommitLimit* is instead calculated as:

```
CommitLimit = overcommit_kbytes + total_swap
```

See also the description of */proc/sys/vm/admin_reserve_kbytes* and */proc/sys/vm/user_reserve_kbytes*.

/proc/sys/vm/overcommit_ratio (since Linux 2.6.0)

This writable file defines a percentage by which memory can be overcommitted. The default value in the file is 50. See the description of */proc/sys/vm/overcommit_memory*.

/proc/sys/vm/panic_on_oom (since Linux 2.6.18)

This enables or disables a kernel panic in an out-of-memory situation.

If this file is set to the value 0, the kernel's OOM-killer will kill some rogue process. Usually, the OOM-killer is able to kill a rogue process and the system will survive.

If this file is set to the value 1, then the kernel normally panics when out-of-memory happens. However, if a process limits allocations to certain nodes using memory policies (**mbind**(2) **MPOL_BIND**) or cpusets (**cpuset**(7)) and those nodes reach memory exhaustion status, one process may be killed by the OOM-killer. No panic occurs in this case: because other nodes' memory may be free, this means the system as a whole may not have reached an out-of-memory situation yet.

If this file is set to the value 2, the kernel always panics when an out-of-memory condition occurs.

The default value is 0. 1 and 2 are for failover of clustering. Select either according to your policy of failover.

/proc/sys/vm/swappiness

The value in this file controls how aggressively the kernel will swap memory pages. Higher values increase aggressiveness, lower values decrease aggressiveness. The default value is 60.

/proc/sys/vm/user_reserve_kbytes (since Linux 3.10)
Specifies an amount of memory (in KiB) to reserve for user processes. This is intended to prevent a user from starting a single memory hogging process, such that they cannot recover (kill the hog). The value in this file has an effect only when */proc/sys/vm/overcommit_memory* is set to 2 ("overcommit never" mode). In this case, the system reserves an amount of memory that is the minimum of [3% of current process size, *user_reserve_kbytes*].

The default value in this file is the minimum of [3% of free pages, 128MiB] expressed as KiB.

If the value in this file is set to zero, then a user will be allowed to allocate all free memory with a single process (minus the amount reserved by */proc/sys/vm/admin_reserve_kbytes*). Any subsequent attempts to execute a command will result in "fork: Cannot allocate memory".

Changing the value in this file takes effect whenever an application requests memory.

/proc/sys/vm/unprivileged_userfaultfd (since Linux 5.2)
This (writable) file exposes a flag that controls whether unprivileged processes are allowed to employ *userfaultfd*(2). If this file has the value 1, then unprivileged processes may use *userfaultfd*(2). If this file has the value 0, then only processes that have the **CAP_SYS_PTRACE** capability may employ *userfaultfd*(2). The default value in this file is 1.

NAME

/proc/sysrq−trigger − SysRq function

DESCRIPTION

/proc/sysrq−trigger (since Linux 2.4.21)

Writing a character to this file triggers the same SysRq function as typing ALT-SysRq-<character> (see the description of */proc/sys/kernel/sysrq*). This file is normally writable only by *root*. For further details see the Linux kernel source file *Documentation/admin−guide/sysrq.rst* (or *Documentation/sysrq.txt* before Linux 4.10).

SEE ALSO

proc(5)

NAME

/proc/sysvipc/ − System V IPC

DESCRIPTION

/proc/sysvipc/

Subdirectory containing the pseudo-files *msg*, *sem* and *shm*. These files list the System V Interprocess Communication (IPC) objects (respectively: message queues, semaphores, and shared memory) that currently exist on the system, providing similar information to that available via *ipcs*(1)These files have headers and are formatted (one IPC object per line) for easy understanding. *sysvipc*(7) provides further background on the information shown by these files.

SEE ALSO

proc(5)

NAME

/proc/tid/children − child tasks

DESCRIPTION

*/proc/*tid*/children* (since Linux 3.5)

A space-separated list of child tasks of this task. Each child task is represented by its TID.

This option is intended for use by the checkpoint-restore (CRIU) system, and reliably provides a list of children only if all of the child processes are stopped or frozen. It does not work properly if children of the target task exit while the file is being read! Exiting children may cause non-exiting children to be omitted from the list. This makes this interface even more unreliable than classic PID-based approaches if the inspected task and its children aren't frozen, and most code should probably not use this interface.

Until Linux 4.2, the presence of this file was governed by the **CONFIG_CHECKPOINT_RESTORE** kernel configuration option. Since Linux 4.2, it is governed by the **CONFIG_PROC_CHILDREN** option.

SEE ALSO

proc(5)

NAME

/proc/timer_list − pending timers

DESCRIPTION

/proc/timer_list (since Linux 2.6.21)

This read-only file exposes a list of all currently pending (high-resolution) timers, all clock-event sources, and their parameters in a human-readable form.

SEE ALSO

proc(5)

NAME

/proc/timer_stats − timer statistics

DESCRIPTION

/proc/timer_stats (from Linux 2.6.21 until Linux 4.10)

This is a debugging facility to make timer (ab)use in a Linux system visible to kernel and user-space developers. It can be used by kernel and user-space developers to verify that their code does not make undue use of timers. The goal is to avoid unnecessary wakeups, thereby optimizing power consumption.

If enabled in the kernel (**CONFIG_TIMER_STATS**), but not used, it has almost zero run-time overhead and a relatively small data-structure overhead. Even if collection is enabled at run time, overhead is low: all the locking is per-CPU and lookup is hashed.

The */proc/timer_stats* file is used both to control sampling facility and to read out the sampled information.

The *timer_stats* functionality is inactive on bootup. A sampling period can be started using the following command:

```
# echo 1 > /proc/timer_stats
```

The following command stops a sampling period:

```
# echo 0 > /proc/timer_stats
```

The statistics can be retrieved by:

```
$ cat /proc/timer_stats
```

While sampling is enabled, each readout from */proc/timer_stats* will see newly updated statistics. Once sampling is disabled, the sampled information is kept until a new sample period is started. This allows multiple readouts.

Sample output from */proc/timer_stats*:

```
$ cat /proc/timer_stats
Timer Stats Version: v0.3
Sample period: 1.764 s
Collection: active
  255,     0 swapper/3        hrtimer_start_range_ns (tick_sched_timer)
   71,     0 swapper/1        hrtimer_start_range_ns (tick_sched_timer)
   58,     0 swapper/0        hrtimer_start_range_ns (tick_sched_timer)
    4,  1694 gnome-shell      mod_delayed_work_on (delayed_work_timer_fn)
   17,     7 rcu_sched        rcu_gp_kthread (process_timeout)
...
    1,  4911 kworker/u16:0    mod_delayed_work_on (delayed_work_timer_fn)
   1D,  2522 kworker/0:0      queue_delayed_work_on (delayed_work_timer_fn)
1029 total events, 583.333 events/sec
```

The output columns are:

[1] a count of the number of events, optionally (since Linux 2.6.23) followed by the letter 'D' if this is a deferrable timer;

[2] the PID of the process that initialized the timer;

[3] the name of the process that initialized the timer;

[4] the function where the timer was initialized; and (in parentheses) the callback function that is associated with the timer.

During the Linux 4.11 development cycle, this file was removed because of security concerns, as it exposes information across namespaces. Furthermore, it is possible to obtain the same information via in-kernel tracing facilities such as ftrace.

SEE ALSO

proc(5)

NAME

/proc/tty/ − tty

DESCRIPTION

/proc/tty/

Subdirectory containing the pseudo-files and subdirectories for tty drivers and line disciplines.

SEE ALSO

proc(5)

NAME

/proc/uptime − system uptime

DESCRIPTION

/proc/uptime

This file contains two numbers (values in seconds): the uptime of the system (including time spent in suspend) and the amount of time spent in the idle process.

SEE ALSO

proc(5)

NAME

/proc/version − kernel version

DESCRIPTION

/proc/version

This string identifies the kernel version that is currently running. It includes the contents of */proc/sys/kernel/ostype*, */proc/sys/kernel/osrelease*, and */proc/sys/kernel/version*. For example:

```
Linux version 1.0.9 (quinlan@phaze) #1 Sat May 14 01:51:54 EDT 1994
```

SEE ALSO

proc(5)

NAME

/proc/vmstat − virtual memory statistics

DESCRIPTION

/proc/vmstat (since Linux 2.6.0)

This file displays various virtual memory statistics. Each line of this file contains a single name-value pair, delimited by white space. Some lines are present only if the kernel was configured with suitable options. (In some cases, the options required for particular files have changed across kernel versions, so they are not listed here. Details can be found by consulting the kernel source code.) The following fields may be present:

nr_free_pages (since Linux 2.6.31)

nr_alloc_batch (since Linux 3.12)

nr_inactive_anon (since Linux 2.6.28)

nr_active_anon (since Linux 2.6.28)

nr_inactive_file (since Linux 2.6.28)

nr_active_file (since Linux 2.6.28)

proc(5)

NAME

protocols − protocols definition file

DESCRIPTION

This file is a plain ASCII file, describing the various DARPA internet protocols that are available from the TCP/IP subsystem. It should be consulted instead of using the numbers in the ARPA include files, or, even worse, just guessing them. These numbers will occur in the protocol field of any IP header.

Keep this file untouched since changes would result in incorrect IP packages. Protocol numbers and names are specified by the IANA (Internet Assigned Numbers Authority).

Each line is of the following format:

protocol number aliases ...

where the fields are delimited by spaces or tabs. Empty lines are ignored. If a line contains a hash mark (#), the hash mark and the part of the line following it are ignored.

The field descriptions are:

protocol
: the native name for the protocol. For example *ip*, *tcp*, or *udp*.

number
: the official number for this protocol as it will appear within the IP header.

aliases optional aliases for the protocol.

This file might be distributed over a network using a network-wide naming service like Yellow Pages/NIS or BIND/Hesiod.

FILES

/etc/protocols
: The protocols definition file.

getprotoent(3)

NAME

repertoiremap − map symbolic character names to Unicode code points

DESCRIPTION

A repertoire map defines mappings between symbolic character names (mnemonics) and Unicode code points when compiling a locale with *localedef*(1). Using a repertoire map is optional, it is needed only when symbolic names are used instead of now preferred Unicode code points.

Syntax

The repertoiremap file starts with a header that may consist of the following keywords:

comment_char
: is followed by a character that will be used as the comment character for the rest of the file. It defaults to the number sign (#).

escape_char
: is followed by a character that should be used as the escape character for the rest of the file to mark characters that should be interpreted in a special way. It defaults to the backslash (\).

The mapping section starts with the keyword *CHARIDS* in the first column.

The mapping lines have the following form:

<*symbolic-name*> <*code-point*> *comment*
: This defines exactly one mapping, *comment* being optional.

The mapping section ends with the string *END CHARIDS*.

FILES

/usr/share/i18n/repertoiremaps
: Usual default repertoire map path.

STANDARDS

POSIX.2.

NOTES

Repertoire maps are deprecated in favor of Unicode code points.

EXAMPLES

A mnemonic for the Euro sign can be defined as follows:

<Eu> <U20AC> EURO SIGN

NAME

resolv.conf − resolver configuration file

SYNOPSIS

/etc/resolv.conf

DESCRIPTION

The *resolver* is a set of routines in the C library that provide access to the Internet Domain Name System (DNS). The resolver configuration file contains information that is read by the resolver routines the first time they are invoked by a process. The file is designed to be human readable and contains a list of keywords with values that provide various types of resolver information. The configuration file is considered a trusted source of DNS information; see the **trust-ad** option below for details.

If this file does not exist, only the name server on the local machine will be queried, and the search list contains the local domain name determined from the hostname.

The different configuration options are:

nameserver Name server IP address

Internet address of a name server that the resolver should query, either an IPv4 address (in dot notation), or an IPv6 address in colon (and possibly dot) notation as per RFC 2373. Up to **MAXNS** (currently 3, see <*resolv.h*>) name servers may be listed, one per keyword. If there are multiple servers, the resolver library queries them in the order listed. If no **nameserver** entries are present, the default is to use the name server on the local machine. (The algorithm used is to try a name server, and if the query times out, try the next, until out of name servers, then repeat trying all the name servers until a maximum number of retries are made.)

search Search list for host-name lookup.

By default, the search list contains one entry, the local domain name. It is determined from the local hostname returned by *gethostname*(2); the local domain name is taken to be everything after the first '.'. Finally, if the hostname does not contain a '.', the root domain is assumed as the local domain name.

This may be changed by listing the desired domain search path following the *search* keyword with spaces or tabs separating the names. Resolver queries having fewer than *ndots* dots (default is 1) in them will be attempted using each component of the search path in turn until a match is found. For environments with multiple subdomains please read **options ndots:***n* below to avoid man-in-the-middle attacks and unnecessary traffic for the root-dns-servers. Note that this process may be slow and will generate a lot of network traffic if the servers for the listed domains are not local, and that queries will time out if no server is available for one of the domains.

If there are multiple **search** directives, only the search list from the last instance is used.

In glibc 2.25 and earlier, the search list is limited to six domains with a total of 256 characters. Since glibc 2.26, the search list is unlimited.

The **domain** directive is an obsolete name for the **search** directive that handles one search list entry only.

sortlist This option allows addresses returned by *gethostbyname*(3) to be sorted. A sortlist is specified by IP-address-netmask pairs. The netmask is optional and defaults to the natural netmask of the net. The IP address and optional network pairs are separated by slashes. Up to 10 pairs may be specified. Here is an example:

```
sortlist 130.155.160.0/255.255.240.0 130.155.0.0
```

options

Options allows certain internal resolver variables to be modified. The syntax is

options *option* ...

where *option* is one of the following:

debug Sets **RES_DEBUG** in *_res.options* (effective only if glibc was built with debug support; see *resolver*(3)).

ndots:*n*
Sets a threshold for the number of dots which must appear in a name given to *res_query*(3) (see *resolver*(3)) before an *initial absolute query* will be made. The default for *n* is 1, meaning that if there are any dots in a name, the name will be tried first as an absolute name before any *search list* elements are appended to it. The value for this option is silently capped to 15.

timeout:*n*
Sets the amount of time the resolver will wait for a response from a remote name server before retrying the query via a different name server. This may **not** be the total time taken by any resolver API call and there is no guarantee that a single resolver API call maps to a single timeout. Measured in seconds, the default is **RES_TIMEOUT** (currently 5, see <*resolv.h*>). The value for this option is silently capped to 30.

attempts:*n*
Sets the number of times the resolver will send a query to its name servers before giving up and returning an error to the calling application. The default is **RES_DFLRETRY** (currently 2, see <*resolv.h*>). The value for this option is silently capped to 5.

rotate Sets **RES_ROTATE** in *_res.options*, which causes round-robin selection of name servers from among those listed. This has the effect of spreading the query load among all listed servers, rather than having all clients try the first listed server first every time.

no−aaaa (since glibc 2.36)
Sets **RES_NOAAAA** in *_res.options*, which suppresses AAAA queries made by the stub resolver, including AAAA lookups triggered by NSS-based interfaces such as *getaddrinfo*(3). Only DNS lookups are affected: IPv6 data in *hosts*(5) is still used, *getaddrinfo*(3) with **AI_PASSIVE** will still produce IPv6 addresses, and configured IPv6 name servers are still used. To produce correct Name Error (NXDOMAIN) results, AAAA queries are translated to A queries. This option is intended preliminary for diagnostic purposes, to rule out that AAAA DNS queries have adverse impact. It is incompatible with EDNS0 usage and DNSSEC validation by applications.

no−check−names
Sets **RES_NOCHECKNAME** in *_res.options*, which disables the modern BIND checking of incoming hostnames and mail names for invalid characters such as underscore (_), non-ASCII, or control characters.

inet6 Sets **RES_USE_INET6** in *_res.options*. This has the effect of trying an AAAA query before an A query inside the *gethostbyname*(3) function, and of mapping IPv4 responses in IPv6 "tunneled form" if no AAAA records are found but an A record set exists. Since glibc 2.25, this option is deprecated; applications should use *getaddrinfo*(3), rather than *gethostbyname*(3).

ip6-bytestring (since glibc 2.3.4 to glibc 2.24)
Sets **RES_USEBSTRING** in *_res.options*. This causes reverse IPv6 lookups to be made using the bit-label format described in RFC 2673; if this option is not set (which is the default), then nibble format is used. This option was removed in glibc 2.25, since it relied on a backward-incompatible DNS extension that was never deployed on the Internet.

ip6-dotint/**no-ip6-dotint** (glibc 2.3.4 to glibc 2.24)
Clear/set **RES_NOIP6DOTINT** in *_res.options*. When this option is clear (**ip6−dotint**), reverse IPv6 lookups are made in the (deprecated) *ip6.int* zone; when this option is set (**no−ip6−dotint**), reverse IPv6 lookups are made in the *ip6.arpa* zone by default. These options are available up to glibc 2.24, where **no−ip6−dotint** is the default. Since **ip6−dotint** support long ago ceased to be available on the Internet, these options were removed in glibc 2.25.

edns0 (since glibc 2.6)
Sets **RES_USE_EDNS0** in *_res.options*. This enables support for the DNS extensions described in RFC 2671.

single-request (since glibc 2.10)
Sets **RES_SNGLKUP** in *_res.options*. By default, glibc performs IPv4 and IPv6 lookups in parallel since glibc 2.9. Some appliance DNS servers cannot handle these queries properly and make the requests time out. This option disables the behavior and makes glibc perform the IPv6 and IPv4 requests sequentially (at the cost of some slowdown of the resolving process).

single-request-reopen (since glibc 2.9)
Sets **RES_SNGLKUPREOP** in *_res.options*. The resolver uses the same socket for the A and AAAA requests. Some hardware mistakenly sends back only one reply. When that happens the client system will sit and wait for the second reply. Turning this option on changes this behavior so that if two requests from the same port are not handled correctly it will close the socket and open a new one before sending the second request.

no-tld-query (since glibc 2.14)
Sets **RES_NOTLDQUERY** in *_res.options*. This option causes **res_nsearch**() to not attempt to resolve an unqualified name as if it were a top level domain (TLD). This option can cause problems if the site has ‘‘localhost’’ as a TLD rather than having localhost on one or more elements of the search list. This option has no effect if neither RES_DEFNAMES or RES_DNSRCH is set.

use-vc (since glibc 2.14)
Sets **RES_USEVC** in *_res.options*. This option forces the use of TCP for DNS resolutions.

no-reload (since glibc 2.26)
Sets **RES_NORELOAD** in *_res.options*. This option disables automatic reloading of a changed configuration file.

trust-ad (since glibc 2.31)
Sets **RES_TRUSTAD** in *_res.options*. This option controls the AD bit behavior of the stub resolver. If a validating resolver sets the AD bit in a response, it indicates that the data in the response was verified according to the DNSSEC protocol. In order to rely on the AD bit, the local system has to trust both the DNSSEC-validating resolver and the network path to it, which is why an explicit opt-in is required. If the **trust−ad** option is active, the stub resolver sets the AD bit in outgoing DNS queries (to enable AD bit support), and preserves the AD bit in responses. Without this option, the AD bit is not set in queries, and it is always removed from responses before they are returned to the application. This means that applications can trust the AD bit in responses if the **trust−ad** option has been set correctly.

In glibc 2.30 and earlier, the AD is not set automatically in queries, and is passed through unchanged to applications in responses.

The *search* keyword of a system’s *resolv.conf* file can be overridden on a per-process basis by setting the environment variable **LOCALDOMAIN** to a space-separated list of search domains.

The *options* keyword of a system’s *resolv.conf* file can be amended on a per-process basis by setting the environment variable **RES_OPTIONS** to a space-separated list of resolver options as explained above under **options**.

The keyword and value must appear on a single line, and the keyword (e.g., **nameserver**) must start the line. The value follows the keyword, separated by white space.

Lines that contain a semicolon (;) or hash character (#) in the first column are treated as comments.

Name Server Operations Guide for BIND

NAME

rpc − RPC program number data base

SYNOPSIS

/etc/rpc

DESCRIPTION

The *rpc* file contains user readable names that can be used in place of RPC program numbers. Each line has the following information:

- name of server for the RPC program
- RPC program number
- aliases

Items are separated by any number of blanks and/or tab characters. A '#' indicates the beginning of a comment; characters from the '#' to the end of the line are not interpreted by routines which search the file.

Here is an example of the */etc/rpc* file from the Sun RPC Source distribution.

```
#
# rpc 88/08/01 4.0 RPCSRC; from 1.12   88/02/07 SMI
#

NAME

securetty − list of terminals on which root is allowed to login

DESCRIPTION

The file */etc/securetty* contains the names of terminals (one per line, without leading */dev/*) which are considered secure for the transmission of certain authentication tokens.

It is used by (some versions of) *login*(1) to restrict the terminals on which root is allowed to login. See *login.defs*(5) if you use the shadow suite.

On PAM enabled systems, it is used for the same purpose by *pam_securetty*(8) to restrict the terminals on which empty passwords are accepted.

FILES

/etc/securetty

SEE ALSO

login(1), *login.defs*(5), *pam_securetty*(8)

NAME

services − Internet network services list

DESCRIPTION

services is a plain ASCII file providing a mapping between human-friendly textual names for internet services, and their underlying assigned port numbers and protocol types. Every networking program should look into this file to get the port number (and protocol) for its service. The C library routines *getservent*(3), *getservbyname*(3), *getservbyport*(3), *setservent*(3), and *endservent*(3) support querying this file from programs.

Port numbers are assigned by the IANA (Internet Assigned Numbers Authority), and their current policy is to assign both TCP and UDP protocols when assigning a port number. Therefore, most entries will have two entries, even for TCP-only services.

Port numbers below 1024 (so-called "low numbered" ports) can be bound to only by root (see *bind*(2), *tcp*(7), and *udp*(7)). This is so clients connecting to low numbered ports can trust that the service running on the port is the standard implementation, and not a rogue service run by a user of the machine. Well-known port numbers specified by the IANA are normally located in this root-only space.

The presence of an entry for a service in the **services** file does not necessarily mean that the service is currently running on the machine. See *inetd.conf* (5) for the configuration of Internet services offered. Note that not all networking services are started by *inetd*(8), and so won't appear in *inetd.conf* (5)In particular, news (NNTP) and mail (SMTP) servers are often initialized from the system boot scripts.

The location of the **services** file is defined by **_PATH_SERVICES** in <*netdb.h*>. This is usually set to */etc/services*.

Each line describes one service, and is of the form:

service-name *port/protocol* [*aliases* ...]

where:

service-name
: is the friendly name the service is known by and looked up under. It is case sensitive. Often, the client program is named after the *service-name*.

port : is the port number (in decimal) to use for this service.

protocol
: is the type of protocol to be used. This field should match an entry in the *protocols*(5) file. Typical values include **tcp** and **udp**.

aliases : is an optional space or tab separated list of other names for this service. Again, the names are case sensitive.

Either spaces or tabs may be used to separate the fields.

Comments are started by the hash sign (#) and continue until the end of the line. Blank lines are skipped.

The *service-name* should begin in the first column of the file, since leading spaces are not stripped. *service-names* can be any printable characters excluding space and tab. However, a conservative choice of characters should be used to minimize compatibility problems. For example, a−z, 0−9, and hyphen (−) would seem a sensible choice.

Lines not matching this format should not be present in the file. (Currently, they are silently skipped by *getservent*(3), *getservbyname*(3), and *getservbyport*(3). However, this behavior should not be relied on.)

This file might be distributed over a network using a network-wide naming service like Yellow Pages/NIS or BIND/Hesiod.

A sample **services** file might look like this:

```
netstat         15/tcp
qotd            17/tcp          quote
msp             18/tcp          # message send protocol
msp             18/udp          # message send protocol
chargen         19/tcp          ttytst source
```

```
chargen         19/udp          ttytst source
ftp             21/tcp
# 22 - unassigned
telnet          23/tcp
```

FILES

/etc/services
: The Internet network services list

<netdb.h>
: Definition of **_PATH_SERVICES**

NAME

shells − pathnames of valid login shells

DESCRIPTION

/etc/shells is a text file which contains the full pathnames of valid login shells. This file is consulted by *chsh*(1) and available to be queried by other programs.

Be aware that there are programs which consult this file to find out if a user is a normal user; for example, FTP daemons traditionally disallow access to users with shells not included in this file.

FILES

/etc/shells

EXAMPLES

/etc/shells may contain the following paths:

```
/bin/sh
/bin/bash
/bin/csh
```

SEE ALSO

chsh(1), *getusershell*(3), *pam_shells*(8)

NAME

slabinfo − kernel slab allocator statistics

SYNOPSIS

cat /proc/slabinfo

DESCRIPTION

Frequently used objects in the Linux kernel (buffer heads, inodes, dentries, etc.) have their own cache. The file */proc/slabinfo* gives statistics on these caches. The following (edited) output shows an example of the contents of this file:

```
$ sudo cat /proc/slabinfo
slabinfo − version: 2.1
# name    <active_objs> <num_objs> <objsize> <objperslab> <pagesperslab> ...
sigqueue      100  100  160   25  1 : tunables  0  0  0 : slabdata   4   4  0
sighand_cache 355   405 2112  15  8 : tunables  0  0  0 : slabdata  27  27  0
kmalloc-8192   96   96  8192   4  8 : tunables  0  0  0 : slabdata  24  24  0
...
```

The first line of output includes a version number, which allows an application that is reading the file to handle changes in the file format. (See VERSIONS, below.) The next line lists the names of the columns in the remaining lines.

Each of the remaining lines displays information about a specified cache. Following the cache name, the output shown in each line shows three components for each cache:

- statistics
- tunables
- slabdata

The statistics are as follows:

active_objs
: The number of objects that are currently active (i.e., in use).

num_objs
: The total number of allocated objects (i.e., objects that are both in use and not in use).

objsize The size of objects in this slab, in bytes.

objperslab
: The number of objects stored in each slab.

pagesperslab
: The number of pages allocated for each slab.

The *tunables* entries in each line show tunable parameters for the corresponding cache. When using the default SLUB allocator, there are no tunables, the */proc/slabinfo* file is not writable, and the value 0 is shown in these fields. When using the older SLAB allocator, the tunables for a particular cache can be set by writing lines of the following form to */proc/slabinfo*:

```
# echo 'name limit batchcount sharedfactor' > /proc/slabinfo
```

Here, *name* is the cache name, and *limit*, *batchcount*, and *sharedfactor* are integers defining new values for the corresponding tunables. The *limit* value should be a positive value, *batchcount* should be a positive value that is less than or equal to *limit*, and *sharedfactor* should be nonnegative. If any of the specified values is invalid, the cache settings are left unchanged.

The *tunables* entries in each line contain the following fields:

limit The maximum number of objects that will be cached.

batchcount
: On SMP systems, this specifies the number of objects to transfer at one time when refilling the available object list.

sharedfactor
: [To be documented]

The *slabdata* entries in each line contain the following fields:

active_slabs
The number of active slabs.

nums_slabs
The total number of slabs.

sharedavail
[To be documented]

Note that because of object alignment and slab cache overhead, objects are not normally packed tightly into pages. Pages with even one in-use object are considered in-use and cannot be freed.

Kernels configured with **CONFIG_DEBUG_SLAB** will also have additional statistics fields in each line, and the first line of the file will contain the string "(statistics)". The statistics field include : the high water mark of active objects; the number of times objects have been allocated; the number of times the cache has grown (new pages added to this cache); the number of times the cache has been reaped (unused pages removed from this cache); and the number of times there was an error allocating new pages to this cache.

VERSIONS

The */proc/slabinfo* file first appeared in Linux 2.1.23. The file is versioned, and over time there have been a number of versions with different layouts:

1.0 Present throughout the Linux 2.2.x kernel series.

1.1 Present in the Linux 2.4.x kernel series.

1.2 A format that was briefly present in the Linux 2.5 development series.

2.0 Present in Linux 2.6.x kernels up to and including Linux 2.6.9.

2.1 The current format, which first appeared in Linux 2.6.10.

NOTES

Only root can read and (if the kernel was configured with **CONFIG_SLAB**) write the */proc/slabinfo* file.

The total amount of memory allocated to the SLAB/SLUB cache is shown in the *Slab* field of */proc/meminfo*.

NAME

sysfs − a filesystem for exporting kernel objects

DESCRIPTION

The **sysfs** filesystem is a pseudo-filesystem which provides an interface to kernel data structures. (More precisely, the files and directories in **sysfs** provide a view of the *kobject* structures defined internally within the kernel.) The files under **sysfs** provide information about devices, kernel modules, filesystems, and other kernel components.

The **sysfs** filesystem is commonly mounted at */sys*. Typically, it is mounted automatically by the system, but it can also be mounted manually using a command such as:

```
mount -t sysfs sysfs /sys
```

Many of the files in the **sysfs** filesystem are read-only, but some files are writable, allowing kernel variables to be changed. To avoid redundancy, symbolic links are heavily used to connect entries across the filesystem tree.

Files and directories

The following list describes some of the files and directories under the */sys* hierarchy.

/sys/block
: This subdirectory contains one symbolic link for each block device that has been discovered on the system. The symbolic links point to corresponding directories under */sys/devices*.

/sys/bus
: This directory contains one subdirectory for each of the bus types in the kernel. Inside each of these directories are two subdirectories:

  devices This subdirectory contains symbolic links to entries in */sys/devices* that correspond to the devices discovered on this bus.

  drivers This subdirectory contains one subdirectory for each device driver that is loaded on this bus.

/sys/class
: This subdirectory contains a single layer of further subdirectories for each of the device classes that have been registered on the system (e.g., terminals, network devices, block devices, graphics devices, sound devices, and so on). Inside each of these subdirectories are symbolic links for each of the devices in this class. These symbolic links refer to entries in the */sys/devices* directory.

/sys/class/net
: Each of the entries in this directory is a symbolic link representing one of the real or virtual networking devices that are visible in the network namespace of the process that is accessing the directory. Each of these symbolic links refers to entries in the */sys/devices* directory.

/sys/dev
: This directory contains two subdirectories *block/* and *char/*, corresponding, respectively, to the block and character devices on the system. Inside each of these subdirectories are symbolic links with names of the form *major-ID*:*minor-ID*, where the ID values correspond to the major and minor ID of a specific device. Each symbolic link points to the **sysfs** directory for a device. The symbolic links inside */sys/dev* thus provide an easy way to look up the **sysfs** interface using the device IDs returned by a call to *stat*(2) (or similar).

  The following shell session shows an example from */sys/dev*:

```
$ stat -c "%t %T" /dev/null
1 3
$ readlink /sys/dev/char/1\:3
../../devices/virtual/mem/null
$ ls -Fd /sys/devices/virtual/mem/null
/sys/devices/virtual/mem/null/
$ ls -d1 /sys/devices/virtual/mem/null/*
/sys/devices/virtual/mem/null/dev
/sys/devices/virtual/mem/null/power/
/sys/devices/virtual/mem/null/subsystem@
```

```
/sys/devices/virtual/mem/null/uevent
```

/sys/devices
: This is a directory that contains a filesystem representation of the kernel device tree, which is a hierarchy of *device* structures within the kernel.

/sys/firmware
: This subdirectory contains interfaces for viewing and manipulating firmware-specific objects and attributes.

/sys/fs
: This directory contains subdirectories for some filesystems. A filesystem will have a subdirectory here only if it chose to explicitly create the subdirectory.

/sys/fs/cgroup
: This directory conventionally is used as a mount point for a *tmpfs*(5) filesystem containing mount points for *cgroups*(7) filesystems.

/sys/fs/smackfs
: The directory contains configuration files for the SMACK LSM. See the kernel source file *Documentation/admin−guide/LSM/Smack.rst*.

/sys/hypervisor
: [To be documented]

/sys/kernel
: This subdirectory contains various files and subdirectories that provide information about the running kernel.

/sys/kernel/cgroup/
: For information about the files in this directory, see *cgroups*(7).

/sys/kernel/debug/tracing
: Mount point for the *tracefs* filesystem used by the kernel's *ftrace* facility. (For information on *ftrace*, see the kernel source file *Documentation/trace/ftrace.txt*.)

/sys/kernel/mm
: This subdirectory contains various files and subdirectories that provide information about the kernel's memory management subsystem.

/sys/kernel/mm/hugepages
: This subdirectory contains one subdirectory for each of the huge page sizes that the system supports. The subdirectory name indicates the huge page size (e.g., *hugepages−2048kB*). Within each of these subdirectories is a set of files that can be used to view and (in some cases) change settings associated with that huge page size. For further information, see the kernel source file *Documentation/admin−guide/mm/hugetlbpage.rst*.

/sys/module
: This subdirectory contains one subdirectory for each module that is loaded into the kernel. The name of each directory is the name of the module. In each of the subdirectories, there may be following files:

  coresize
  : [to be documented]

  initsize [to be documented]

  initstate
  : [to be documented]

  refcnt [to be documented]

  srcversion
  : [to be documented]

  taint [to be documented]

  uevent [to be documented]

  version [to be documented]

In each of the subdirectories, there may be following subdirectories:

drivers [To be documented]

holders [To be documented]

notes [To be documented]

parameters
This directory contains one file for each module parameter, with each file containing the value of the corresponding parameter. Some of these files are writable, allowing the

sections
This subdirectories contains files with information about module sections. This information is mainly used for debugging.

NAME

termcap − terminal capability database

DESCRIPTION

The termcap database is an obsolete facility for describing the capabilities of character-cell terminals and printers. It is retained only for compatibility with old programs; new programs should use the *terminfo*(5) database and associated libraries.

/etc/termcap is an ASCII file (the database master) that lists the capabilities of many different types of terminals. Programs can read termcap to find the particular escape codes needed to control the visual attributes of the terminal actually in use. (Other aspects of the terminal are handled by *stty*(1)The termcap database is indexed on the **TERM** environment variable.

Termcap entries must be defined on a single logical line, with '\' used to suppress the newline. Fields are separated by ':'. The first field of each entry starts at the left-hand margin, and contains a list of names for the terminal, separated by '|'.

The first subfield may (in BSD termcap entries from 4.3BSD and earlier) contain a short name consisting of two characters. This short name may consist of capital or small letters. In 4.4BSD, termcap entries this field is omitted.

The second subfield (first, in the newer 4.4BSD format) contains the name used by the environment variable **TERM**. It should be spelled in lowercase letters. Selectable hardware capabilities should be marked by appending a hyphen and a suffix to this name. See below for an example. Usual suffixes are w (more than 80 characters wide), am (automatic margins), nam (no automatic margins), and rv (reverse video display). The third subfield contains a long and descriptive name for this termcap entry.

Subsequent fields contain the terminal capabilities; any continued capability lines must be indented one tab from the left margin.

Although there is no defined order, it is suggested to write first boolean, then numeric, and then string capabilities, each sorted alphabetically without looking at lower or upper spelling. Capabilities of similar functions can be written in one line.

Example for:

Head line: vt|vt101|DEC VT 101 terminal in 80 character mode:\
Head line: Vt|vt101-w|DEC VT 101 terminal in (wide) 132 character mode:\
Boolean: :bs:\
Numeric: :co#80:\
String: :sr=\E[H:\

Boolean capabilities

5i	Printer will not echo on screen
am	Automatic margins which means automatic line wrap
bs	Control-H (8 dec.) performs a backspace
bw	Backspace on left margin wraps to previous line and right margin
da	Display retained above screen
db	Display retained below screen
eo	A space erases all characters at cursor position
es	Escape sequences and special characters work in status line
gn	Generic device
hc	This is a hardcopy terminal
HC	The cursor is hard to see when not on bottom line
hs	Has a status line
hz	Hazeltine bug, the terminal can not print tilde characters
in	Terminal inserts null bytes, not spaces, to fill whitespace
km	Terminal has a meta key
mi	Cursor movement works in insert mode
ms	Cursor movement works in standout/underline mode
NP	No pad character
NR	ti does not reverse te
nx	No padding, must use XON/XOFF
os	Terminal can overstrike
ul	Terminal underlines although it can not overstrike

xb	Beehive glitch, f1 sends ESCAPE, f2 sends **^C**
xn	Newline/wraparound glitch
xo	Terminal uses xon/xoff protocol
xs	Text typed over standout text will be displayed in standout
xt	Teleray glitch, destructive tabs and odd standout mode

Numeric capabilities

co	Number of columns
dB	Delay in milliseconds for backspace on hardcopy terminals
dC	Delay in milliseconds for carriage return on hardcopy terminals
dF	Delay in milliseconds for form feed on hardcopy terminals
dN	Delay in milliseconds for new line on hardcopy terminals
dT	Delay in milliseconds for tabulator stop on hardcopy terminals
dV	Delay in milliseconds for vertical tabulator stop on hardcopy terminals
it	Difference between tab positions
lh	Height of soft labels
lm	Lines of memory
lw	Width of soft labels
li	Number of lines
Nl	Number of soft labels
pb	Lowest baud rate which needs padding
sg	Standout glitch
ug	Underline glitch
vt	virtual terminal number
ws	Width of status line if different from screen width

String capabilities

!1	shifted save key
!2	shifted suspend key
!3	shifted undo key
#1	shifted help key
#2	shifted home key
#3	shifted input key
#4	shifted cursor left key
%0	redo key

%5	next-object key
%6	open key
%7	options key
%8	previous-object key
%9	print key
%a	shifted message key
%b	shifted move key
%c	shifted next key
%d	shifted options key
%e	shifted previous key
%f	shifted print key
%g	shifted redo key
%h	shifted replace key
%i	shifted cursor right key
%j	shifted resume key
&0	shifted cancel key
&1	reference key
&2	refresh key
&3	replace key
&4	restart key

&5	resume key
&6	save key
&7	suspend key
&8	undo key
&9	shifted begin key
*0	shifted find key
*1	shifted command key
*2	shifted copy key
*3	shifted create key
*4	shifted delete character
*5	shifted delete line
*6	select key
*7	shifted end key
*8	shifted clear line key
*9	shifted exit key
@0	find key
@1	begin key
@2	cancel key
@3	close key
@4	command key
@5	copy key
@6	create key
@7	end key
@8	enter/send key
@9	exit key
al	Insert one line
AL	Insert %1 lines
ac	Pairs of block graphic characters to map alternate character set
ae	End alternative character set
as	Start alternative character set for block graphic characters
bc	Backspace, if not **^H**
bl	Audio bell
bt	Move to previous tab stop
cb	Clear from beginning of line to cursor
cc	Dummy command character
cd	Clear to end of screen
ce	Clear to end of line
ch	Move cursor horizontally only to column %1
cl	Clear screen and cursor home
cm	Cursor move to row %1 and column %2 (on screen)
CM	Move cursor to row %1 and column %2 (in memory)
cr	Carriage return
cs	Scroll region from line %1 to %2
ct	Clear tabs
cv	Move cursor vertically only to line %1
dc	Delete one character
DC	Delete %1 characters
dl	Delete one line
DL	Delete %1 lines
dm	Begin delete mode
do	Cursor down one line
DO	Cursor down #1 lines
ds	Disable status line
eA	Enable alternate character set
ec	Erase %1 characters starting at cursor
ed	End delete mode
ei	End insert mode
ff	Formfeed character on hardcopy terminals
fs	Return character to its position before going to status line

ke	turn keypad off
kE	Key for clear to end of line
kF	Key for scrolling forward/down
kh	Cursor home key
kH	Cursor hown down key
kI	Insert character/Insert mode key
kl	Cursor left key
kL	Key for delete line
kM	Key for exit insert mode
kN	Key for next page
kP	Key for previous page

kr	Cursor right key
kR	Key for scrolling backward/up
ks	Turn keypad on
kS	Clear to end of screen key
kt	Clear this tab key
kT	Set tab here key
ku	Cursor up key
l0	Label of zeroth function key, if not f0
l1	Label of first function key, if not f1
l2	Label of first function key, if not f2
...	...
la	Label of tenth function key, if not f10
le	Cursor left one character
ll	Move cursor to lower left corner
LE	Cursor left %1 characters
LF	Turn soft labels off
LO	Turn soft labels on
mb	Start blinking
MC	Clear soft margins
md	Start bold mode
me	End all mode like so, us, mb, md, and mr
mh	Start half bright mode
mk	Dark mode (Characters invisible)
ML	Set left soft margin
mm	Put terminal in meta mode
mo	Put terminal out of meta mode
mp	Turn on protected attribute
mr	Start reverse mode
MR	Set right soft margin
nd	Cursor right one character
nw	Carriage return command
pc	Padding character
pf	Turn printer off
pk	Program key %1 to send string %2 as if typed by user
pl	Program key %1 to execute string %2 in local mode
pn	Program soft label %1 to show string %2
po	Turn the printer on
pO	Turn the printer on for %1 (<256) bytes
ps	Print screen contents on printer
px	Program key %1 to send string %2 to computer
r1	Reset string 1 to set terminal to sane modes
r2	Reset string 2 to set terminal to sane modes
r3	Reset string 3 to set terminal to sane modes
RA	disable automatic margins
rc	Restore saved cursor position
rf	Reset string filename
RF	Request for input from terminal
RI	Cursor right %1 characters
rp	Repeat character %1 for %2 times
rP	Padding after character sent in replace mode
rs	Reset string
RX	Turn off XON/XOFF flow control
sa	Set %1 %2 %3 %4 %5 %6 %7 %8 %9 attributes
SA	enable automatic margins
sc	Save cursor position
se	End standout mode
sf	Normal scroll one line
SF	Normal scroll %1 lines
so	Start standout mode

sr Reverse scroll
SR scroll back %1 lines
st Set tabulator stop in all rows at current column
SX Turn on XON/XOFF flow control
ta move to next hardware tab
tc Read in terminal description from another entry
te End program that uses cursor motion
ti Begin program that uses cursor motion
ts Move cursor to column %1 of status line
uc Underline character under cursor and move cursor right
ue End underlining
up Cursor up one line
UP Cursor up %1 lines
us Start underlining
vb Visible bell
ve Normal cursor visible
vi Cursor invisible
vs Standout cursor
wi Set window from line %1 to %2 and column %3 to %4
XF XOFF character if not **^S**

There are several ways of defining the control codes for string capabilities:

Every normal character represents itself, except '^', '\', and '%'.

A **^x** means Control-x. Control-A equals 1 decimal.

\x means a special code. x can be one of the following characters:
E Escape (27)
n Linefeed (10)
r Carriage return (13)
t Tabulation (9)
b Backspace (8)
f Form feed (12)
0 Null character. A \xxx specifies the octal character xxx.

i Increments parameters by one.

r Single parameter capability

\+ Add value of next character to this parameter and do binary output

2 Do ASCII output of this parameter with a field with of 2

d Do ASCII output of this parameter with a field with of 3

% Print a '%'

If you use binary output, then you should avoid the null character ('\0') because it terminates the string. You should reset tabulator expansion if a tabulator can be the binary output of a parameter.

Warning:
The above metacharacters for parameters may be wrong: they document Minix termcap which may not be compatible with Linux termcap.

The block graphic characters can be specified by three string capabilities:

as start the alternative charset

ae end the alternative charset

ac pairs of characters. The first character is the name of the block graphic symbol and the second characters is its definition.

The following names are available:

\+ right arrow (>)
, left arrow (<)
. down arrow (v)

0	full square (#)
I	lantern (#)
-	upper arrow (^)
’	rhombus (+)
a	chess board (:)
f	degree (’)
g	plus-minus (#)
h	square (#)
j	right bottom corner (+)
k	right upper corner (+)
l	left upper corner (+)
m	left bottom corner (+)
n	cross (+)
o	upper horizontal line (-)
q	middle horizontal line (-)
s	bottom horizontal line (_)
t	left tee (+)
u	right tee (+)
v	bottom tee (+)
w	normal tee (+)
x	vertical line (|)
~	paragraph (???)

The values in parentheses are suggested defaults which are used by the *curses* library, if the capabilities are missing.

NAME

tmpfs − a virtual memory filesystem

DESCRIPTION

The **tmpfs** facility allows the creation of filesystems whose contents reside in virtual memory. Since the files on such filesystems typically reside in RAM, file access is extremely fast.

The filesystem is automatically created when mounting a filesystem with the type **tmpfs** via a command such as the following:

```
$ sudo mount −t tmpfs −o size=10M tmpfs /mnt/mytmpfs
```

A **tmpfs** filesystem has the following properties:

- The filesystem can employ swap space when physical memory pressure demands it.
- The filesystem consumes only as much physical memory and swap space as is required to store the current contents of the filesystem.
- During a remount operation (*mount −o remount*), the filesystem size can be changed (without losing the existing contents of the filesystem).

If a **tmpfs** filesystem is unmounted, its contents are discarded (lost).

Mount options

The **tmpfs** filesystem supports the following mount options:

size=*bytes*
: Specify an upper limit on the size of the filesystem. The size is given in bytes, and rounded up to entire pages. The limit is removed if the size is **0**.

  The size may have a **k**, **m**, or **g** suffix for Ki, Mi, Gi (binary kilo (kibi), binary mega (mebi), and binary giga (gibi)).

  The size may also have a % suffix to limit this instance to a percentage of physical RAM.

  The default, when neither **size** nor **nr_blocks** is specified, is *size=50%*.

nr_blocks=*blocks*
: The same as **size**, but in blocks of **PAGE_CACHE_SIZE**.

  Blocks may be specified with **k**, **m**, or **g** suffixes like **size**, but not a % suffix.

nr_inodes=*inodes*
: The maximum number of inodes for this instance. The default is half of the number of your physical RAM pages, or (on a machine with highmem) the number of lowmem RAM pages, whichever is smaller. The limit is removed if the number is **0**.

  Inodes may be specified with **k**, **m**, or **g** suffixes like **size**, but not a % suffix.

noswap(since Linux 6.4)
: Disables swap. Remounts must respect the original settings. By default swap is enabled.

mode=*mode*
: Set initial permissions of the root directory.

gid=*gid* (since Linux 2.5.7)
: Set the initial group ID of the root directory.

uid=*uid* (since Linux 2.5.7)
: Set the initial user ID of the root directory.

huge=*huge_option* (since Linux 4.7.0)
: Set the huge table memory allocation policy for all files in this instance (if **CONFIG_TRANSPARENT_HUGEPAGE** is enabled).

  The *huge_option* value is one of the following:

  never Do not allocate huge pages. This is the default.

  always Attempt to allocate huge pages every time a new page is needed.

within_size
Only allocate huge page if it will be fully within *i_size*. Also respect *fadvise*(2) and *madvise*(2) hints

advise Only allocate huge pages if requested with *fadvise*(2) or *madvise*(2).

deny For use in emergencies, to force the huge option off from all mounts.

force Force the huge option on for all mounts; useful for testing.

mpol=*mpol_option* (since Linux 2.6.15)
Set the NUMA memory allocation policy for all files in this instance (if **CONFIG_NUMA** is enabled).

The *mpol_option* value is one of the following:

default Use the process allocation policy (see *set_mempolicy*(2)).

prefer:*node*
Preferably allocate memory from the given *node*.

bind:*nodelist*
Allocate memory only from nodes in *nodelist*.

interleave
Allocate from each node in turn.

interleave:*nodelist*
Allocate from each node of *in* turn.

local Preferably allocate memory from the local node.

In the above, *nodelist* is a comma-separated list of decimal numbers and ranges that specify NUMA nodes. A range is a pair of hyphen-separated decimal numbers, the smallest and largest node numbers in the range. For example, *mpol=bind:0−3,5,7,9−15*.

VERSIONS

The **tmpfs** facility was added in Linux 2.4, as a successor to the older **ramfs** facility, which did not provide limit checking or allow for the use of swap space.

NOTES

In order for user-space tools and applications to create **tmpfs** filesystems, the kernel must be configured with the **CONFIG_TMPFS** option.

The **tmpfs** filesystem supports extended attributes (see *xattr*(7)), but *user* extended attributes are not permitted.

An internal shared memory filesystem is used for System V shared memory (**shmget**(2)) and shared anonymous mappings (**mmap**(2) with the **MAP_SHARED** and **MAP_ANONYMOUS** flags). This filesystem is available regardless of whether the kernel was configured with the **CONFIG_TMPFS** option.

A **tmpfs** filesystem mounted at */dev/shm* is used for the implementation of POSIX shared memory (**shm_overview**(7)) and POSIX semaphores (**sem_overview**(7)).

The amount of memory consumed by all **tmpfs** filesystems is shown in the *Shmem* field of */proc/meminfo* and in the *shared* field displayed by *free*(1)

The **tmpfs** facility was formerly called **shmfs**.

NAME

ttytype − terminal device to default terminal type mapping

DESCRIPTION

The */etc/ttytype* file associates *termcap*(5) and *terminfo*(5) terminal type names with tty lines. Each line consists of a terminal type, followed by whitespace, followed by a tty name (a device name without the */dev/* prefix).

This association is used by the program *tset*(1) to set the environment variable **TERM** to the default terminal name for the user's current tty.

This facility was designed for a traditional time-sharing environment featuring character-cell terminals hardwired to a UNIX minicomputer. It is little used on modern workstation and personal UNIX systems.

FILES

/etc/ttytype
: the tty definitions file.

EXAMPLES

A typical */etc/ttytype* is:

```
con80x25 tty1
vt320 ttys0
```

SEE ALSO

termcap(5), *terminfo*(5), *agetty*(8), *mingetty*(8)

NAME

tzfile − timezone information

DESCRIPTION

The timezone information files used by *tzset*(3) are typically found under a directory with a name like */usr/share/zoneinfo*. These files use the format described in Internet RFC 8536. Each file is a sequence of 8-bit bytes. In a file, a binary integer is represented by a sequence of one or more bytes in network order (bigendian, or high-order byte first), with all bits significant, a signed binary integer is represented using two's complement, and a boolean is represented by a one-byte binary integer that is either 0 (false) or 1 (true). The format begins with a 44-byte header containing the following fields:

- The magic four-byte ASCII sequence "TZif" identifies the file as a timezone information file.
- A byte identifying the version of the file's format (as of 2021, either an ASCII NUL, "2", "3", or "4").
- Fifteen bytes containing zeros reserved for future use.
- Six four-byte integer values, in the following order:

  tzh_ttisutcnt
  The number of UT/local indicators stored in the file. (UT is Universal Time.)

  tzh_ttisstdcnt
  The number of standard/wall indicators stored in the file.

  tzh_leapcnt
  The number of leap seconds for which data entries are stored in the file.

  tzh_timecnt
  The number of transition times for which data entries are stored in the file.

  tzh_typecnt
  The number of local time types for which data entries are stored in the file (must not be zero).

  tzh_charcnt
  The number of bytes of time zone abbreviation strings stored in the file.

The above header is followed by the following fields, whose lengths depend on the contents of the header:

- **tzh_timecnt** four-byte signed integer values sorted in ascending order. These values are written in network byte order. Each is used as a transition time (as returned by *time*(2)) at which the rules for computing local time change.
- **tzh_timecnt** one-byte unsigned integer values; each one but the last tells which of the different types of local time types described in the file is associated with the time period starting with the same-indexed transition time and continuing up to but not including the next transition time. (The last time type is present only for consistency checking with the POSIX.1-2017-style TZ string described below.) These values serve as indices into the next field.
- **tzh_typecnt ttinfo** entries, each defined as follows:

```
struct ttinfo {
        int32_t         tt_utoff;
        unsigned char   tt_isdst;
        unsigned char   tt_desigidx;
};
```

  Each structure is written as a four-byte signed integer value for **tt_utoff**, in network byte order, followed by a one-byte boolean for **tt_isdst** and a one-byte value for **tt_desigidx**. In each structure, **tt_utoff** gives the number of seconds to be added to UT, **tt_isdst** tells whether **tm_isdst** should be set by *localtime*(3) and **tt_desigidx** serves as an index into the array of time zone abbreviation bytes that follow the **ttinfo** entries in the file; if the designated string is "-00", the **ttinfo** entry is a placeholder indicating that local time is unspecified. The **tt_utoff** value is never equal to −2**31, to let 32-bit clients negate it without overflow. Also, in realistic applications **tt_utoff** is in the range [−89999, 93599] (i.e., more than −25 hours and less than 26 hours); this allows easy support by implementations that already support the POSIX-required range

[−24:59:59, 25:59:59].

- **tzh_charcnt** bytes that represent time zone designations, which are null-terminated byte strings, each indexed by the **tt_desigidx** values mentioned above. The byte strings can overlap if one is a suffix of the other. The encoding of these strings is not specified.
- **tzh_leapcnt** pairs of four-byte values, written in network byte order; the first value of each pair gives the nonnegative time (as returned by *time*(2)) at which a leap second occurs or at which the leap second table expires; the second is a signed integer specifying the correction, which is the *total* number of leap seconds to be applied during the time period starting at the given time. The pairs of values are sorted in strictly ascending order by time. Each pair denotes one leap second, either positive or negative, except that if the last pair has the same correction as the previous one, the last pair denotes the leap second table's expiration time. Each leap second is at the end of a UTC calendar month. The first leap second has a nonnegative occurrence time, and is a positive leap second if and only if its correction is positive; the correction for each leap second after the first differs from the previous leap second by either 1 for a positive leap second, or −1 for a negative leap second. If the leap second table is empty, the leap-second correction is zero for all timestamps; otherwise, for timestamps before the first occurrence time, the leap-second correction is zero if the first pair's correction is 1 or −1, and is unspecified otherwise (which can happen only in files truncated at the start).
- **tzh_ttisstdcnt** standard/wall indicators, each stored as a one-byte boolean; they tell whether the transition times associated with local time types were specified as standard time or local (wall clock) time.
- **tzh_ttisutcnt** UT/local indicators, each stored as a one-byte boolean; they tell whether the transition times associated with local time types were specified as UT or local time. If a UT/local indicator is set, the corresponding standard/wall indicator must also be set.

The standard/wall and UT/local indicators were designed for transforming a TZif file's transition times into transitions appropriate for another time zone specified via a POSIX.1-2017-style TZ string that lacks rules. For example, when TZ="EET-2EEST" and there is no TZif file "EET-2EEST", the idea was to adapt the transition times from a TZif file with the well-known name "posixrules" that is present only for this purpose and is a copy of the file "Europe/Brussels", a file with a different UT offset. POSIX does not specify this obsolete transformational behavior, the default rules are installation-dependent, and no implementation is known to support this feature for timestamps past 2037, so users desiring (say) Greek time should instead specify TZ="Europe/Athens" for better historical coverage, falling back on TZ="EET-2EEST,M3.5.0/3,M10.5.0/4" if POSIX conformance is required and older timestamps need not be handled accurately.

The *localtime*(3) function normally uses the first **ttinfo** structure in the file if either **tzh_timecnt** is zero or the time argument is less than the first transition time recorded in the file.

Version 2 format

For version-2-format timezone files, the above header and data are followed by a second header and data, identical in format except that eight bytes are used for each transition time or leap second time. (Leap second counts remain four bytes.) After the second header and data comes a newline-enclosed string in the style of the contents of a POSIX.1-2017 TZ environment variable, for use in handling instants after the last transition time stored in the file or for all instants if the file has no transitions. The TZ string is empty (i.e., nothing between the newlines) if there is no POSIX.1-2017-style representation for such instants. If nonempty, the TZ string must agree with the local time type after the last transition time if present in the eight-byte data; for example, given the string "WET0WEST,M3.5.0/1,M10.5.0" then if a last transition time is in July, the transition's local time type must specify a daylight-saving time abbreviated "WEST" that is one hour east of UT. Also, if there is at least one transition, time type 0 is associated with the time period from the indefinite past up to but not including the earliest transition time.

Version 3 format

For version-3-format timezone files, the TZ string may use two minor extensions to the POSIX.1-2017 TZ format, as described in *newtzset*(3)First, the hours part of its transition times may be signed and range from −167 through 167 instead of the POSIX-required unsigned values from 0 through 24. Second, DST is in effect all year if it starts January 1 at 00:00 and ends December 31 at 24:00 plus the difference between daylight saving and standard time.

Version 4 format

For version-4-format TZif files, the first leap second record can have a correction that is neither +1 nor −1, to represent truncation of the TZif file at the start. Also, if two or more leap second transitions are present and the last entry's correction equals the previous one, the last entry denotes the expiration of the leap second table instead of a leap second; timestamps after this expiration are unreliable in that future releases will likely add leap second entries after the expiration, and the added leap seconds will change how post-expiration timestamps are treated.

Interoperability considerations

Future changes to the format may append more data.

Version 1 files are considered a legacy format and should not be generated, as they do not support transition times after the year 2038. Readers that understand only Version 1 must ignore any data that extends beyond the calculated end of the version 1 data block.

Other than version 1, writers should generate the lowest version number needed by a file's data. For example, a writer should generate a version 4 file only if its leap second table either expires or is truncated at the start. Likewise, a writer not generating a version 4 file should generate a version 3 file only if TZ string extensions are necessary to accurately model transition times.

The sequence of time changes defined by the version 1 header and data block should be a contiguous sub-sequence of the time changes defined by the version 2+ header and data block, and by the footer. This guideline helps obsolescent version 1 readers agree with current readers about timestamps within the contiguous sub-sequence. It also lets writers not supporting obsolescent readers use a **tzh_timecnt** of zero in the version 1 data block to save space.

When a TZif file contains a leap second table expiration time, TZif readers should either refuse to process post-expiration timestamps, or process them as if the expiration time did not exist (possibly with an error indication).

Time zone designations should consist of at least three (3) and no more than six (6) ASCII characters from the set of alphanumerics, "-", and "+". This is for compatibility with POSIX requirements for time zone abbreviations.

When reading a version 2 or higher file, readers should ignore the version 1 header and data block except for the purpose of skipping over them.

Readers should calculate the total lengths of the headers and data blocks and check that they all fit within the actual file size, as part of a validity check for the file.

When a positive leap second occurs, readers should append an extra second to the local minute containing the second just before the leap second. If this occurs when the UTC offset is not a multiple of 60 seconds, the leap second occurs earlier than the last second of the local minute and the minute's remaining local seconds are numbered through 60 instead of the usual 59; the UTC offset is unaffected.

Common interoperability issues

This section documents common problems in reading or writing TZif files. Most of these are problems in generating TZif files for use by older readers. The goals of this section are:

- to help TZif writers output files that avoid common pitfalls in older or buggy TZif readers,
- to help TZif readers avoid common pitfalls when reading files generated by future TZif writers, and
- to help any future specification authors see what sort of problems arise when the TZif format is changed.

When new versions of the TZif format have been defined, a design goal has been that a reader can successfully use a TZif file even if the file is of a later TZif version than what the reader was designed for. When complete compatibility was not achieved, an attempt was made to limit glitches to rarely used timestamps and allow simple partial workarounds in writers designed to generate new-version data useful even for older-version readers. This section attempts to document these compatibility issues and workarounds, as well as to document other common bugs in readers.

Interoperability problems with TZif include the following:

- Some readers examine only version 1 data. As a partial workaround, a writer can output as much version 1 data as possible. However, a reader should ignore version 1 data, and should use version 2+ data even if the reader's native timestamps have only 32 bits.
- Some readers designed for version 2 might mishandle timestamps after a version 3 or higher file's last transition, because they cannot parse extensions to POSIX.1-2017 in the TZ-like string. As a partial workaround, a writer can output more transitions than necessary, so that only far-future timestamps are mishandled by version 2 readers.
- Some readers designed for version 2 do not support permanent daylight saving time with transitions after 24:00 – e.g., a TZ string "EST5EDT,0/0,J365/25" denoting permanent Eastern Daylight Time (−04). As a workaround, a writer can substitute standard time for two time zones east, e.g., "XXX3EDT4,0/0,J365/23" for a time zone with a never-used standard time (XXX, −03) and negative daylight saving time (EDT, −04) all year. Alternatively, as a partial workaround a writer can substitute standard time for the next time zone east – e.g., "AST4" for permanent Atlantic Standard Time (−04).
- Some readers designed for version 2 or 3, and that require strict conformance to RFC 8536, reject version 4 files whose leap second tables are truncated at the start or that end in expiration times.
- Some readers ignore the footer, and instead predict future timestamps from the time type of the last transition. As a partial workaround, a writer can output more transitions than necessary.
- Some readers do not use time type 0 for timestamps before the first transition, in that they infer a time type using a heuristic that does not always select time type 0. As a partial workaround, a writer can output a dummy (no-op) first transition at an early time.
- Some readers mishandle timestamps before the first transition that has a timestamp not less than −2**31. Readers that support only 32-bit timestamps are likely to be more prone to this problem, for example, when they process 64-bit transitions only some of which are representable in 32 bits. As a partial workaround, a writer can output a dummy transition at timestamp −2**31.
- Some readers mishandle a transition if its timestamp has the minimum possible signed 64-bit value. Timestamps less than −2**59 are not recommended.
- Some readers mishandle TZ strings that contain "<" or ">". As a partial workaround, a writer can avoid using "<" or ">" for time zone abbreviations containing only alphabetic characters.
- Many readers mishandle time zone abbreviations that contain non-ASCII characters. These characters are not recommended.
- Some readers may mishandle time zone abbreviations that contain fewer than 3 or more than 6 characters, or that contain ASCII characters other than alphanumerics, "-", and "+". These abbreviations are not recommended.
- Some readers mishandle TZif files that specify daylight-saving time UT offsets that are less than the UT offsets for the corresponding standard time. These readers do not support locations like Ireland, which uses the equivalent of the TZ string "IST-1GMT0,M10.5.0,M3.5.0/1", observing standard time (IST, +01) in summer and daylight saving time (GMT, +00) in winter. As a partial workaround, a writer can output data for the equivalent of the TZ string "GMT0IST,M3.5.0/1,M10.5.0", thus swapping standard and daylight saving time. Although this workaround misidentifies which part of the year uses daylight saving time, it records UT offsets and time zone abbreviations correctly.
- Some readers generate ambiguous timestamps for positive leap seconds that occur when the UTC offset is not a multiple of 60 seconds. For example, in a timezone with UTC offset +01:23:45 and with a positive leap second 78796801 (1972-06-30 23:59:60 UTC), some readers will map both 78796800 and 78796801 to 01:23:45 local time the next day instead of mapping the latter to 01:23:46, and they will map 78796815 to 01:23:59 instead of to 01:23:60. This has not yet been a practical problem, since no civil authority has observed such UTC offsets since leap seconds were introduced in 1972.

Some interoperability problems are reader bugs that are listed here mostly as warnings to developers of readers.

- Some readers do not support negative timestamps. Developers of distributed applications should keep this in mind if they need to deal with pre-1970 data.
- Some readers mishandle timestamps before the first transition that has a nonnegative timestamp. Readers that do not support negative timestamps are likely to be more prone to this problem.
- Some readers mishandle time zone abbreviations like "-08" that contain "+", "-", or digits.
- Some readers mishandle UT offsets that are out of the traditional range of −12 through +12 hours, and so do not support locations like Kiritimati that are outside this range.
- Some readers mishandle UT offsets in the range [−3599, −1] seconds from UT, because they integer-divide the offset by 3600 to get 0 and then display the hour part as "+00".
- Some readers mishandle UT offsets that are not a multiple of one hour, or of 15 minutes, or of 1 minute.

NAME

utmp, wtmp − login records

SYNOPSIS

#include <utmp.h>

DESCRIPTION

The *utmp* file allows one to discover information about who is currently using the system. There may be more users currently using the system, because not all programs use utmp logging.

Warning: *utmp* must not be writable by the user class "other", because many system programs (foolishly) depend on its integrity. You risk faked system logfiles and modifications of system files if you leave *utmp* writable to any user other than the owner and group owner of the file.

The file is a sequence of *utmp* structures, declared as follows in <*utmp.h*> (note that this is only one of several definitions around; details depend on the version of libc):

```
/* Values for ut_type field, below */

#define EMPTY         0 /* Record does not contain valid info
                           (formerly known as UT_UNKNOWN on Linux) */
#define RUN_LVL       1 /* Change in system run-level (see
                           init(1)) */
#define BOOT_TIME     2 /* Time of system boot (in ut_tv) */
#define NEW_TIME      3 /* Time after system clock change
                           (in ut_tv) */
#define OLD_TIME      4 /* Time before system clock change
                           (in ut_tv) */
#define INIT_PROCESS  5 /* Process spawned by init(1) */
#define LOGIN_PROCESS 6 /* Session leader process for user login */
#define USER_PROCESS  7 /* Normal process */
#define DEAD_PROCESS  8 /* Terminated process */
#define ACCOUNTING    9 /* Not implemented */

#define UT_LINESIZE      32
#define UT_NAMESIZE      32
#define UT_HOSTSIZE     256

struct exit_status {              /* Type for ut_exit, below */
    short e_termination;          /* Process termination status */
    short e_exit;                 /* Process exit status */
};

struct utmp {
    short   ut_type;              /* Type of record */
    pid_t   ut_pid;               /* PID of login process */
    char    ut_line[UT_LINESIZE]; /* Device name of tty - "/dev/" */
    char    ut_id[4];             /* Terminal name suffix,
                                     or inittab(5) ID */
    char    ut_user[UT_NAMESIZE]; /* Username */
    char    ut_host[UT_HOSTSIZE]; /* Hostname for remote login, or
                                     kernel version for run-level
                                     messages */
    struct  exit_status ut_exit;  /* Exit status of a process
                                     marked as DEAD_PROCESS; not
                                     used by Linux init(1) */
    /* The ut_session and ut_tv fields must be the same size when
       compiled 32- and 64-bit.  This allows data files and shared
       memory to be shared between 32- and 64-bit applications. */
#if __WORDSIZE == 64 && defined __WORDSIZE_COMPAT32
    int32_t ut_session;           /* Session ID (getsid(2)),
                                     used for windowing */
```

```
    struct {
        int32_t tv_sec;         /* Seconds */
        int32_t tv_usec;        /* Microseconds */
    } ut_tv;                    /* Time entry was made */
#else
     long   ut_session;         /* Session ID */
     struct timeval ut_tv;      /* Time entry was made */
#endif

    int32_t ut_addr_v6[4];      /* Internet address of remote
                                   host; IPv4 address uses
                                   just ut_addr_v6[0] */
    char __unused[20];          /* Reserved for future use */
};

/* Backward compatibility hacks */
#define ut_name ut_user
#ifndef _NO_UT_TIME
#define ut_time ut_tv.tv_sec
#endif
#define ut_xtime ut_tv.tv_sec
#define ut_addr ut_addr_v6[0]
```

This structure gives the name of the special file associated with the user's terminal, the user's login name, and the time of login in the form of *time*(2). String fields are terminated by a null byte ('\0') if they are shorter than the size of the field.

The first entries ever created result from *init*(1) processing *inittab*(5)Before an entry is processed, though, *init*(1) cleans up utmp by setting *ut_type* to **DEAD_PROCESS**, clearing *ut_user*, *ut_host*, and *ut_time* with null bytes for each record which *ut_type* is not **DEAD_PROCESS** or **RUN_LVL** and where no process with PID *ut_pid* exists. If no empty record with the needed *ut_id* can be found, *init*(1) creates a new one. It sets *ut_id* from the inittab, *ut_pid* and *ut_time* to the current values, and *ut_type* to **INIT_PROCESS**.

mingetty(8) (or *agetty*(8)) locates the entry by the PID, changes *ut_type* to **LOGIN_PROCESS**, changes *ut_time*, sets *ut_line*, and waits for connection to be established. *login*(1), after a user has been authenticated, changes *ut_type* to **USER_PROCESS**, changes *ut_time*, and sets *ut_host* and *ut_addr*. Depending on *mingetty*(8) (or *agetty*(8)) and *login*(1), records may be located by *ut_line* instead of the preferable *ut_pid*.

When *init*(1) finds that a process has exited, it locates its utmp entry by *ut_pid*, sets *ut_type* to **DEAD_PROCESS**, and clears *ut_user*, *ut_host*, and *ut_time* with null bytes.

xterm(1) and other terminal emulators directly create a **USER_PROCESS** record and generate the *ut_id* by using the string that suffix part of the terminal name (the characters following */dev/*[pt]*ty*). If they find a **DEAD_PROCESS** for this ID, they recycle it, otherwise they create a new entry. If they can, they will mark it as **DEAD_PROCESS** on exiting and it is advised that they null *ut_line*, *ut_time*, *ut_user*, and *ut_host* as well.

telnetd(8) sets up a **LOGIN_PROCESS** entry and leaves the rest to *login*(1) as usual. After the telnet session ends, *telnetd*(8) cleans up utmp in the described way.

The *wtmp* file records all logins and logouts. Its format is exactly like *utmp* except that a null username indicates a logout on the associated terminal. Furthermore, the terminal name ~ with username **shutdown** or **reboot** indicates a system shutdown or reboot and the pair of terminal names |/**}** logs the old/new system time when *date*(1) changes it. *wtmp* is maintained by *login*(1), *init*(1), and some versions of *getty*(8) (e.g., *mingetty*(8) or *agetty*(8)). None of these programs creates the file, so if it is removed, record-keeping is turned off.

FILES

/var/run/utmp
/var/log/wtmp

VERSIONS

POSIX.1 does not specify a *utmp* structure, but rather one named *utmpx* (as part of the XSI extension), with specifications for the fields *ut_type*, *ut_pid*, *ut_line*, *ut_id*, *ut_user*, and *ut_tv*. POSIX.1 does not specify the lengths of the *ut_line* and *ut_user* fields.

Linux defines the *utmpx* structure to be the same as the *utmp* structure.

STANDARDS

Linux.

HISTORY

Linux utmp entries conform neither to v7/BSD nor to System V; they are a mix of the two.

v7/BSD has fewer fields; most importantly it lacks *ut_type*, which causes native v7/BSD-like programs to display (for example) dead or login entries. Further, there is no configuration file which allocates slots to sessions. BSD does so because it lacks *ut_id* fields.

In Linux (as in System V), the *ut_id* field of a record will never change once it has been set, which reserves that slot without needing a configuration file. Clearing *ut_id* may result in race conditions leading to corrupted utmp entries and potential security holes. Clearing the abovementioned fields by filling them with null bytes is not required by System V semantics, but makes it possible to run many programs which assume BSD semantics and which do not modify utmp. Linux uses the BSD conventions for line contents, as documented above.

System V has no *ut_host* or *ut_addr_v6* fields.

NOTES

Unlike various other systems, where utmp logging can be disabled by removing the file, utmp must always exist on Linux. If you want to disable *who*(1), then do not make utmp world readable.

The file format is machine-dependent, so it is recommended that it be processed only on the machine architecture where it was created.

Note that on *biarch* platforms, that is, systems which can run both 32-bit and 64-bit applications (x86-64, ppc64, s390x, etc.), *ut_tv* is the same size in 32-bit mode as in 64-bit mode. The same goes for *ut_session* and *ut_time* if they are present. This allows data files and shared memory to be shared between 32-bit and 64-bit applications. This is achieved by changing the type of *ut_session* to *int32_t*, and that of *ut_tv* to a struct with two *int32_t* fields *tv_sec* and *tv_usec*. Since *ut_tv* may not be the same as *struct timeval*, then instead of the call:

```
gettimeofday((struct timeval *) &ut.ut_tv, NULL);
```

the following method of setting this field is recommended:

```
struct utmp ut;
struct timeval tv;

gettimeofday(&tv, NULL);
ut.ut_tv.tv_sec = tv.tv_sec;
ut.ut_tv.tv_usec = tv.tv_usec;
```

NAME

address_families − socket address families (domains)

SYNOPSIS

#include <sys/types.h> /* See NOTES */
#include <sys/socket.h>

int socket(int *domain***, int** *type***, int** *protocol***);**

DESCRIPTION

The *domain* argument of the *socket*(2) specifies a communication domain; this selects the protocol family which will be used for communication. These families are defined in <*sys/socket.h*>. The formats currently understood by the Linux kernel include:

AF_UNIX
AF_LOCAL
Local communication. For further information, see *unix*(7).

AF_INET
IPv4 Internet protocols. For further information, see *ip*(7).

AF_AX25
Amateur radio AX.25 protocol. For further information, see *ax25*(4)

AF_IPX
IPX − Novell protocols.

AF_APPLETALK
AppleTalk For further information, see *ddp*(7).

AF_NETROM
AX.25 packet layer protocol. For further information, see *netrom*(4), *The Packet Radio Protocols and Linux* and the *AX.25*, *NET/ROM*, and *ROSE network programming* chapters of the *Linux Amateur Radio AX.25 HOWTO*.

AF_BRIDGE
Can't be used for creating sockets; mostly used for bridge links in *rtnetlink*(7) protocol commands.

AF_ATMPVC
Access to raw ATM Permanent Virtual Circuits (PVCs). For further information, see the *ATM on Linux HOWTO*.

AF_X25
ITU-T X.25 / ISO/IEC 8208 protocol. For further information, see *x25*(7).

AF_INET6
IPv6 Internet protocols. For further information, see *ipv6*(7).

AF_ROSE
RATS (Radio Amateur Telecommunications Society). Open Systems environment (ROSE) AX.25 packet layer protocol. For further information, see the resources listed for **AF_NETROM**.

AF_DECnet
DECet protocol sockets. See *Documentation/networking/decnet.txt* in the Linux kernel source tree for details.

AF_NETBEUI
Reserved for "802.2LLC project"; never used.

AF_SECURITY
This was a short-lived (between Linux 2.1.30 and 2.1.99pre2) protocol family for firewall upcalls.

AF_KEY
Key management protocol, originally developed for usage with IPsec (since Linux 2.1.38). This has no relation to *keyctl*(2) and the in-kernel key storage facility. See RFC 2367 *PF_KEY Key Management API, Version 2* for details.

AF_NETLINK
Kernel user interface device. For further information, see *netlink*(7).

AF_PACKET
Low-level packet interface. For further information, see *packet*(7).

AF_ECONET
Acorn Econet protocol (removed in Linux 3.5). See the Econet documentation for details.

AF_ATMSVC
Access to ATM Switched Virtual Circuits (SVCs) See the *ATM on Linux HOWTO* for details.

AF_RDS
Reliable Datagram Sockets (RDS) protocol (since Linux 2.6.30). RDS over RDMA has no relation to **AF_SMC** or **AF_XDP**. For further information, see *rds*(7), *rds-rdma*(7), and *Documentation/networking/rds.txt* in the Linux kernel source tree.

AF_IRDA
Socket interface over IrDA (moved to staging in Linux 4.14, removed in Linux 4.17). For further information, see *irda*(7)

AF_PPPOX
Generic PPP transport layer, for setting up L2 tunnels (L2TP and PPPoE). See *Documentation/networking/l2tp.txt* in the Linux kernel source tree for details.

AF_WANPIPE
Legacy protocol for wide area network (WAN) connectivity that was used by Sangoma WAN cards (called "WANPIPE"); removed in Linux 2.6.21.

AF_LLC
Logical link control (IEEE 802.2 LLC) protocol, upper part of data link layer of ISO/OSI networking protocol stack (since Linux 2.4); has no relation to **AF_PACKET**. See chapter *13.5.3. Logical Link Control* in *Understanding Linux Kernel Internals* (O'Reilly Media, 2006) and *IEEE Standards for Local Area Networks: Logical Link Control* (The Institute of Electronics and Electronics Engineers, Inc., New York, New York, 1985) for details. See also some historical notes regarding its development.

AF_IB InfiniBand native addressing (since Linux 3.11).

AF_MPLS
Multiprotocol Label Switching (since Linux 4.1); mostly used for configuring MPLS routing via *netlink*(7), as it doesn't expose ability to create sockets to user space.

AF_CAN
Controller Area Network automotive bus protocol (since Linux 2.6.25). See *Documentation/networking/can.rst* in the Linux kernel source tree for details.

AF_TIPC
TIPC, "cluster domain sockets" protocol (since Linux 2.6.16). See *TIPC Programmer's Guide* and the protocol description for details.

AF_BLUETOOTH
Bluetooth low-level socket protocol (since Linux 3.11). See *Bluetooth Management API overview* and *An Introduction to Bluetooth Programming* by Albert Huang for details.

AF_IUCV
IUCV (inter-user communication vehicle) z/VM protocol for hypervisor-guest interaction (since Linux 2.6.21); has no relation to **AF_VSOCK** and/or **AF_SMC** See *IUCV protocol overview* for details.

AF_RXRPC
Rx, Andrew File System remote procedure call protocol (since Linux 2.6.22). See *Documentation/networking/rxrpc.txt* in the Linux kernel source tree for details.

AF_ISDN
New "modular ISDN" driver interface protocol (since Linux 2.6.27). See the mISDN wiki for details.

AF_PHONET
Nokia cellular modem IPC/RPC interface (since Linux 2.6.31). See *Documentation/networking/phonet.txt* in the Linux kernel source tree for details.

AF_IEEE802154
IEEE 802.15.4 WPAN (wireless personal area network) raw packet protocol (since Linux 2.6.31). See *Documentation/networking/ieee802154.txt* in the Linux kernel source tree for details.

AF_CAIF
Ericsson's Communication CPU to Application CPU interface (CAIF) protocol (since Linux 2.6.36). See *Documentation/networking/caif/Linux−CAIF.txt* in the Linux kernel source tree for details.

AF_ALG
Interface to kernel crypto API (since Linux 2.6.38). See *Documentation/crypto/userspace−if.rst* in the Linux kernel source tree for details.

AF_VSOCK
VMWare VSockets protocol for hypervisor-guest interaction (since Linux 3.9); has no relation to **AF_IUCV** and **AF_SMC**. For further information, see *vsock*(7).

AF_KCM
KCM (kernel connection multiplexer) interface (since Linux 4.6). See *Documentation/networking/kcm.txt* in the Linux kernel source tree for details.

AF_QIPCRTR
Qualcomm IPC router interface protocol (since Linux 4.7).

AF_SMC
SMC-R (shared memory communications over RDMA) protocol (since Linux 4.11), and SMC-D (shared memory communications, direct memory access) protocol for intra-node z/VM quest interaction (since Linux 4.19); has no relation to **AF_RDS**, **AF_IUCV** or **AF_VSOCK**. See RFC 7609 *IBM's Shared Memory Communications over RDMA (SMC-R) Protocol* for details regarding SMC-R. See *SMC-D Reference Information* for details regarding SMC-D.

AF_XDP
XDP (express data path) interface (since Linux 4.18). See *Documentation/networking/af_xdp.rst* in the Linux kernel source tree for details.

NAME

aio − POSIX asynchronous I/O overview

DESCRIPTION

The POSIX asynchronous I/O (AIO) interface allows applications to initiate one or more I/O operations that are performed asynchronously (i.e., in the background). The application can elect to be notified of completion of the I/O operation in a variety of ways: by delivery of a signal, by instantiation of a thread, or no notification at all.

The POSIX AIO interface consists of the following functions:

aio_read(3)
: Enqueue a read request. This is the asynchronous analog of *read*(2).

aio_write(3)
: Enqueue a write request. This is the asynchronous analog of *write*(2).

aio_fsync(3)
: Enqueue a sync request for the I/O operations on a file descriptor. This is the asynchronous analog of *fsync*(2) and *fdatasync*(2).

aio_error(3)
: Obtain the error status of an enqueued I/O request.

aio_return(3)
: Obtain the return status of a completed I/O request.

aio_suspend(3)
: Suspend the caller until one or more of a specified set of I/O requests completes.

aio_cancel(3)
: Attempt to cancel outstanding I/O requests on a specified file descriptor.

lio_listio(3)
: Enqueue multiple I/O requests using a single function call.

The *aiocb* ("asynchronous I/O control block") structure defines parameters that control an I/O operation. An argument of this type is employed with all of the functions listed above. This structure has the following form:

```
#include <aiocb.h>

struct aiocb {
    /* The order of these fields is implementation-dependent */

    int             aio_fildes;     /* File descriptor */
    off_t           aio_offset;     /* File offset */
    volatile void  *aio_buf;        /* Location of buffer */
    size_t          aio_nbytes;     /* Length of transfer */
    int             aio_reqprio;    /* Request priority */
    struct sigevent aio_sigevent;   /* Notification method */
    int             aio_lio_opcode; /* Operation to be performed;
                                       lio_listio() only */

    /* Various implementation-internal fields not shown */
};

/* Operation codes for 'aio_lio_opcode': */

enum { LIO_READ, LIO_WRITE, LIO_NOP };
```

The fields of this structure are as follows:

aio_fildes
: The file descriptor on which the I/O operation is to be performed.

aio_offset
: This is the file offset at which the I/O operation is to be performed.

aio_buf
: This is the buffer used to transfer data for a read or write operation.

aio_nbytes
: This is the size of the buffer pointed to by *aio_buf*.

aio_reqprio
: This field specifies a value that is subtracted from the calling thread's real-time priority in order to determine the priority for execution of this I/O request (see *pthread_setschedparam*(3)). The specified value must be between 0 and the value returned by *sysconf(_SC_AIO_PRIO_DELTA_MAX)*. This field is ignored for file synchronization operations.

aio_sigevent
: This field is a structure that specifies how the caller is to be notified when the asynchronous I/O operation completes. Possible values for *aio_sigevent.sigev_notify* are **SIGEV_NONE**, **SIGEV_SIGNAL**, and **SIGEV_THREAD**. See *sigevent*(3type) for further details.

aio_lio_opcode
: The type of operation to be performed; used only for *lio_listio*(3).

In addition to the standard functions listed above, the GNU C library provides the following extension to the POSIX AIO API:

aio_init(3)
: Set parameters for tuning the behavior of the glibc POSIX AIO implementation.

ERRORS

EINVAL
: The *aio_reqprio* field of the *aiocb* structure was less than 0, or was greater than the limit returned by the call *sysconf(_SC_AIO_PRIO_DELTA_MAX)*.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001. glibc 2.1.

NOTES

It is a good idea to zero out the control block buffer before use (see *memset*(3)). The control block buffer and the buffer pointed to by *aio_buf* must not be changed while the I/O operation is in progress. These buffers must remain valid until the I/O operation completes.

Simultaneous asynchronous read or write operations using the same *aiocb* structure yield undefined results.

The current Linux POSIX AIO implementation is provided in user space by glibc. This has a number of limitations, most notably that maintaining multiple threads to perform I/O operations is expensive and scales poorly. Work has been in progress for some time on a kernel state-machine-based implementation of asynchronous I/O (see *io_submit*(2), *io_setup*(2), *io_cancel*(2), *io_destroy*(2), *io_getevents*(2)), but this implementation hasn't yet matured to the point where the POSIX AIO implementation can be completely reimplemented using the kernel system calls.

EXAMPLES

The program below opens each of the files named in its command-line arguments and queues a request on the resulting file descriptor using *aio_read*(3). The program then loops, periodically monitoring each of the I/O operations that is still in progress using *aio_error*(3). Each of the I/O requests is set up to provide notification by delivery of a signal. After all I/O requests have completed, the program retrieves their status using *aio_return*(3).

The **SIGQUIT** signal (generated by typing control-\) causes the program to request cancelation of each of the outstanding requests using *aio_cancel*(3).

Here is an example of what we might see when running this program. In this example, the program queues two requests to standard input, and these are satisfied by two lines of input containing "abc" and

"x".

```
$ ./a.out /dev/stdin /dev/stdin
opened /dev/stdin on descriptor 3
opened /dev/stdin on descriptor 4
aio_error():
    for request 0 (descriptor 3): In progress
    for request 1 (descriptor 4): In progress
abc
I/O completion signal received
aio_error():
    for request 0 (descriptor 3): I/O succeeded
    for request 1 (descriptor 4): In progress
aio_error():
    for request 1 (descriptor 4): In progress
x
I/O completion signal received
aio_error():
    for request 1 (descriptor 4): I/O succeeded
All I/O requests completed
aio_return():
    for request 0 (descriptor 3): 4
    for request 1 (descriptor 4): 2
```

NAME

arp − Linux ARP kernel module.

DESCRIPTION

This kernel protocol module implements the Address Resolution Protocol defined in RFC 826. It is used to convert between Layer2 hardware addresses and IPv4 protocol addresses on directly connected networks. The user normally doesn't interact directly with this module except to configure it; instead it provides a service for other protocols in the kernel.

A user process can receive ARP packets by using *packet*(7) sockets. There is also a mechanism for managing the ARP cache in user-space by using *netlink*(7) sockets. The ARP table can also be controlled via *ioctl*(2) on any **AF_INET** socket.

The ARP module maintains a cache of mappings between hardware addresses and protocol addresses. The cache has a limited size so old and less frequently used entries are garbage-collected. Entries which are marked as permanent are never deleted by the garbage-collector. The cache can be directly manipulated by the use of ioctls and its behavior can be tuned by the */proc* interfaces described below.

When there is no positive feedback for an existing mapping after some time (see the */proc* interfaces below), a neighbor cache entry is considered stale. Positive feedback can be gotten from a higher layer; for example from a successful TCP ACK. Other protocols can signal forward progress using the **MSG_CONFIRM** flag to *sendmsg*(2). When there is no forward progress, ARP tries to reprobe. It first tries to ask a local arp daemon **app_solicit** times for an updated MAC address. If that fails and an old MAC address is known, a unicast probe is sent **ucast_solicit** times. If that fails too, it will broadcast a new ARP request to the network. Requests are sent only when there is data queued for sending.

Linux will automatically add a nonpermanent proxy arp entry when it receives a request for an address it forwards to and proxy arp is enabled on the receiving interface. When there is a reject route for the target, no proxy arp entry is added.

Ioctls

Three ioctls are available on all **AF_INET** sockets. They take a pointer to a *struct arpreq* as their argument.

```
struct arpreq {
    struct sockaddr arp_pa;      /* protocol address */
    struct sockaddr arp_ha;      /* hardware address */
    int             arp_flags;   /* flags */
    struct sockaddr arp_netmask; /* netmask of protocol address */
    char            arp_dev[16];
};
```

SIOCSARP, **SIOCDARP** and **SIOCGARP** respectively set, delete, and get an ARP mapping. Setting and deleting ARP maps are privileged operations and may be performed only by a process with the **CAP_NET_ADMIN** capability or an effective UID of 0.

arp_pa must be an **AF_INET** address and *arp_ha* must have the same type as the device which is specified in *arp_dev*. *arp_dev* is a zero-terminated string which names a device.

arp_flags	
flag	meaning
ATF_COM	Lookup complete
ATF_PERM	Permanent entry
ATF_PUBL	Publish entry
ATF_USETRAILERS	Trailers requested
ATF_NETMASK	Use a netmask
ATF_DONTPUB	Don't answer

If the **ATF_NETMASK** flag is set, then *arp_netmask* should be valid. Linux 2.2 does not support proxy network ARP entries, so this should be set to 0xffffffff, or 0 to remove an existing proxy arp entry. **ATF_USETRAILERS** is obsolete and should not be used.

/proc interfaces

ARP supports a range of */proc* interfaces to configure parameters on a global or per-interface basis. The interfaces can be accessed by reading or writing the */proc/sys/net/ipv4/neigh/*/** files. Each

interface in the system has its own directory in */proc/sys/net/ipv4/neigh/*. The setting in the "default" directory is used for all newly created devices. Unless otherwise specified, time-related interfaces are specified in seconds.

anycast_delay (since Linux 2.2)
: The maximum number of jiffies to delay before replying to a IPv6 neighbor solicitation message. Anycast support is not yet implemented. Defaults to 1 second.

app_solicit (since Linux 2.2)
: The maximum number of probes to send to the user space ARP daemon via netlink before dropping back to multicast probes (see *mcast_solicit*). Defaults to 0.

base_reachable_time (since Linux 2.2)
: Once a neighbor has been found, the entry is considered to be valid for at least a random value between *base_reachable_time*/2 and 3**base_reachable_time*/2. An entry's validity will be extended if it receives positive feedback from higher level protocols. Defaults to 30 seconds. This file is now obsolete in favor of *base_reachable_time_ms*.

base_reachable_time_ms (since Linux 2.6.12)
: As for *base_reachable_time*, but measures time in milliseconds. Defaults to 30000 milliseconds.

delay_first_probe_time (since Linux 2.2)
: Delay before first probe after it has been decided that a neighbor is stale. Defaults to 5 seconds.

gc_interval (since Linux 2.2)
: How frequently the garbage collector for neighbor entries should attempt to run. Defaults to 30 seconds.

gc_stale_time (since Linux 2.2)
: Determines how often to check for stale neighbor entries. When a neighbor entry is considered stale, it is resolved again before sending data to it. Defaults to 60 seconds.

gc_thresh1 (since Linux 2.2)
: The minimum number of entries to keep in the ARP cache. The garbage collector will not run if there are fewer than this number of entries in the cache. Defaults to 128.

gc_thresh2 (since Linux 2.2)
: The soft maximum number of entries to keep in the ARP cache. The garbage collector will allow the number of entries to exceed this for 5 seconds before collection will be performed. Defaults to 512.

gc_thresh3 (since Linux 2.2)
: The hard maximum number of entries to keep in the ARP cache. The garbage collector will always run if there are more than this number of entries in the cache. Defaults to 1024.

locktime (since Linux 2.2)
: The minimum number of jiffies to keep an ARP entry in the cache. This prevents ARP cache thrashing if there is more than one potential mapping (generally due to network misconfiguration). Defaults to 1 second.

mcast_solicit (since Linux 2.2)
: The maximum number of attempts to resolve an address by multicast/broadcast before marking the entry as unreachable. Defaults to 3.

proxy_delay (since Linux 2.2)
: When an ARP request for a known proxy-ARP address is received, delay up to *proxy_delay* jiffies before replying. This is used to prevent network flooding in some cases. Defaults to 0.8 seconds.

proxy_qlen (since Linux 2.2)
: The maximum number of packets which may be queued to proxy-ARP addresses. Defaults to 64.

retrans_time (since Linux 2.2)
: The number of jiffies to delay before retransmitting a request. Defaults to 1 second. This file is now obsolete in favor of *retrans_time_ms*.

retrans_time_ms (since Linux 2.6.12)
: The number of milliseconds to delay before retransmitting a request. Defaults to 1000 milliseconds.

ucast_solicit (since Linux 2.2)
: The maximum number of attempts to send unicast probes before asking the ARP daemon (see *app_solicit*). Defaults to 3.

unres_qlen (since Linux 2.2)
: The maximum number of packets which may be queued for each unresolved address by other network layers. Defaults to 3.

VERSIONS

The *struct arpreq* changed in Linux 2.0 to include the *arp_dev* member and the ioctl numbers changed at the same time. Support for the old ioctls was dropped in Linux 2.2.

Support for proxy arp entries for networks (netmask not equal 0xffffffff) was dropped in Linux 2.2. It is replaced by automatic proxy arp setup by the kernel for all reachable hosts on other interfaces (when forwarding and proxy arp is enabled for the interface).

The *neigh/** interfaces did not exist before Linux 2.2.

BUGS

Some timer settings are specified in jiffies, which is architecture- and kernel version-dependent; see *time*(7).

There is no way to signal positive feedback from user space. This means connection-oriented protocols implemented in user space will generate excessive ARP traffic, because ndisc will regularly reprobe the MAC address. The same problem applies for some kernel protocols (e.g., NFS over UDP).

This man page mashes together functionality that is IPv4-specific with functionality that is shared between IPv4 and IPv6.

NAME

ascii − ASCII character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

ASCII is the American Standard Code for Information Interchange. It is a 7-bit code. Many 8-bit codes (e.g., ISO/IEC 8859-1) contain ASCII as their lower half. The international counterpart of ASCII is known as ISO/IEC 646-IRV.

The following table contains the 128 ASCII characters.

C program '\X' escapes are noted.

Oct	Dec	Hex	Char	Oct	Dec	Hex	Char
000	0	00	NUL '\0' (null character)	100	64	40	@
001	1	01	SOH (start of heading)	101	65	41	A
002	2	02	STX (start of text)	102	66	42	B
003	3	03	ETX (end of text)	103	67	43	C
004	4	04	EOT (end of transmission)	104	68	44	D
005	5	05	ENQ (enquiry)	105	69	45	E
006	6	06	ACK (acknowledge)	106	70	46	F
007	7	07	BEL '\a' (bell)	107	71	47	G
010	8	08	BS '\b' (backspace)	110	72	48	H
011	9	09	HT '\t' (horizontal tab)	111	73	49	I

NOTES

History

/etc/ascii (VII) appears in the UNIX Programmer's Manual.

On older terminals, the underscore code is displayed as a left arrow, called backarrow, the caret is displayed as an up-arrow and the vertical bar has a hole in the middle.

Uppercase and lowercase characters differ by just one bit and the ASCII character 2 differs from the double quote by just one bit, too. That made it much easier to encode characters mechanically or with a non-microcontroller-based electronic keyboard and that pairing was found on old teletypes.

The ASCII standard was published by the United States of America Standards Institute (USASI) in 1968.

NAME

attributes − POSIX safety concepts

DESCRIPTION

Note: the text of this man page is based on the material taken from the "POSIX Safety Concepts" section of the GNU C Library manual. Further details on the topics described here can be found in that manual.

Various function manual pages include a section ATTRIBUTES that describes the safety of calling the function in various contexts. This section annotates functions with the following safety markings:

MT-Safe
: *MT-Safe* or Thread-Safe functions are safe to call in the presence of other threads. MT, in MT-Safe, stands for Multi Thread.

  Being MT-Safe does not imply a function is atomic, nor that it uses any of the memory synchronization mechanisms POSIX exposes to users. It is even possible that calling MT-Safe functions in sequence does not yield an MT-Safe combination. For example, having a thread call two MT-Safe functions one right after the other does not guarantee behavior equivalent to atomic execution of a combination of both functions, since concurrent calls in other threads may interfere in a destructive way.

  Whole-program optimizations that could inline functions across library interfaces may expose unsafe reordering, and so performing inlining across the GNU C Library interface is not recommended. The documented MT-Safety status is not guaranteed under whole-program optimization. However, functions defined in user-visible headers are designed to be safe for inlining.

MT-Unsafe
: *MT-Unsafe* functions are not safe to call in a multithreaded programs.

Other keywords that appear in safety notes are defined in subsequent sections.

Conditionally safe features

For some features that make functions unsafe to call in certain contexts, there are known ways to avoid the safety problem other than refraining from calling the function altogether. The keywords that follow refer to such features, and each of their definitions indicates how the whole program needs to be constrained in order to remove the safety problem indicated by the keyword. Only when all the reasons that make a function unsafe are observed and addressed, by applying the documented constraints, does the function become safe to call in a context.

init Functions marked with *init* as an MT-Unsafe feature perform MT-Unsafe initialization when they are first called.

Calling such a function at least once in single-threaded mode removes this specific cause for the function to be regarded as MT-Unsafe. If no other cause for that remains, the function can then be safely called after other threads are started.

race Functions annotated with *race* as an MT-Safety issue operate on objects in ways that may cause data races or similar forms of destructive interference out of concurrent execution. In some cases, the objects are passed to the functions by users; in others, they are used by the functions to return values to users; in others, they are not even exposed to users.

const Functions marked with *const* as an MT-Safety issue non-atomically modify internal objects that are better regarded as constant, because a substantial portion of the GNU C Library accesses them without synchronization. Unlike *race*, which causes both readers and writers of internal objects to be regarded as MT-Unsafe, this mark is applied to writers only. Writers remain MT-Unsafe to call, but the then-mandatory constness of objects they modify enables readers to be regarded as MT-Safe (as long as no other reasons for them to be unsafe remain), since the lack of synchronization is not a problem when the objects are effectively constant.

The identifier that follows the *const* mark will appear by itself as a safety note in readers. Programs that wish to work around this safety issue, so as to call writers, may use a non-recursive read-write lock associated with the identifier, and guard *all* calls to functions marked with *const* followed by the identifier with a write lock, and *all* calls to functions marked with the identifier by itself with a read lock.

sig Functions marked with *sig* as a MT-Safety issue may temporarily install a signal handler for internal purposes, which may interfere with other uses of the signal, identified after a colon.

This safety problem can be worked around by ensuring that no other uses of the signal will take place for the duration of the call. Holding a non-recursive mutex while calling all functions that use the same temporary signal; blocking that signal before the call and resetting its handler afterwards is recommended.

term Functions marked with *term* as an MT-Safety issue may change the terminal settings in the recommended way, namely: call *tcgetattr*(3), modify some flags, and then call *tcsetattr*(3), this creates a window in which changes made by other threads are lost. Thus, functions marked with *term* are MT-Unsafe.

It is thus advisable for applications using the terminal to avoid concurrent and reentrant interactions with it, by not using it in signal handlers or blocking signals that might use it, and holding a lock while calling these functions and interacting with the terminal. This lock should also be used for mutual exclusion with functions marked with *race:tcattr(fd)*, where *fd* is a file descriptor for the controlling terminal. The caller may use a single mutex for simplicity, or use one mutex per terminal, even if referenced by different file descriptors.

Other safety remarks

Additional keywords may be attached to functions, indicating features that do not make a function unsafe to call, but that may need to be taken into account in certain classes of programs:

locale Functions annotated with *locale* as an MT-Safety issue read from the locale object without any form of synchronization. Functions annotated with *locale* called concurrently with locale changes may behave in ways that do not correspond to any of the locales active during their execution, but an unpredictable mix thereof.

We do not mark these functions as MT-Unsafe, however, because functions that modify the locale object are marked with *const:locale* and regarded as unsafe. Being unsafe, the latter are not to be called when multiple threads are running or asynchronous signals are enabled, and so the locale can be considered effectively constant in these contexts, which makes the former safe.

env Functions marked with *env* as an MT-Safety issue access the environment with *getenv*(3) or similar, without any guards to ensure safety in the presence of concurrent modifications.

We do not mark these functions as MT-Unsafe, however, because functions that modify the environment are all marked with *const:env* and regarded as unsafe. Being unsafe, the latter are not to be called when multiple threads are running or asynchronous signals are enabled, and so the environment can be considered effectively constant in these contexts, which makes the former safe.

hostid The function marked with *hostid* as an MT-Safety issue reads from the system-wide data structures that hold the "host ID" of the machine. These data structures cannot generally be modified atomically. Since it is expected that the "host ID" will not normally change, the function that reads from it (**gethostid**(3)) is regarded as safe, whereas the function that modifies it (**sethostid**(3)) is marked with *const:hostid*, indicating it may require special care if it is to be called. In this specific case, the special care amounts to system-wide (not merely intra-process) coordination.

sigintr Functions marked with *sigintr* as an MT-Safety issue access the GNU C Library *_sigintr* internal data structure without any guards to ensure safety in the presence of concurrent modifications.

We do not mark these functions as MT-Unsafe, however, because functions that modify this data structure are all marked with *const:sigintr* and regarded as unsafe. Being unsafe, the latter are not to be called when multiple threads are running or asynchronous signals are enabled, and so the data structure can be considered effectively constant in these contexts, which makes the former safe.

cwd Functions marked with *cwd* as an MT-Safety issue may temporarily change the current working directory during their execution, which may cause relative pathnames to be resolved in unexpected ways in other threads or within asynchronous signal or cancelation handlers.

This is not enough of a reason to mark so-marked functions as MT-Unsafe, but when this behavior is optional (e.g., *nftw*(3) with **FTW_CHDIR**), avoiding the option may be a good alternative to using full pathnames or file descriptor-relative (e.g., *openat*(2)) system calls.

:identifier

Annotations may sometimes be followed by identifiers, intended to group several functions that, for example, access the data structures in an unsafe way, as in *race* and *const*, or to provide more specific information, such as naming a signal in a function marked with *sig*. It is envisioned that it may be applied to *lock* and *corrupt* as well in the future.

In most cases, the identifier will name a set of functions, but it may name global objects or function arguments, or identifiable properties or logical components associated with them, with a notation such as, for example, *:buf(arg)* to denote a buffer associated with the argument *arg*, or *:tcattr(fd)* to denote the terminal attributes of a file descriptor *fd*.

The most common use for identifiers is to provide logical groups of functions and arguments that need to be protected by the same synchronization primitive in order to ensure safe operation in a given context.

/condition

Some safety annotations may be conditional, in that they only apply if a boolean expression involving arguments, global variables or even the underlying kernel evaluates to true. For example, */!ps* and */one_per_line* indicate the preceding marker only applies when argument *ps* is NULL, or global variable *one_per_line* is nonzero.

When all marks that render a function unsafe are adorned with such conditions, and none of the named conditions hold, then the function can be regarded as safe.

NAME

boot − System bootup process based on UNIX System V Release 4

DESCRIPTION

The **bootup process** (or "**boot sequence**") varies in details among systems, but can be roughly divided into phases controlled by the following components:

(1) hardware

(2) operating system (OS) loader

(3) kernel

(4) root user-space process (*init* and *inittab*)

(5) boot scripts

Each of these is described below in more detail.

Hardware

After power-on or hard reset, control is given to a program stored in read-only memory (normally PROM); for historical reasons involving the personal computer, this program is often called "the **BIOS**".

This program normally performs a basic self-test of the machine and accesses nonvolatile memory to read further parameters. This memory in the PC is battery-backed CMOS memory, so most people refer to it as "the **CMOS**"; outside of the PC world, it is usually called "the **NVRAM**" (nonvolatile RAM).

The parameters stored in the NVRAM vary among systems, but as a minimum, they should specify which device can supply an OS loader, or at least which devices may be probed for one; such a device is known as "the **boot device**". The hardware boot stage loads the OS loader from a fixed position on the boot device, and then transfers control to it.

Note: The device from which the OS loader is read may be attached via a network, in which case the details of booting are further specified by protocols such as DHCP, TFTP, PXE, Etherboot, etc.

OS loader

The main job of the OS loader is to locate the kernel on some device, load it, and run it. Most OS loaders allow interactive use, in order to enable specification of an alternative kernel (maybe a backup in case the one last compiled isn't functioning) and to pass optional parameters to the kernel.

In a traditional PC, the OS loader is located in the initial 512-byte block of the boot device; this block is known as "the **MBR**" (Master Boot Record).

In most systems, the OS loader is very limited due to various constraints. Even on non-PC systems, there are some limitations on the size and complexity of this loader, but the size limitation of the PC MBR (512 bytes, including the partition table) makes it almost impossible to squeeze much functionality into it.

Therefore, most systems split the role of loading the OS between a primary OS loader and a secondary OS loader; this secondary OS loader may be located within a larger portion of persistent storage, such as a disk partition.

In Linux, the OS loader is often *grub*(8) (an alternative is *lilo*(8)).

Kernel

When the kernel is loaded, it initializes various components of the computer and operating system; each portion of software responsible for such a task is usually consider "a **driver**" for the applicable component. The kernel starts the virtual memory swapper (it is a kernel process, called "kswapd" in a modern Linux kernel), and mounts some filesystem at the root path, `/`.

Some of the parameters that may be passed to the kernel relate to these activities (for example, the default root filesystem can be overridden); for further information on Linux kernel parameters, read *boot-param*(7).

Only then does the kernel create the initial userland process, which is given the number 1 as its **PID** (process ID). Traditionally, this process executes the program */sbin/init*, to which are passed the parameters that haven't already been handled by the kernel.

Root user-space process

Note: The following description applies to an OS based on UNIX System V Release 4. However, a number of widely used systems have adopted a related but fundamentally different approach known as *systemd*(1), for which the bootup process is detailed in its associated *bootup*(7)

When */sbin/init* starts, it reads */etc/inittab* for further instructions. This file defines what should be run when the */sbin/init* program is instructed to enter a particular run level, giving the administrator an easy way to establish an environment for some usage; each run level is associated with a set of services (for example, run level **S** is single-user mode, and run level **2** entails running most network services).

The administrator may change the current run level via *init*(1), and query the current run level via *runlevel*(8)

However, since it is not convenient to manage individual services by editing this file, */etc/inittab* only bootstraps a set of scripts that actually start/stop the individual services.

Boot scripts

Note: The following description applies to an OS based on UNIX System V Release 4. However, a number of widely used systems (Slackware Linux, FreeBSD, OpenBSD) have a somewhat different scheme for boot scripts.

For each managed service (mail, nfs server, cron, etc.), there is a single startup script located in a specific directory (*/etc/init.d* in most versions of Linux). Each of these scripts accepts as a single argument the word "start" (causing it to start the service) or the word "stop" (causing it to stop the service). The script may optionally accept other "convenience" parameters (e.g., "restart" to stop and then start, "status" to display the service status, etc.). Running the script without parameters displays the possible arguments.

Sequencing directories

To make specific scripts start/stop at specific run levels and in a specific order, there are *sequencing directories*, normally of the form */etc/rc[0−6S].d*. In each of these directories, there are links (usually symbolic) to the scripts in the */etc/init.d* directory.

A primary script (usually */etc/rc*) is called from *inittab*(5); this primary script calls each service's script via a link in the relevant sequencing directory. Each link whose name begins with 'S' is called with the argument "start" (thereby starting the service). Each link whose name begins with 'K' is called with the argument "stop" (thereby stopping the service).

To define the starting or stopping order within the same run level, the name of a link contains an **ordernumber**. Also, for clarity, the name of a link usually ends with the name of the service to which it refers. For example, the link */etc/rc2.d/S80sendmail* starts the *sendmail*(8) service on run level 2. This happens after */etc/rc2.d/S12syslog* is run but before */etc/rc2.d/S90xfs* is run.

To manage these links is to manage the boot order and run levels; under many systems, there are tools to help with this task (e.g., *chkconfig*(8)).

Boot configuration

A program that provides a service is often called a "**daemon**". Usually, a daemon may receive various command-line options and parameters. To allow a system administrator to change these inputs without editing an entire boot script, some separate configuration file is used, and is located in a specific directory where an associated boot script may find it (*/etc/sysconfig* on older Red Hat systems).

In older UNIX systems, such a file contained the actual command line options for a daemon, but in modern Linux systems (and also in HP-UX), it just contains shell variables. A boot script in */etc/init.d* reads and includes its configuration file (that is, it "**sources**" its configuration file) and then uses the variable values.

FILES

/etc/init.d/ , */etc/rc[S0−6].d/* , */etc/sysconfig/*

NAME

bootparam − introduction to boot time parameters of the Linux kernel

DESCRIPTION

The Linux kernel accepts certain 'command-line options' or 'boot time parameters' at the moment it is started. In general, this is used to supply the kernel with information about hardware parameters that the kernel would not be able to determine on its own, or to avoid/override the values that the kernel would otherwise detect.

When the kernel is booted directly by the BIOS, you have no opportunity to specify any parameters. So, in order to take advantage of this possibility you have to use a boot loader that is able to pass parameters, such as GRUB.

The argument list

The kernel command line is parsed into a list of strings (boot arguments) separated by spaces. Most of the boot arguments have the form:

```
name[=value_1][,value_2]...[,value_10]
```

where 'name' is a unique keyword that is used to identify what part of the kernel the associated values (if any) are to be given to. Note the limit of 10 is real, as the present code handles only 10 comma separated parameters per keyword. (However, you can reuse the same keyword with up to an additional 10 parameters in unusually complicated situations, assuming the setup function supports it.)

Most of the sorting is coded in the kernel source file *init/main.c*. First, the kernel checks to see if the argument is any of the special arguments 'root=', 'nfsroot=', 'nfsaddrs=', 'ro', 'rw', 'debug', or 'init'. The meaning of these special arguments is described below.

Then it walks a list of setup functions to see if the specified argument string (such as 'foo') has been associated with a setup function ('foo_setup()') for a particular device or part of the kernel. If you passed the kernel the line foo=3,4,5,6 then the kernel would search the bootsetups array to see if 'foo' was registered. If it was, then it would call the setup function associated with 'foo' (foo_setup()) and hand it the arguments 3, 4, 5, and 6 as given on the kernel command line.

Anything of the form 'foo=bar' that is not accepted as a setup function as described above is then interpreted as an environment variable to be set. A (useless?) example would be to use 'TERM=vt100' as a boot argument.

Any remaining arguments that were not picked up by the kernel and were not interpreted as environment variables are then passed onto PID 1, which is usually the *init*(1) program. The most common argument that is passed to the *init* process is the word 'single' which instructs it to boot the computer in single user mode, and not launch all the usual daemons. Check the manual page for the version of *init*(1) installed on your system to see what arguments it accepts.

General non-device-specific boot arguments

'init=...'

This sets the initial command to be executed by the kernel. If this is not set, or cannot be found, the kernel will try */sbin/init*, then */etc/init*, then */bin/init*, then */bin/sh* and panic if all of this fails.

'nfsaddrs=...'

This sets the NFS boot address to the given string. This boot address is used in case of a net boot.

'nfsroot=...'

This sets the NFS root name to the given string. If this string does not begin with '/' or ',' or a digit, then it is prefixed by '/tftpboot/'. This root name is used in case of a net boot.

'root=...'

This argument tells the kernel what device is to be used as the root filesystem while booting. The default of this setting is determined at compile time, and usually is the value of the root device of the system that the kernel was built on. To override this value, and select the second floppy drive as the root device, one would use 'root=/dev/fd1'.

The root device can be specified symbolically or numerically. A symbolic specification has the form */dev/XXYN*, where XX designates the device type (e.g., 'hd' for ST-506 compatible hard disk, with Y in 'a'–'d'; 'sd' for SCSI compatible disk, with Y in 'a'–'e'), Y the driver

letter or number, and N the number (in decimal) of the partition on this device.

Note that this has nothing to do with the designation of these devices on your filesystem. The '/dev/' part is purely conventional.

The more awkward and less portable numeric specification of the above possible root devices in major/minor format is also accepted. (For example, */dev/sda3* is major 8, minor 3, so you could use 'root=0x803' as an alternative.)

'rootdelay='
This parameter sets the delay (in seconds) to pause before attempting to mount the root filesystem.

'rootflags=...'
This parameter sets the mount option string for the root filesystem (see also *fstab*(5)).

'rootfstype=...'
The 'rootfstype' option tells the kernel to mount the root filesystem as if it where of the type specified. This can be useful (for example) to mount an ext3 filesystem as ext2 and then remove the journal in the root filesystem, in fact reverting its format from ext3 to ext2 without the need to boot the box from alternate media.

'ro' and **'rw'**
The 'ro' option tells the kernel to mount the root filesystem as 'read-only' so that filesystem consistency check programs (fsck) can do their work on a quiescent filesystem. No processes can write to files on the filesystem in question until it is 'remounted' as read/write capable, for example, by 'mount −w −n −o remount /'. (See also *mount*(8)

The 'rw' option tells the kernel to mount the root filesystem read/write. This is the default.

'resume=...'
This tells the kernel the location of the suspend-to-disk data that you want the machine to resume from after hibernation. Usually, it is the same as your swap partition or file. Example:

```
resume=/dev/hda2
```

'reserve=...'
This is used to protect I/O port regions from probes. The form of the command is:

reserve=*iobase,extent[,iobase,extent]...*

In some machines it may be necessary to prevent device drivers from checking for devices (auto-probing) in a specific region. This may be because of hardware that reacts badly to the probing, or hardware that would be mistakenly identified, or merely hardware you don't want the kernel to initialize.

The reserve boot-time argument specifies an I/O port region that shouldn't be probed. A device driver will not probe a reserved region, unless another boot argument explicitly specifies that it do so.

For example, the boot line

```
reserve=0x300,32  blah=0x300
```

keeps all device drivers except the driver for 'blah' from probing 0x300−0x31f.

'panic=N'
By default, the kernel will not reboot after a panic, but this option will cause a kernel reboot after N seconds (if N is greater than zero). This panic timeout can also be set by

```
echo N > /proc/sys/kernel/panic
```

'reboot=[warm|cold][,[bios|hard]]'
Since Linux 2.0.22, a reboot is by default a cold reboot. One asks for the old default with 'reboot=warm'. (A cold reboot may be required to reset certain hardware, but might destroy not yet written data in a disk cache. A warm reboot may be faster.) By default, a reboot is hard, by asking the keyboard controller to pulse the reset line low, but there is at least one type of motherboard where that doesn't work. The option 'reboot=bios' will instead jump through the BIOS.

'nosmp' and **'maxcpus=N'**
(Only when __SMP__ is defined.) A command-line option of 'nosmp' or 'maxcpus=0' will disable SMP activation entirely; an option 'maxcpus=N' limits the maximum number of CPUs activated in SMP mode to N.

Boot arguments for use by kernel developers

'debug'
Kernel messages are handed off to a daemon (e.g., *klogd*(8) or similar) so that they may be logged to disk. Messages with a priority above *console_loglevel* are also printed on the console. (For a discussion of log levels, see *syslog*(2).) By default, *console_loglevel* is set to log messages at levels higher than **KERN_DEBUG**. This boot argument will cause the kernel to also print messages logged at level **KERN_DEBUG**. The console loglevel can also be set on a booted system via the */proc/sys/kernel/printk* file (described in *syslog*(2)), the *syslog*(2) **SYSLOG_ACTION_CONSOLE_LEVEL** operation, or *dmesg*(8)

'profile=N'
It is possible to enable a kernel profiling function, if one wishes to find out where the kernel is spending its CPU cycles. Profiling is enabled by setting the variable *prof_shift* to a nonzero value. This is done either by specifying **CONFIG_PROFILE** at compile time, or by giving the 'profile=' option. Now the value that *prof_shift* gets will be N, when given, or **CONFIG_PROFILE_SHIFT**, when that is given, or 2, the default. The significance of this variable is that it gives the granularity of the profiling: each clock tick, if the system was executing kernel code, a counter is incremented:

```
profile[address >> prof_shift]++;
```

The raw profiling information can be read from */proc/profile*. Probably you'll want to use a tool such as readprofile.c to digest it. Writing to */proc/profile* will clear the counters.

Boot arguments for ramdisk use

(Only if the kernel was compiled with **CONFIG_BLK_DEV_RAM**.) In general it is a bad idea to use a ramdisk under Linux—the system will use available memory more efficiently itself. But while booting, it is often useful to load the floppy contents into a ramdisk. One might also have a system in which first some modules (for filesystem or hardware) must be loaded before the main disk can be accessed.

In Linux 1.3.48, ramdisk handling was changed drastically. Earlier, the memory was allocated statically, and there was a 'ramdisk=N' parameter to tell its size. (This could also be set in the kernel image at compile time.) These days ram disks use the buffer cache, and grow dynamically. For a lot of information on the current ramdisk setup, see the kernel source file *Documentation/blockdev/ramdisk.txt* (*Documentation/ramdisk.txt* in older kernels).

There are four parameters, two boolean and two integral.

'load_ramdisk=N'
If N=1, do load a ramdisk. If N=0, do not load a ramdisk. (This is the default.)

'prompt_ramdisk=N'
If N=1, do prompt for insertion of the floppy. (This is the default.) If N=0, do not prompt. (Thus, this parameter is never needed.)

'ramdisk_size=N' or (obsolete) **'ramdisk=N'**
Set the maximal size of the ramdisk(s) to N kB. The default is 4096 (4 MB).

'ramdisk_start=N'
Sets the starting block number (the offset on the floppy where the ramdisk starts) to N. This is needed in case the ramdisk follows a kernel image.

'noinitrd'
(Only if the kernel was compiled with **CONFIG_BLK_DEV_RAM** and **CONFIG_BLK_DEV_INITRD**.) These days it is possible to compile the kernel to use initrd. When this feature is enabled, the boot process will load the kernel and an initial ramdisk; then the kernel converts initrd into a "normal" ramdisk, which is mounted read-write as root device; then */linuxrc* is executed; afterward the "real" root filesystem is mounted, and the initrd filesystem is moved over to */initrd*; finally the usual boot sequence (e.g., invocation of */sbin/init*) is performed.

For a detailed description of the initrd feature, see the kernel source file *Documentation/admin−guide/initrd.rst* (or *Documentation/initrd.txt* before Linux 4.10).

The 'noinitrd' option tells the kernel that although it was compiled for operation with initrd, it should not go through the above steps, but leave the initrd data under */dev/initrd*. (This device can be used only once: the data is freed as soon as the last process that used it has closed */dev/initrd*.)

Boot arguments for SCSI devices

General notation for this section:

iobase -- the first I/O port that the SCSI host occupies. These are specified in hexadecimal notation, and usually lie in the range from 0x200 to 0x3ff.

irq -- the hardware interrupt that the card is configured to use. Valid values will be dependent on the card in question, but will usually be 5, 7, 9, 10, 11, 12, and 15. The other values are usually used for common peripherals like IDE hard disks, floppies, serial ports, and so on.

scsi−id -- the ID that the host adapter uses to identify itself on the SCSI bus. Only some host adapters allow you to change this value, as most have it permanently specified internally. The usual default value is 7, but the Seagate and Future Domain TMC-950 boards use 6.

parity -- whether the SCSI host adapter expects the attached devices to supply a parity value with all information exchanges. Specifying a one indicates parity checking is enabled, and a zero disables parity checking. Again, not all adapters will support selection of parity behavior as a boot argument.

'max_scsi_luns=...'

A SCSI device can have a number of 'subdevices' contained within itself. The most common example is one of the new SCSI CD-ROMs that handle more than one disk at a time. Each CD is addressed as a 'Logical Unit Number' (LUN) of that particular device. But most devices, such as hard disks, tape drives, and such are only one device, and will be assigned to LUN zero.

Some poorly designed SCSI devices cannot handle being probed for LUNs not equal to zero. Therefore, if the compile-time flag **CONFIG_SCSI_MULTI_LUN** is not set, newer kernels will by default probe only LUN zero.

To specify the number of probed LUNs at boot, one enters 'max_scsi_luns=n' as a boot arg, where n is a number between one and eight. To avoid problems as described above, one would use n=1 to avoid upsetting such broken devices.

SCSI tape configuration

Some boot time configuration of the SCSI tape driver can be achieved by using the following:

```
st=buf_size[,write_threshold[,max_bufs]]
```

The first two numbers are specified in units of kB. The default *buf_size* is 32k B, and the maximum size that can be specified is a ridiculous 16384 kB. The *write_threshold* is the value at which the buffer is committed to tape, with a default value of 30 kB. The maximum number of buffers varies with the number of drives detected, and has a default of two. An example usage would be:

```
st=32,30,2
```

Full details can be found in the file *Documentation/scsi/st.txt* (or *drivers/scsi/README.st* for older kernels) in the Linux kernel source.

Hard disks

IDE Disk/CD-ROM Driver Parameters

The IDE driver accepts a number of parameters, which range from disk geometry specifications, to support for broken controller chips. Drive-specific options are specified by using 'hdX=' with X in 'a'–'h'.

Non-drive-specific options are specified with the prefix 'hd='. Note that using a drive-specific prefix for a non-drive-specific option will still work, and the option will just be applied as expected.

Also note that 'hd=' can be used to refer to the next unspecified drive in the (a, ..., h) sequence. For the following discussions, the 'hd=' option will be cited for brevity. See the file

Documentation/ide/ide.txt (or *Documentation/ide.txt* in older kernels, or *drivers/block/README.ide* in ancient kernels) in the Linux kernel source for more details.

The 'hd=cyls,heads,sects[,wpcom[,irq]]' options
These options are used to specify the physical geometry of the disk. Only the first three values are required. The cylinder/head/sectors values will be those used by fdisk. The write precompensation value is ignored for IDE disks. The IRQ value specified will be the IRQ used for the interface that the drive resides on, and is not really a drive-specific parameter.

The 'hd=serialize' option
The dual IDE interface CMD-640 chip is broken as designed such that when drives on the secondary interface are used at the same time as drives on the primary interface, it will corrupt your data. Using this option tells the driver to make sure that both interfaces are never used at the same time.

The 'hd=noprobe' option
Do not probe for this drive. For example,

```
hdb=noprobe hdb=1166,7,17
```

would disable the probe, but still specify the drive geometry so that it would be registered as a valid block device, and hence usable.

The 'hd=nowerr' option
Some drives apparently have the **WRERR_STAT** bit stuck on permanently. This enables a work-around for these broken devices.

The 'hd=cdrom' option
This tells the IDE driver that there is an ATAPI compatible CD-ROM attached in place of a normal IDE hard disk. In most cases the CD-ROM is identified automatically, but if it isn't then this may help.

Standard ST-506 Disk Driver Options ('hd=')
The standard disk driver can accept geometry arguments for the disks similar to the IDE driver. Note however that it expects only three values (C/H/S); any more or any less and it will silently ignore you. Also, it accepts only 'hd=' as an argument, that is, 'hda=' and so on are not valid here. The format is as follows:

```
hd=cyls,heads,sects
```

If there are two disks installed, the above is repeated with the geometry parameters of the second disk.

Ethernet devices
Different drivers make use of different parameters, but they all at least share having an IRQ, an I/O port base value, and a name. In its most generic form, it looks something like this:

```
ether=irq,iobase[,param_1[,...param_8]],name
```

The first nonnumeric argument is taken as the name. The param_n values (if applicable) usually have different meanings for each different card/driver. Typical param_n values are used to specify things like shared memory address, interface selection, DMA channel and the like.

The most common use of this parameter is to force probing for a second ethercard, as the default is to probe only for one. This can be accomplished with a simple:

```
ether=0,0,eth1
```

Note that the values of zero for the IRQ and I/O base in the above example tell the driver(s) to autoprobe.

The Ethernet-HowTo has extensive documentation on using multiple cards and on the card/driver-specific implementation of the param_n values where used. Interested readers should refer to the section in that document on their particular card.

The floppy disk driver
There are many floppy driver options, and they are all listed in *Documentation/blockdev/floppy.txt* (or *Documentation/floppy.txt* in older kernels, or *drivers/block/README.fd* for ancient kernels) in the Linux kernel source. See that file for the details.

The sound driver

The sound driver can also accept boot arguments to override the compiled-in values. This is not recommended, as it is rather complex. It is described in the Linux kernel source file *Documentation/sound/oss/README.OSS* (*drivers/sound/Readme.linux* in older kernel versions). It accepts a boot argument of the form:

```
sound=device1[,device2[,device3...[,device10]]]
```

where each deviceN value is of the following format 0xTaaaId and the bytes are used as follows:

T − device type: 1=FM, 2=SB, 3=PAS, 4=GUS, 5=MPU401, 6=SB16, 7=SB16-MPU401

aaa − I/O address in hex.

I − interrupt line in hex (i.e., 10=a, 11=b, ...)

d − DMA channel.

As you can see, it gets pretty messy, and you are better off to compile in your own personal values as recommended. Using a boot argument of 'sound=0' will disable the sound driver entirely.

The line printer driver

'lp='

Syntax:

```
lp=0
lp=auto
lp=reset
lp=port[,port...]
```

You can tell the printer driver what ports to use and what ports not to use. The latter comes in handy if you don't want the printer driver to claim all available parallel ports, so that other drivers (e.g., PLIP, PPA) can use them instead.

The format of the argument is multiple port names. For example, lp=none,parport0 would use the first parallel port for lp1, and disable lp0. To disable the printer driver entirely, one can use lp=0.

NAME

BPF-HELPERS − list of eBPF helper functions

DESCRIPTION

The extended Berkeley Packet Filter (eBPF) subsystem consists in programs written in a pseudo−assembly language, then attached to one of the several kernel hooks and run in reaction of specific events. This framework differs from the older, "classic" BPF (or "cBPF") in several aspects, one of them being the ability to call special functions (or "helpers") from within a program. These functions are restricted to a white−list of helpers defined in the kernel.

These helpers are used by eBPF programs to interact with the system, or with the context in which they work. For instance, they can be used to print debugging messages, to get the time since the system was booted, to interact with eBPF maps, or to manipulate network packets. Since there are several eBPF program types, and that they do not run in the same context, each program type can only call a subset of those helpers.

Due to eBPF conventions, a helper can not have more than five arguments.

Internally, eBPF programs call directly into the compiled helper functions without requiring any foreign−function interface. As a result, calling helpers introduces no overhead, thus offering excellent performance.

This document is an attempt to list and document the helpers available to eBPF developers. They are sorted by chronological order (the oldest helpers in the kernel at the top).

HELPERS

void *bpf_map_lookup_elem(struct bpf_map ***map*, const void ***key***)**

Description

Perform a lookup in *map* for an entry associated to *key*.

Return Map value associated to *key*, or **NULL** if no entry was found.

long bpf_map_update_elem(struct bpf_map ***map*, const void ***key***, const void ***value***, u64** *flags***)**

Description

Add or update the value of the entry associated to *key* in *map* with *value*. *flags* is one of:

BPF_NOEXIST

The entry for *key* must not exist in the map.

BPF_EXIST

The entry for *key* must already exist in the map.

BPF_ANY

No condition on the existence of the entry for *key*.

Flag value **BPF_NOEXIST** cannot be used for maps of types **BPF_MAP_TYPE_ARRAY** or **BPF_MAP_TYPE_PERCPU_ARRAY** (all elements always exist), the helper would return an error.

Return 0 on success, or a negative error in case of failure.

long bpf_map_delete_elem(struct bpf_map ***map*, const void ***key***)**

Description

Delete entry with *key* from *map*.

Return 0 on success, or a negative error in case of failure.

long bpf_probe_read(void ***dst*, u32** *size***, const void ***unsafe_ptr***)**

Description

For tracing programs, safely attempt to read *size* bytes from kernel space address *unsafe_ptr* and store the data in *dst*.

Generally, use **bpf_probe_read_user**() or **bpf_probe_read_kernel**() instead.

Return 0 on success, or a negative error in case of failure.

u64 bpf_ktime_get_ns(void)

Description

Return the time elapsed since system boot, in nanoseconds. Does not include time the system was suspended. See: **clock_gettime**(**CLOCK_MONOTONIC**)

Return Current *ktime*.

long bpf_trace_printk(const char ****fmt*, u32** *fmt_size***, ...)**

Description

This helper is a "printk()−like" facility for debugging. It prints a message defined by format *fmt* (of size *fmt_size*) to file */sys/kernel/tracing/trace* from TraceFS, if available. It can take up to three additional **u64** arguments (as an eBPF helpers, the total number of arguments is limited to five).

Each time the helper is called, it appends a line to the trace. Lines are discarded while */sys/kernel/tracing/trace* is open, use */sys/kernel/tracing/trace_pipe* to avoid this. The format of the trace is customizable, and the exact output one will get depends on the options set in */sys/kernel/tracing/trace_options* (see also the *README* file under the same directory). However, it usually defaults to something like:

```
telnet-470   [001] .N.. 419421.045894: 0x00000001: <formatted msg>
```

In the above:

- **telnet** is the name of the current task.
- **470** is the PID of the current task.
- **001** is the CPU number on which the task is running.
- In **.N..**, each character refers to a set of options (whether irqs are enabled, scheduling options, whether hard/softirqs are running, level of preempt_disabled respectively). **N** means that **TIF_NEED_RESCHED** and **PREEMPT_NEED_RESCHED** are set.
- **419421.045894** is a timestamp.
- **0x00000001** is a fake value used by BPF for the instruction pointer register.
- **<formatted msg>** is the message formatted with *fmt*.

The conversion specifiers supported by *fmt* are similar, but more limited than for printk(). They are **%d**, **%i**, **%u**, **%x**, **%ld**, **%li**, **%lu**, **%lx**, **%lld**, **%lli**, **%llu**, **%llx**, **%p**, **%s**. No modifier (size of field, padding with zeroes, etc.) is available, and the helper will return **−EINVAL** (but print nothing) if it encounters an unknown specifier.

Also, note that **bpf_trace_printk**() is slow, and should only be used for debugging purposes. For this reason, a notice block (spanning several lines) is printed to kernel logs and states that the helper should not be used "for production use" the first time this helper is used (or more precisely, when **trace_printk**() buffers are allocated). For passing values to user space, perf events should be preferred.

Return The number of bytes written to the buffer, or a negative error in case of failure.

u32 bpf_get_prandom_u32(void)

Description

Get a pseudo−random number.

From a security point of view, this helper uses its own pseudo−random internal state, and cannot be used to infer the seed of other random functions in the kernel. However, it is essential to note that the generator used by the helper is not cryptographically secure.

Return A random 32−bit unsigned value.

u32 bpf_get_smp_processor_id(void)

Description

Get the SMP (symmetric multiprocessing) processor id. Note that all programs run with migration disabled, which means that the SMP processor id is stable during all the execution of the program.

Return The SMP id of the processor running the program.

long bpf_skb_store_bytes(struct sk_buff *_skb_, u32 _offset_, const void *_from_, u32 _len_, u64 _flags_)

Description

Store *len* bytes from address *from* into the packet associated to *skb*, at *offset*. *flags* are a combination of **BPF_F_RECOMPUTE_CSUM** (automatically recompute the checksum for the packet after storing the bytes) and **BPF_F_INVALIDATE_HASH** (set *skb*−>**hash**, *skb*−>**swhash** and *skb*−>**l4hash** to 0).

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_l3_csum_replace(struct sk_buff *_skb_, u32 _offset_, u64 _from_, u64 _to_, u64 _size_)

Description

Recompute the layer 3 (e.g. IP) checksum for the packet associated to *skb*. Computation is incremental, so the helper must know the former value of the header field that was modified (*from*), the new value of this field (*to*), and the number of bytes (2 or 4) for this field, stored in *size*. Alternatively, it is possible to store the difference between the previous and the new values of the header field in *to*, by setting *from* and *size* to 0. For both methods, *offset* indicates the location of the IP checksum within the packet.

This helper works in combination with **bpf_csum_diff**(), which does not update the checksum in−place, but offers more flexibility and can handle sizes larger than 2 or 4 for the checksum to update.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_l4_csum_replace(struct sk_buff *_skb_, u32 _offset_, u64 _from_, u64 _to_, u64 _flags_)

Description

Recompute the layer 4 (e.g. TCP, UDP or ICMP) checksum for the packet associated to *skb*. Computation is incremental, so the helper must know the former value of the header field that was modified (*from*), the new value of this field (*to*), and the number of bytes (2 or 4) for this field, stored on the lowest four bits of *flags*. Alternatively, it is possible to store the difference between the previous and the new values of the header field in *to*, by setting *from* and the four lowest bits of *flags* to 0. For both methods, *offset* indicates the location of the IP checksum within the packet. In addition to the size of the field, *flags* can be added (bitwise OR) actual flags. With **BPF_F_MARK_MANGLED_0**, a null checksum is left untouched (unless **BPF_F_MARK_ENFORCE** is added as well), and for updates resulting in a null checksum the value is set to **CSUM_MANGLED_0** instead. Flag **BPF_F_PSEUDO_HDR** indicates the checksum is to be computed against a pseudo−header.

This helper works in combination with **bpf_csum_diff**(), which does not update the checksum in−place, but offers more flexibility and can handle sizes larger than 2 or 4 for the checksum to update.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_tail_call(void *_ctx_, struct bpf_map *_prog_array_map_, u32 _index_)

Description

This special helper is used to trigger a "tail call", or in other words, to jump into another eBPF program. The same stack frame is used (but values on stack and in registers for the caller are not accessible to the callee). This mechanism allows for program chaining, either for raising the maximum number of available eBPF instructions, or to execute given programs in conditional blocks. For security reasons, there is an upper limit to the number of successive tail calls that can be performed.

Upon call of this helper, the program attempts to jump into a program referenced at index *index* in *prog_array_map*, a special map of type **BPF_MAP_TYPE_PROG_ARRAY**, and passes *ctx*, a pointer to the context.

If the call succeeds, the kernel immediately runs the first instruction of the new program. This is not a function call, and it never returns to the previous program. If the call fails, then the helper has no effect, and the caller continues to run its subsequent instructions. A call can fail if the destination program for the jump does not exist (i.e. *index* is superior to the number of entries in *prog_array_map*), or if the maximum number of tail calls has been reached for this chain of programs. This limit is defined in the kernel by the macro **MAX_TAIL_CALL_CNT** (not accessible to user space), which is currently set to 33.

Return 0 on success, or a negative error in case of failure.

long bpf_clone_redirect(struct sk_buff *_skb_, u32 _ifindex_, u64 _flags_)

Description

Clone and redirect the packet associated to *skb* to another net device of index *ifindex*. Both ingress and egress interfaces can be used for redirection. The **BPF_F_INGRESS** value in *flags* is used to make the distinction (ingress path is selected if the flag is present, egress path otherwise). This is the only flag supported for now.

In comparison with **bpf_redirect**() helper, **bpf_clone_redirect**() has the associated cost of duplicating the packet buffer, but this can be executed out of the eBPF program. Conversely, **bpf_redirect**() is more efficient, but it is handled through an action code where the redirection happens only after the eBPF program has returned.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure. Positive error indicates a potential drop or congestion in the target device. The particular positive error codes are not defined.

u64 bpf_get_current_pid_tgid(void)

Description

Get the current pid and tgid.

Return A 64−bit integer containing the current tgid and pid, and created as such: *current_task*−>**tgid << 32 |** *current_task*−>**pid**.

u64 bpf_get_current_uid_gid(void)

Description

Get the current uid and gid.

Return A 64−bit integer containing the current GID and UID, and created as such: *current_gid* **<< 32 |** *current_uid*.

long bpf_get_current_comm(void *****buf***, u32** *size_of_buf***)**

Description

Copy the **comm** attribute of the current task into *buf* of *size_of_buf*. The **comm** attribute contains the name of the executable (excluding the path) for the current task. The *size_of_buf* must be strictly positive. On success, the helper makes sure that the *buf* is NUL−terminated. On failure, it is filled with zeroes.

Return 0 on success, or a negative error in case of failure.

u32 bpf_get_cgroup_classid(struct sk_buff *****skb***)**

Description

Retrieve the classid for the current task, i.e. for the net_cls cgroup to which *skb* belongs.

This helper can be used on TC egress path, but not on ingress.

The net_cls cgroup provides an interface to tag network packets based on a user−provided identifier for all traffic coming from the tasks belonging to the related cgroup. See also the related kernel documentation, available from the Linux sources in file *Documentation/admin−guide/cgroup−v1/net_cls.rst*.

The Linux kernel has two versions for cgroups: there are cgroups v1 and cgroups v2. Both are available to users, who can use a mixture of them, but note that the net_cls cgroup is for cgroup v1 only. This makes it incompatible with BPF programs run on cgroups, which is a cgroup−v2−only feature (a socket can only hold data for one version of cgroups at a time).

This helper is only available is the kernel was compiled with the **CONFIG_CGROUP_NET_CLASSID** configuration option set to "**y**" or to "**m**".

Return The classid, or 0 for the default unconfigured classid.

long bpf_skb_vlan_push(struct sk_buff *****skb***, __be16** *vlan_proto***, u16** *vlan_tci***)**

Description

Push a *vlan_tci* (VLAN tag control information) of protocol *vlan_proto* to the packet associated to *skb*, then update the checksum. Note that if *vlan_proto* is different from **ETH_P_8021Q** and **ETH_P_8021AD**, it is considered to be **ETH_P_8021Q**.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_vlan_pop(struct sk_buff *****skb***)**

Description

Pop a VLAN header from the packet associated to *skb*.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet

access.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_get_tunnel_key(struct sk_buff ****skb*, struct bpf_tunnel_key ****key***, u32** *size***, u64** *flags***)**

Description

Get tunnel metadata. This helper takes a pointer *key* to an empty **struct bpf_tunnel_key** of **size**, that will be filled with tunnel metadata for the packet associated to *skb*. The *flags* can be set to **BPF_F_TUNINFO_IPV6**, which indicates that the tunnel is based on IPv6 protocol instead of IPv4.

The **struct bpf_tunnel_key** is an object that generalizes the principal parameters used by various tunneling protocols into a single struct. This way, it can be used to easily make a decision based on the contents of the encapsulation header, "summarized" in this struct. In particular, it holds the IP address of the remote end (IPv4 or IPv6, depending on the case) in *key*->**remote_ipv4** or *key*->**remote_ipv6**. Also, this struct exposes the *key*->**tunnel_id**, which is generally mapped to a VNI (Virtual Network Identifier), making it programmable together with the **bpf_skb_set_tunnel_key**() helper.

Let's imagine that the following code is part of a program attached to the TC ingress interface, on one end of a GRE tunnel, and is supposed to filter out all messages coming from remote ends with IPv4 address other than 10.0.0.1:

```
int ret;
struct bpf_tunnel_key key = {};
ret = bpf_skb_get_tunnel_key(skb, &key, sizeof(key), 0);
if (ret < 0)
        return TC_ACT_SHOT;     // drop packet
if (key.remote_ipv4 != 0x0a000001)
        return TC_ACT_SHOT;     // drop packet
return TC_ACT_OK;               // accept packet
```

This interface can also be used with all encapsulation devices that can operate in "collect metadata" mode: instead of having one network device per specific configuration, the "collect metadata" mode only requires a single device where the configuration can be extracted from this helper.

This can be used together with various tunnels such as VXLan, Geneve, GRE or IP in IP (IPIP).

Return 0 on success, or a negative error in case of failure.

long bpf_skb_set_tunnel_key(struct sk_buff ****skb*, struct bpf_tunnel_key ****key***, u32** *size***, u64** *flags***)**

Description

Populate tunnel metadata for packet associated to *skb.* The tunnel metadata is set to the contents of *key*, of *size*. The *flags* can be set to a combination of the following values:

BPF_F_TUNINFO_IPV6
: Indicate that the tunnel is based on IPv6 protocol instead of IPv4.

BPF_F_ZERO_CSUM_TX
: For IPv4 packets, add a flag to tunnel metadata indicating that checksum computation should be skipped and checksum set to zeroes.

BPF_F_DONT_FRAGMENT
: Add a flag to tunnel metadata indicating that the packet should not be fragmented.

BPF_F_SEQ_NUMBER
: Add a flag to tunnel metadata indicating that a sequence number should be added to tunnel header before sending the packet. This flag was added for

GRE encapsulation, but might be used with other protocols as well in the future.

BPF_F_NO_TUNNEL_KEY
Add a flag to tunnel metadata indicating that no tunnel key should be set in the resulting tunnel header.

Here is a typical usage on the transmit path:

```
struct bpf_tunnel_key key;
     populate key ...
bpf_skb_set_tunnel_key(skb, &key, sizeof(key), 0);
bpf_clone_redirect(skb, vxlan_dev_ifindex, 0);
```

See also the description of the **bpf_skb_get_tunnel_key**() helper for additional information.

Return 0 on success, or a negative error in case of failure.

u64 bpf_perf_event_read(struct bpf_map *_map_, u64 _flags_)

Description
Read the value of a perf event counter. This helper relies on a *map* of type **BPF_MAP_TYPE_PERF_EVENT_ARRAY**. The nature of the perf event counter is selected when *map* is updated with perf event file descriptors. The *map* is an array whose size is the number of available CPUs, and each cell contains a value relative to one CPU. The value to retrieve is indicated by *flags*, that contains the index of the CPU to look up, masked with **BPF_F_INDEX_MASK**. Alternatively, *flags* can be set to **BPF_F_CURRENT_CPU** to indicate that the value for the current CPU should be retrieved.

Note that before Linux 4.13, only hardware perf event can be retrieved.

Also, be aware that the newer helper **bpf_perf_event_read_value**() is recommended over **bpf_perf_event_read**() in general. The latter has some ABI quirks where error and counter value are used as a return code (which is wrong to do since ranges may overlap). This issue is fixed with **bpf_perf_event_read_value**(), which at the same time provides more features over the **bpf_perf_event_read**() interface. Please refer to the description of **bpf_perf_event_read_value**() for details.

Return The value of the perf event counter read from the map, or a negative error code in case of failure.

long bpf_redirect(u32 _ifindex_, u64 _flags_)

Description
Redirect the packet to another net device of index *ifindex*. This helper is somewhat similar to **bpf_clone_redirect**(), except that the packet is not cloned, which provides increased performance.

Except for XDP, both ingress and egress interfaces can be used for redirection. The **BPF_F_INGRESS** value in *flags* is used to make the distinction (ingress path is selected if the flag is present, egress path otherwise). Currently, XDP only supports redirection to the egress interface, and accepts no flag at all.

The same effect can also be attained with the more generic **bpf_redirect_map**(), which uses a BPF map to store the redirect target instead of providing it directly to the helper.

Return For XDP, the helper returns **XDP_REDIRECT** on success or **XDP_ABORTED** on error. For other program types, the values are **TC_ACT_REDIRECT** on success or **TC_ACT_SHOT** on error.

u32 bpf_get_route_realm(struct sk_buff *_skb_)

Description

Retrieve the realm or the route, that is to say the **tclassid** field of the destination for the *skb*. The identifier retrieved is a user−provided tag, similar to the one used with the net_cls cgroup (see description for **bpf_get_cgroup_classid**() helper), but here this tag is held by a route (a destination entry), not by a task.

Retrieving this identifier works with the clsact TC egress hook (see also **tc−bpf(8)**), or alternatively on conventional classful egress qdiscs, but not on TC ingress path. In case of clsact TC egress hook, this has the advantage that, internally, the destination entry has not been dropped yet in the transmit path. Therefore, the destination entry does not need to be artificially held via **netif_keep_dst**() for a classful qdisc until the *skb* is freed.

This helper is available only if the kernel was compiled with **CONFIG_IP_ROUTE_CLASSID** configuration option.

Return The realm of the route for the packet associated to *skb*, or 0 if none was found.

long bpf_perf_event_output(void *_ctx_, struct bpf_map *_map_, u64 _flags_, void *_data_, u64 _size_)

Description

Write raw *data* blob into a special BPF perf event held by *map* of type **BPF_MAP_TYPE_PERF_EVENT_ARRAY**. This perf event must have the following attributes: **PERF_SAMPLE_RAW** as **sample_type**, **PERF_TYPE_SOFTWARE** as **type**, and **PERF_COUNT_SW_BPF_OUTPUT** as **config**.

The *flags* are used to indicate the index in *map* for which the value must be put, masked with **BPF_F_INDEX_MASK**. Alternatively, *flags* can be set to **BPF_F_CURRENT_CPU** to indicate that the index of the current CPU core should be used.

The value to write, of *size*, is passed through eBPF stack and pointed by *data*.

The context of the program *ctx* needs also be passed to the helper.

On user space, a program willing to read the values needs to call **perf_event_open**() on the perf event (either for one or for all CPUs) and to store the file descriptor into the *map*. This must be done before the eBPF program can send data into it. An example is available in file *samples/bpf/trace_output_user.c* in the Linux kernel source tree (the eBPF program counterpart is in *samples/bpf/trace_output_kern.c*).

bpf_perf_event_output() achieves better performance than **bpf_trace_printk**() for sharing data with user space, and is much better suitable for streaming data from eBPF programs.

Note that this helper is not restricted to tracing use cases and can be used with programs attached to TC or XDP as well, where it allows for passing data to user space listeners. Data can be:

- Only custom structs,
- Only the packet payload, or
- A combination of both.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_load_bytes(const void *_skb_, u32 _offset_, void *_to_, u32 _len_)

Description

This helper was provided as an easy way to load data from a packet. It can be used to load *len* bytes from *offset* from the packet associated to *skb*, into the buffer pointed by *to*.

Since Linux 4.7, usage of this helper has mostly been replaced by "direct packet access", enabling packet data to be manipulated with *skb*−>**data** and *skb*−>**data_end** pointing respectively to the first byte of packet data and to the byte after the last byte of packet data. However, it remains useful if one wishes to read large quantities of data at once from a packet into the eBPF stack.

Return 0 on success, or a negative error in case of failure.

long bpf_get_stackid(void *_ctx_, struct bpf_map *_map_, u64 _flags_)

Description

Walk a user or a kernel stack and return its id. To achieve this, the helper needs *ctx*, which is a pointer to the context on which the tracing program is executed, and a pointer to a *map* of type **BPF_MAP_TYPE_STACK_TRACE**.

The last argument, *flags*, holds the number of stack frames to skip (from 0 to 255), masked with **BPF_F_SKIP_FIELD_MASK**. The next bits can be used to set a combination of the following flags:

BPF_F_USER_STACK
Collect a user space stack instead of a kernel stack.

BPF_F_FAST_STACK_CMP
Compare stacks by hash only.

BPF_F_REUSE_STACKID
If two different stacks hash into the same *stackid*, discard the old one.

The stack id retrieved is a 32 bit long integer handle which can be further combined with other data (including other stack ids) and used as a key into maps. This can be useful for generating a variety of graphs (such as flame graphs or off−cpu graphs).

For walking a stack, this helper is an improvement over **bpf_probe_read**(), which can be used with unrolled loops but is not efficient and consumes a lot of eBPF instructions. Instead, **bpf_get_stackid**() can collect up to **PERF_MAX_STACK_DEPTH** both kernel and user frames. Note that this limit can be controlled with the **sysctl** program, and that it should be manually increased in order to profile long user stacks (such as stacks for Java programs). To do so, use:

```
# sysctl kernel.perf_event_max_stack=<new value>
```

Return The positive or null stack id on success, or a negative error in case of failure.

s64 bpf_csum_diff(__be32 *_from_, u32 _from_size_, __be32 *_to_, u32 _to_size_, __wsum _seed_)

Description

Compute a checksum difference, from the raw buffer pointed by *from*, of length *from_size* (that must be a multiple of 4), towards the raw buffer pointed by *to*, of size *to_size* (same remark). An optional *seed* can be added to the value (this can be cascaded, the seed may come from a previous call to the helper).

This is flexible enough to be used in several ways:

- With *from_size* == 0, *to_size* > 0 and *seed* set to checksum, it can be used when pushing new data.
- With *from_size* > 0, *to_size* == 0 and *seed* set to checksum, it can be used when removing data from a packet.
- With *from_size* > 0, *to_size* > 0 and *seed* set to 0, it can be used to compute a diff. Note that *from_size* and *to_size* do not need to be equal.

This helper can be used in combination with **bpf_l3_csum_replace**() and **bpf_l4_csum_replace**(), to which one can feed in the difference computed with **bpf_csum_diff**().

Return The checksum result, or a negative error code in case of failure.

long bpf_skb_get_tunnel_opt(struct sk_buff *_skb_, void *_opt_, u32 _size_)

Description

Retrieve tunnel options metadata for the packet associated to *skb*, and store the raw tunnel option data to the buffer *opt* of *size*.

This helper can be used with encapsulation devices that can operate in "collect metadata" mode (please refer to the related note in the description of **bpf_skb_get_tunnel_key**() for more details). A particular example where this can be used is in combination with the Geneve encapsulation protocol, where it allows for pushing (with **bpf_skb_get_tunnel_opt**() helper) and retrieving arbitrary TLVs (Type−Length−Value headers) from the eBPF program. This allows for full customization of these headers.

Return The size of the option data retrieved.

long bpf_skb_set_tunnel_opt(struct sk_buff *_skb_, void *_opt_, u32 _size_)

Description

Set tunnel options metadata for the packet associated to *skb* to the option data contained in the raw buffer *opt* of *size*.

See also the description of the **bpf_skb_get_tunnel_opt**() helper for additional information.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_change_proto(struct sk_buff *_skb_, __be16 _proto_, u64 _flags_)

Description

Change the protocol of the *skb* to *proto*. Currently supported are transition from IPv4 to IPv6, and from IPv6 to IPv4. The helper takes care of the groundwork for the transition, including resizing the socket buffer. The eBPF program is expected to fill the new headers, if any, via **skb_store_bytes**() and to recompute the checksums with **bpf_l3_csum_replace**() and **bpf_l4_csum_replace**(). The main case for this helper is to perform NAT64 operations out of an eBPF program.

Internally, the GSO type is marked as dodgy so that headers are checked and segments are recalculated by the GSO/GRO engine. The size for GSO target is adapted as well.

All values for *flags* are reserved for future usage, and must be left at zero.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_change_type(struct sk_buff *_skb_, u32 _type_)

Description

Change the packet type for the packet associated to *skb*. This comes down to setting *skb*−>**pkt_type** to *type*, except the eBPF program does not have a write access to *skb*−>**pkt_type** beside this helper. Using a helper here allows for graceful handling of errors.

The major use case is to change incoming *skb*s to **PACKET_HOST*** in a programmatic way instead of having to recirculate via **redirect**(..., **BPF_F_INGRESS**), for example.

Note that *type* only allows certain values. At this time, they are:

PACKET_HOST
Packet is for us.

PACKET_BROADCAST
Send packet to all.

PACKET_MULTICAST
Send packet to group.

PACKET_OTHERHOST
Send packet to someone else.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_under_cgroup(struct sk_buff *_skb_, struct bpf_map *_map_, u32 _index_)

Description
Check whether *skb* is a descendant of the cgroup2 held by *map* of type **BPF_MAP_TYPE_CGROUP_ARRAY**, at *index*.

Return The return value depends on the result of the test, and can be:

- 0, if the *skb* failed the cgroup2 descendant test.
- 1, if the *skb* succeeded the cgroup2 descendant test.
- A negative error code, if an error occurred.

u32 bpf_get_hash_recalc(struct sk_buff *_skb_)

Description
Retrieve the hash of the packet, *skb*−>**hash**. If it is not set, in particular if the hash was cleared due to mangling, recompute this hash. Later accesses to the hash can be done directly with *skb*−>**hash**.

Calling **bpf_set_hash_invalid**(), changing a packet prototype with **bpf_skb_change_proto**(), or calling **bpf_skb_store_bytes**() with the **BPF_F_INVALIDATE_HASH** are actions susceptible to clear the hash and to trigger a new computation for the next call to **bpf_get_hash_recalc**().

Return The 32−bit hash.

u64 bpf_get_current_task(void)

Description
Get the current task.

Return A pointer to the current task struct.

long bpf_probe_write_user(void *_dst_, const void *_src_, u32 _len_)

Description
Attempt in a safe way to write *len* bytes from the buffer *src* to *dst* in memory. It only works for threads that are in user context, and *dst* must be a valid user space address.

This helper should not be used to implement any kind of security mechanism because of TOC−TOU attacks, but rather to debug, divert, and manipulate execution of semi−cooperative processes.

Keep in mind that this feature is meant for experiments, and it has a risk of crashing the system and running programs. Therefore, when an eBPF program using this helper is attached, a warning including PID and process name is printed to kernel logs.

Return 0 on success, or a negative error in case of failure.

long bpf_current_task_under_cgroup(struct bpf_map *_map_, u32 _index_)

Description
Check whether the probe is being run is the context of a given subset of the cgroup2 hierarchy. The cgroup2 to test is held by *map* of type

BPF_MAP_TYPE_CGROUP_ARRAY, at *index*.

Return The return value depends on the result of the test, and can be:

- 1, if current task belongs to the cgroup2.
- 0, if current task does not belong to the cgroup2.
- A negative error code, if an error occurred.

long bpf_skb_change_tail(struct sk_buff ***skb*, u32** *len***, u64** *flags***)**

Description

Resize (trim or grow) the packet associated to *skb* to the new *len*. The *flags* are reserved for future usage, and must be left at zero.

The basic idea is that the helper performs the needed work to change the size of the packet, then the eBPF program rewrites the rest via helpers like **bpf_skb_store_bytes**(), **bpf_l3_csum_replace**(), **bpf_l3_csum_replace**() and others. This helper is a slow path utility intended for replies with control messages. And because it is targeted for slow path, the helper itself can afford to be slow: it implicitly linearizes, unclones and drops offloads from the *skb*.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_pull_data(struct sk_buff ***skb*, u32** *len***)**

Description

Pull in non−linear data in case the *skb* is non−linear and not all of *len* are part of the linear section. Make *len* bytes from *skb* readable and writable. If a zero value is passed for *len*, then all bytes in the linear part of *skb* will be made readable and writable.

This helper is only needed for reading and writing with direct packet access.

For direct packet access, testing that offsets to access are within packet boundaries (test on *skb*−>**data_end**) is susceptible to fail if offsets are invalid, or if the requested data is in non−linear parts of the *skb*. On failure the program can just bail out, or in the case of a non−linear buffer, use a helper to make the data available. The **bpf_skb_load_bytes**() helper is a first solution to access the data. Another one consists in using **bpf_skb_pull_data** to pull in once the non−linear parts, then retesting and eventually access the data.

At the same time, this also makes sure the *skb* is uncloned, which is a necessary condition for direct write. As this needs to be an invariant for the write part only, the verifier detects writes and adds a prologue that is calling **bpf_skb_pull_data()** to effectively unclone the *skb* from the very beginning in case it is indeed cloned.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

s64 bpf_csum_update(struct sk_buff ***skb*, __wsum** *csum***)**

Description

Add the checksum *csum* into *skb*−>**csum** in case the driver has supplied a checksum for the entire packet into that field. Return an error otherwise. This helper is intended to be used in combination with **bpf_csum_diff**(), in particular when the checksum

needs to be updated after data has been written into the packet through direct packet access.

Return The checksum on success, or a negative error code in case of failure.

void bpf_set_hash_invalid(struct sk_buff *_skb_)

Description

Invalidate the current *skb*->**hash**. It can be used after mangling on headers through direct packet access, in order to indicate that the hash is outdated and to trigger a recalculation the next time the kernel tries to access this hash or when the **bpf_get_hash_recalc**() helper is called.

Return void.

long bpf_get_numa_node_id(void)

Description

Return the id of the current NUMA node. The primary use case for this helper is the selection of sockets for the local NUMA node, when the program is attached to sockets using the **SO_ATTACH_REUSEPORT_EBPF** option (see also **socket(7)**), but the helper is also available to other eBPF program types, similarly to **bpf_get_smp_processor_id**().

Return The id of current NUMA node.

long bpf_skb_change_head(struct sk_buff *_skb_, u32 _len_, u64 _flags_)

Description

Grows headroom of packet associated to *skb* and adjusts the offset of the MAC header accordingly, adding *len* bytes of space. It automatically extends and reallocates memory as required.

This helper can be used on a layer 3 *skb* to push a MAC header for redirection into a layer 2 device.

All values for *flags* are reserved for future usage, and must be left at zero.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_xdp_adjust_head(struct xdp_buff *_xdp_md_, int _delta_)

Description

Adjust (move) *xdp_md*->**data** by *delta* bytes. Note that it is possible to use a negative value for *delta*. This helper can be used to prepare the packet for pushing or popping headers.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_probe_read_str(void *_dst_, u32 _size_, const void *_unsafe_ptr_)

Description

Copy a NUL terminated string from an unsafe kernel address *unsafe_ptr* to *dst*. See **bpf_probe_read_kernel_str**() for more details.

Generally, use **bpf_probe_read_user_str**() or **bpf_probe_read_kernel_str**() instead.

Return On success, the strictly positive length of the string, including the trailing NUL character. On error, a negative value.

u64 bpf_get_socket_cookie(struct sk_buff ****skb*)**

Description

If the **struct sk_buff** pointed by *skb* has a known socket, retrieve the cookie (generated by the kernel) of this socket. If no cookie has been set yet, generate a new cookie. Once generated, the socket cookie remains stable for the life of the socket. This helper can be useful for monitoring per socket networking traffic statistics as it provides a global socket identifier that can be assumed unique.

Return A 8−byte long unique number on success, or 0 if the socket field is missing inside *skb*.

u64 bpf_get_socket_cookie(struct bpf_sock_addr ****ctx*)**

Description

Equivalent to bpf_get_socket_cookie() helper that accepts *skb*, but gets socket from **struct bpf_sock_addr** context.

Return A 8−byte long unique number.

u64 bpf_get_socket_cookie(struct bpf_sock_ops ****ctx*)**

Description

Equivalent to **bpf_get_socket_cookie**() helper that accepts *skb*, but gets socket from **struct bpf_sock_ops** context.

Return A 8−byte long unique number.

u64 bpf_get_socket_cookie(struct sock ****sk*)**

Description

Equivalent to **bpf_get_socket_cookie**() helper that accepts *sk*, but gets socket from a BTF **struct sock**. This helper also works for sleepable programs.

Return A 8−byte long unique number or 0 if *sk* is NULL.

u32 bpf_get_socket_uid(struct sk_buff ****skb*)**

Description

Get the owner UID of the socked associated to *skb*.

Return The owner UID of the socket associated to *skb*. If the socket is **NULL**, or if it is not a full socket (i.e. if it is a time−wait or a request socket instead), **overflowuid** value is returned (note that **overflowuid** might also be the actual UID value for the socket).

long bpf_set_hash(struct sk_buff ****skb*, u32** *hash***)**

Description

Set the full hash for *skb* (set the field *skb*−>**hash**) to value *hash*.

Return

long bpf_setsockopt(void ****bpf_socket*, int** *level***, int** *optname***, void ****optval***, int** *optlen***)**

Description

Emulate a call to **setsockopt()** on the socket associated to *bpf_socket*, which must be a full socket. The *level* at which the option resides and the name *optname* of the option must be specified, see **setsockopt(2)** for more information. The option value of length *optlen* is pointed by *optval*.

bpf_socket should be one of the following:

- **struct bpf_sock_ops** for **BPF_PROG_TYPE_SOCK_OPS**.
- **struct bpf_sock_addr** for **BPF_CGROUP_INET4_CONNECT**, **BPF_CGROUP_INET6_CONNECT** and **BPF_CGROUP_UNIX_CONNECT**.

This helper actually implements a subset of **setsockopt()**. It supports the following *level*s:

- **SOL_SOCKET**, which supports the following *optname*s: **SO_RCVBUF**, **SO_SNDBUF**, **SO_MAX_PACING_RATE**, **SO_PRIORITY**, **SO_RCVLOWAT**, **SO_MARK**, **SO_BINDTODEVICE**, **SO_KEEPALIVE**, **SO_REUSEADDR**, **SO_REUSEPORT**, **SO_BINDTOIFINDEX**, **SO_TXREHASH**.
- **IPPROTO_TCP**, which supports the following *optname*s: **TCP_CONGESTION**, **TCP_BPF_IW**, **TCP_BPF_SNDCWND_CLAMP**, **TCP_SAVE_SYN**, **TCP_KEEPIDLE**, **TCP_KEEPINTVL**, **TCP_KEEPCNT**, **TCP_SYNCNT**, **TCP_USER_TIMEOUT**, **TCP_NOTSENT_LOWAT**, **TCP_NODELAY**, **TCP_MAXSEG**, **TCP_WINDOW_CLAMP**, **TCP_THIN_LINEAR_TIMEOUTS**, **TCP_BPF_DELACK_MAX**, **TCP_BPF_RTO_MIN**.
- **IPPROTO_IP**, which supports *optname* **IP_TOS**.
- **IPPROTO_IPV6**, which supports the following *optname*s: **IPV6_TCLASS**, **IPV6_AUTOFLOWLABEL**.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_adjust_room(struct sk_buff **skb*, s32 *len_diff***, u32** *mode***, u64** *flags***)**

Description

Grow or shrink the room for data in the packet associated to *skb* by *len_diff*, and according to the selected *mode*.

By default, the helper will reset any offloaded checksum indicator of the skb to CHECKSUM_NONE. This can be avoided by the following flag:

- **BPF_F_ADJ_ROOM_NO_CSUM_RESET**: Do not reset offloaded checksum data of the skb to CHECKSUM_NONE.

There are two supported modes at this time:

- **BPF_ADJ_ROOM_MAC**: Adjust room at the mac layer (room space is added or removed between the layer 2 and layer 3 headers).
- **BPF_ADJ_ROOM_NET**: Adjust room at the network layer (room space is added or removed between the layer 3 and layer 4 headers).

The following flags are supported at this time:

- **BPF_F_ADJ_ROOM_FIXED_GSO**: Do not adjust gso_size. Adjusting mss in this way is not allowed for datagrams.
- **BPF_F_ADJ_ROOM_ENCAP_L3_IPV4**, **BPF_F_ADJ_ROOM_ENCAP_L3_IPV6**: Any new space is reserved to hold a tunnel header. Configure skb offsets and other fields accordingly.
- **BPF_F_ADJ_ROOM_ENCAP_L4_GRE**, **BPF_F_ADJ_ROOM_ENCAP_L4_UDP**: Use with ENCAP_L3 flags to further specify the tunnel type.
- **BPF_F_ADJ_ROOM_ENCAP_L2**(*len*): Use with ENCAP_L3/L4 flags to further specify the tunnel type; *len* is the length of the inner MAC header.
- **BPF_F_ADJ_ROOM_ENCAP_L2_ETH**: Use with BPF_F_ADJ_ROOM_ENCAP_L2 flag to further specify the L2 type as Ethernet.
- **BPF_F_ADJ_ROOM_DECAP_L3_IPV4**, **BPF_F_ADJ_ROOM_DECAP_L3_IPV6**: Indicate the new IP header version after decapsulating the outer IP header. Used when the inner and outer IP versions are different.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_redirect_map(struct bpf_map ****map*, u64** *key***, u64** *flags***)**

Description

Redirect the packet to the endpoint referenced by *map* at index *key*. Depending on its type, this *map* can contain references to net devices (for forwarding packets through other ports), or to CPUs (for redirecting XDP frames to another CPU; but this is only implemented for native XDP (with driver support) as of this writing).

The lower two bits of *flags* are used as the return code if the map lookup fails. This is so that the return value can be one of the XDP program return codes up to **XDP_TX**, as chosen by the caller. The higher bits of *flags* can be set to BPF_F_BROADCAST or BPF_F_EXCLUDE_INGRESS as defined below.

With BPF_F_BROADCAST the packet will be broadcasted to all the interfaces in the map, with BPF_F_EXCLUDE_INGRESS the ingress interface will be excluded when do broadcasting.

See also **bpf_redirect**(), which only supports redirecting to an ifindex, but doesn't require a map to do so.

Return **XDP_REDIRECT** on success, or the value of the two lower bits of the *flags* argument on error.

long bpf_sk_redirect_map(struct sk_buff ****skb*, struct bpf_map ****map***, u32** *key***, u64** *flags***)**

Description

Redirect the packet to the socket referenced by *map* (of type **BPF_MAP_TYPE_SOCKMAP**) at index *key*. Both ingress and egress interfaces can be used for redirection. The **BPF_F_INGRESS** value in *flags* is used to make the distinction (ingress path is selected if the flag is present, egress path otherwise). This is the only flag supported for now.

Return **SK_PASS** on success, or **SK_DROP** on error.

long bpf_sock_map_update(struct bpf_sock_ops ****skops*, struct bpf_map ****map***, void ****key***, u64** *flags***)**

Description

Add an entry to, or update a *map* referencing sockets. The *skops* is used as a new value for the entry associated to *key*. *flags* is one of:

BPF_NOEXIST
The entry for *key* must not exist in the map.

BPF_EXIST
The entry for *key* must already exist in the map.

BPF_ANY
No condition on the existence of the entry for *key*.

If the *map* has eBPF programs (parser and verdict), those will be inherited by the socket being added. If the socket is already attached to eBPF programs, this results in an error.

Return 0 on success, or a negative error in case of failure.

long bpf_xdp_adjust_meta(struct xdp_buff ****xdp_md*, int** *delta***)**

Description

Adjust the address pointed by *xdp_md*−>**data_meta** by *delta* (which can be positive or negative). Note that this operation modifies the address stored in *xdp_md*−>**data**, so the latter must be loaded only after the helper has been called.

The use of *xdp_md*−>**data_meta** is optional and programs are not required to use it. The rationale is that when the packet is processed with XDP (e.g. as DoS filter), it is

possible to push further meta data along with it before passing to the stack, and to give the guarantee that an ingress eBPF program attached as a TC classifier on the same device can pick this up for further post−processing. Since TC works with socket buffers, it remains possible to set from XDP the **mark** or **priority** pointers, or other pointers for the socket buffer. Having this scratch space generic and programmable allows for more flexibility as the user is free to store whatever meta data they need.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_perf_event_read_value(struct bpf_map ****map*, u64** *flags***, struct bpf_perf_event_value ****buf***, u32** *buf_size***)**

Description

Read the value of a perf event counter, and store it into *buf* of size *buf_size*. This helper relies on a *map* of type **BPF_MAP_TYPE_PERF_EVENT_ARRAY**. The nature of the perf event counter is selected when *map* is updated with perf event file descriptors. The *map* is an array whose size is the number of available CPUs, and each cell contains a value relative to one CPU. The value to retrieve is indicated by *flags*, that contains the index of the CPU to look up, masked with **BPF_F_INDEX_MASK**. Alternatively, *flags* can be set to **BPF_F_CURRENT_CPU** to indicate that the value for the current CPU should be retrieved.

This helper behaves in a way close to **bpf_perf_event_read**() helper, save that instead of just returning the value observed, it fills the *buf* structure. This allows for additional data to be retrieved: in particular, the enabled and running times (in *buf*−>**enabled** and *buf*−>**running**, respectively) are copied. In general, **bpf_perf_event_read_value**() is recommended over **bpf_perf_event_read**(), which has some ABI issues and provides fewer functionalities.

These values are interesting, because hardware PMU (Performance Monitoring Unit) counters are limited resources. When there are more PMU based perf events opened than available counters, kernel will multiplex these events so each event gets certain percentage (but not all) of the PMU time. In case that multiplexing happens, the number of samples or counter value will not reflect the case compared to when no multiplexing occurs. This makes comparison between different runs difficult. Typically, the counter value should be normalized before comparing to other experiments. The usual normalization is done as follows.

```
normalized_counter = counter * t_enabled / t_running
```

Where t_enabled is the time enabled for event and t_running is the time running for event since last normalization. The enabled and running times are accumulated since the perf event open. To achieve scaling factor between two invocations of an eBPF program, users can use CPU id as the key (which is typical for perf array usage model) to remember the previous value and do the calculation inside the eBPF program.

Return 0 on success, or a negative error in case of failure.

long bpf_perf_prog_read_value(struct bpf_perf_event_data ****ctx*, struct bpf_perf_event_value ****buf***, u32** *buf_size***)**

Description

For an eBPF program attached to a perf event, retrieve the value of the event counter associated to *ctx* and store it in the structure pointed by *buf* and of size *buf_size*. Enabled and running times are also stored in the structure (see description of helper **bpf_perf_event_read_value**() for more details).

Return 0 on success, or a negative error in case of failure.

long bpf_getsockopt(void ****bpf_socket*, int** *level***, int** *optname***, void ****optval***, int** *optlen***)**

Description

Emulate a call to **getsockopt()** on the socket associated to *bpf_socket*, which must be a full socket. The *level* at which the option resides and the name *optname* of the option must be specified, see **getsockopt(2)** for more information. The retrieved value is stored in the structure pointed by *opval* and of length *optlen*.

bpf_socket should be one of the following:

- **struct bpf_sock_ops** for **BPF_PROG_TYPE_SOCK_OPS**.
- **struct bpf_sock_addr** for **BPF_CGROUP_INET4_CONNECT**, **BPF_CGROUP_INET6_CONNECT** and **BPF_CGROUP_UNIX_CONNECT**.

This helper actually implements a subset of **getsockopt()**. It supports the same set of *optname*s that is supported by the **bpf_setsockopt**() helper. The exceptions are **TCP_BPF_*** is **bpf_setsockopt**() only and **TCP_SAVED_SYN** is **bpf_getsockopt**() only.

Return 0 on success, or a negative error in case of failure.

long bpf_override_return(struct pt_regs ****regs*, u64** *rc***)**

Description

Used for error injection, this helper uses kprobes to override the return value of the probed function, and to set it to *rc*. The first argument is the context *regs* on which the kprobe works.

This helper works by setting the PC (program counter) to an override function which is run in place of the original probed function. This means the probed function is not run at all. The replacement function just returns with the required value.

This helper has security implications, and thus is subject to restrictions. It is only available if the kernel was compiled with the **CONFIG_BPF_KPROBE_OVERRIDE** configuration option, and in this case it only works on functions tagged with **ALLOW_ERROR_INJECTION** in the kernel code.

Also, the helper is only available for the architectures having the CONFIG_FUNCTION_ERROR_INJECTION option. As of this writing, x86 architecture is the only one to support this feature.

Return

long bpf_sock_ops_cb_flags_set(struct bpf_sock_ops ****bpf_sock*, int** *argval***)**

Description

Attempt to set the value of the **bpf_sock_ops_cb_flags** field for the full TCP socket associated to *bpf_sock_ops* to *argval*.

The primary use of this field is to determine if there should be calls to eBPF programs of type **BPF_PROG_TYPE_SOCK_OPS** at various points in the TCP code. A program of the same type can change its value, per connection and as necessary, when the connection is established. This field is directly accessible for reading, but this helper must be used for updates in order to return an error if an eBPF program tries to set a callback that is not supported in the current kernel.

argval is a flag array which can combine these flags:

- **BPF_SOCK_OPS_RTO_CB_FLAG** (retransmission time out)
- **BPF_SOCK_OPS_RETRANS_CB_FLAG** (retransmission)

- **BPF_SOCK_OPS_STATE_CB_FLAG** (TCP state change)
- **BPF_SOCK_OPS_RTT_CB_FLAG** (every RTT)

Therefore, this function can be used to clear a callback flag by setting the appropriate bit to zero. e.g. to disable the RTO callback:

bpf_sock_ops_cb_flags_set(bpf_sock,
bpf_sock−>bpf_sock_ops_cb_flags &
~BPF_SOCK_OPS_RTO_CB_FLAG)

Here are some examples of where one could call such eBPF program:

- When RTO fires.
- When a packet is retransmitted.
- When the connection terminates.
- When a packet is sent.
- When a packet is received.

Return Code **−EINVAL** if the socket is not a full TCP socket; otherwise, a positive number containing the bits that could not be set is returned (which comes down to 0 if all bits were set as required).

long bpf_msg_redirect_map(struct sk_msg_buff ***msg*, struct bpf_map ***map***, u32** *key***, u64** *flags***)**

Description

This helper is used in programs implementing policies at the socket level. If the message *msg* is allowed to pass (i.e. if the verdict eBPF program returns **SK_PASS**), redirect it to the socket referenced by *map* (of type **BPF_MAP_TYPE_SOCKMAP**) at index *key*. Both ingress and egress interfaces can be used for redirection. The **BPF_F_INGRESS** value in *flags* is used to make the distinction (ingress path is selected if the flag is present, egress path otherwise). This is the only flag supported for now.

Return **SK_PASS** on success, or **SK_DROP** on error.

long bpf_msg_apply_bytes(struct sk_msg_buff ***msg*, u32** *bytes***)**

Description

For socket policies, apply the verdict of the eBPF program to the next *bytes* (number of bytes) of message *msg*.

For example, this helper can be used in the following cases:

- A single **sendmsg**() or **sendfile**() system call contains multiple logical messages that the eBPF program is supposed to read and for which it should apply a verdict.
- An eBPF program only cares to read the first *bytes* of a *msg*. If the message has a large payload, then setting up and calling the eBPF program repeatedly for all bytes, even though the verdict is already known, would create unnecessary overhead.

When called from within an eBPF program, the helper sets a counter internal to the BPF infrastructure, that is used to apply the last verdict to the next *bytes*. If *bytes* is smaller than the current data being processed from a **sendmsg**() or **sendfile**() system call, the first *bytes* will be sent and the eBPF program will be re−run with the pointer for start of data pointing to byte number *bytes* **+ 1**. If *bytes* is larger than the current data being processed, then the eBPF verdict will be applied to multiple **sendmsg**() or **sendfile**() calls until *bytes* are consumed.

Note that if a socket closes with the internal counter holding a non−zero value, this is not a problem because data is not being buffered for *bytes* and is sent as it is received.

Return

long bpf_msg_cork_bytes(struct sk_msg_buff ****msg*, u32** *bytes***)**

Description

For socket policies, prevent the execution of the verdict eBPF program for message *msg* until *bytes* (byte number) have been accumulated.

This can be used when one needs a specific number of bytes before a verdict can be assigned, even if the data spans multiple **sendmsg**() or **sendfile**() calls. The extreme case would be a user calling **sendmsg**() repeatedly with 1−byte long message segments. Obviously, this is bad for performance, but it is still valid. If the eBPF program needs *bytes* bytes to validate a header, this helper can be used to prevent the eBPF program to be called again until *bytes* have been accumulated.

Return

long bpf_msg_pull_data(struct sk_msg_buff ****msg*, u32** *start***, u32** *end***, u64** *flags***)**

Description

For socket policies, pull in non−linear data from user space for *msg* and set pointers *msg*−>**data** and *msg*−>**data_end** to *start* and *end* bytes offsets into *msg*, respectively.

If a program of type **BPF_PROG_TYPE_SK_MSG** is run on a *msg* it can only parse data that the (**data**, **data_end**) pointers have already consumed. For **sendmsg**() hooks this is likely the first scatterlist element. But for calls relying on the **sendpage** handler (e.g. **sendfile**()) this will be the range (**0**, **0**) because the data is shared with user space and by default the objective is to avoid allowing user space to modify data while (or after) eBPF verdict is being decided. This helper can be used to pull in data and to set the start and end pointer to given values. Data will be copied if necessary (i.e. if data was not linear and if start and end pointers do not point to the same chunk).

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

All values for *flags* are reserved for future usage, and must be left at zero.

Return 0 on success, or a negative error in case of failure.

long bpf_bind(struct bpf_sock_addr ****ctx*, struct sockaddr ****addr***, int** *addr_len***)**

Description

Bind the socket associated to *ctx* to the address pointed by *addr*, of length *addr_len*. This allows for making outgoing connection from the desired IP address, which can be useful for example when all processes inside a cgroup should use one single IP address on a host that has multiple IP configured.

This helper works for IPv4 and IPv6, TCP and UDP sockets. The domain (*addr*−>**sa_family**) must be **AF_INET** (or **AF_INET6**). It's advised to pass zero port (**sin_port** or **sin6_port**) which triggers IP_BIND_ADDRESS_NO_PORT−like behavior and lets the kernel efficiently pick up an unused port as long as 4−tuple is unique. Passing non−zero port might lead to degraded performance.

Return 0 on success, or a negative error in case of failure.

long bpf_xdp_adjust_tail(struct xdp_buff ****xdp_md*, int** *delta***)**

Description

Adjust (move) *xdp_md*−>**data_end** by *delta* bytes. It is possible to both shrink and grow the packet tail. Shrink done via *delta* being a negative integer.

A call to this helper is susceptible to change the underlying packet buffer. Therefore,

at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_skb_get_xfrm_state(struct sk_buff *_skb_, u32 _index_, struct bpf_xfrm_state *_xfrm_state_, u32 _size_, u64 _flags_)

Description

Retrieve the XFRM state (IP transform framework, see also **ip−xfrm(8)**) at *index* in XFRM "security path" for *skb*.

The retrieved value is stored in the **struct bpf_xfrm_state** pointed by *xfrm_state* and of length *size*.

All values for *flags* are reserved for future usage, and must be left at zero.

This helper is available only if the kernel was compiled with **CONFIG_XFRM** configuration option.

Return 0 on success, or a negative error in case of failure.

long bpf_get_stack(void *_ctx_, void *_buf_, u32 _size_, u64 _flags_)

Description

Return a user or a kernel stack in bpf program provided buffer. To achieve this, the helper needs *ctx*, which is a pointer to the context on which the tracing program is executed. To store the stacktrace, the bpf program provides *buf* with a nonnegative *size*.

The last argument, *flags*, holds the number of stack frames to skip (from 0 to 255), masked with **BPF_F_SKIP_FIELD_MASK**. The next bits can be used to set the following flags:

BPF_F_USER_STACK

Collect a user space stack instead of a kernel stack.

BPF_F_USER_BUILD_ID

Collect (build_id, file_offset) instead of ips for user stack, only valid if **BPF_F_USER_STACK** is also specified.

file_offset is an offset relative to the beginning of the executable or shared object file backing the vma which the *ip* falls in. It is *not* an offset relative to that object's base address. Accordingly, it must be adjusted by adding (sh_addr − sh_offset), where sh_{addr,offset} correspond to the executable section containing *file_offset* in the object, for comparisons to symbols' st_value to be valid.

bpf_get_stack() can collect up to **PERF_MAX_STACK_DEPTH** both kernel and user frames, subject to sufficient large buffer size. Note that this limit can be controlled with the **sysctl** program, and that it should be manually increased in order to profile long user stacks (such as stacks for Java programs). To do so, use:

```
# sysctl kernel.perf_event_max_stack=<new value>
```

Return The non−negative copied *buf* length equal to or less than *size* on success, or a negative error in case of failure.

long bpf_skb_load_bytes_relative(const void *_skb_, u32 _offset_, void *_to_, u32 _len_, u32 _start_header_)

Description

This helper is similar to **bpf_skb_load_bytes**() in that it provides an easy way to load *len* bytes from *offset* from the packet associated to *skb*, into the buffer pointed by *to*. The difference to **bpf_skb_load_bytes**() is that a fifth argument *start_header* exists in order to select a base offset to start from. *start_header* can be one of:

BPF_HDR_START_MAC
Base offset to load data from is *skb*'s mac header.

BPF_HDR_START_NET
Base offset to load data from is *skb*'s network header.

In general, "direct packet access" is the preferred method to access packet data, however, this helper is in particular useful in socket filters where *skb*−**>data** does not always point to the start of the mac header and where "direct packet access" is not available.

Return 0 on success, or a negative error in case of failure.

long bpf_fib_lookup(void *_ctx_, struct bpf_fib_lookup *_params_, int _plen_, u32 _flags_)

Description

Do FIB lookup in kernel tables using parameters in *params*. If lookup is successful and result shows packet is to be forwarded, the neighbor tables are searched for the nexthop. If successful (ie., FIB lookup shows forwarding and nexthop is resolved), the nexthop address is returned in ipv4_dst or ipv6_dst based on family, smac is set to mac address of egress device, dmac is set to nexthop mac address, rt_metric is set to metric from route (IPv4/IPv6 only), and ifindex is set to the device index of the nexthop from the FIB lookup.

plen argument is the size of the passed in struct. *flags* argument can be a combination of one or more of the following values:

BPF_FIB_LOOKUP_DIRECT
Do a direct table lookup vs full lookup using FIB rules.

BPF_FIB_LOOKUP_TBID
Used with BPF_FIB_LOOKUP_DIRECT. Use the routing table ID present in *params*−>tbid for the fib lookup.

BPF_FIB_LOOKUP_OUTPUT
Perform lookup from an egress perspective (default is ingress).

BPF_FIB_LOOKUP_SKIP_NEIGH
Skip the neighbour table lookup. *params*−>dmac and *params*−>smac will not be set as output. A common use case is to call **bpf_redirect_neigh**() after doing **bpf_fib_lookup**().

BPF_FIB_LOOKUP_SRC
Derive and set source IP addr in *params*−>ipv{4,6}_src for the nexthop. If the src addr cannot be derived, **BPF_FIB_LKUP_RET_NO_SRC_ADDR** is returned. In this case, *params*−>dmac and *params*−>smac are not set either.

ctx is either **struct xdp_md** for XDP programs or **struct sk_buff** tc cls_act programs.

Return

- < 0 if any input argument is invalid
- 0 on success (packet is forwarded, nexthop neighbor exists)
- > 0 one of **BPF_FIB_LKUP_RET_** codes explaining why the packet is not forwarded or needs assist from full stack

If lookup fails with BPF_FIB_LKUP_RET_FRAG_NEEDED, then the MTU was exceeded and output params−>mtu_result contains the MTU.

long bpf_sock_hash_update(struct bpf_sock_ops *_skops_, struct bpf_map *_map_, void *_key_, u64 _flags_)

Description

Add an entry to, or update a sockhash *map* referencing sockets. The *skops* is used as a new value for the entry associated to *key*. *flags* is one of:

BPF_NOEXIST
The entry for *key* must not exist in the map.

BPF_EXIST
The entry for *key* must already exist in the map.

BPF_ANY
No condition on the existence of the entry for *key*.

If the *map* has eBPF programs (parser and verdict), those will be inherited by the socket being added. If the socket is already attached to eBPF programs, this results in an error.

Return 0 on success, or a negative error in case of failure.

long bpf_msg_redirect_hash(struct sk_msg_buff ****msg*, struct bpf_map ****map***, void ****key***, u64** *flags***)**

Description
This helper is used in programs implementing policies at the socket level. If the message *msg* is allowed to pass (i.e. if the verdict eBPF program returns **SK_PASS**), redirect it to the socket referenced by *map* (of type **BPF_MAP_TYPE_SOCKHASH**) using hash *key*. Both ingress and egress interfaces can be used for redirection. The **BPF_F_INGRESS** value in *flags* is used to make the distinction (ingress path is selected if the flag is present, egress path otherwise). This is the only flag supported for now.

Return **SK_PASS** on success, or **SK_DROP** on error.

long bpf_sk_redirect_hash(struct sk_buff ****skb*, struct bpf_map ****map***, void ****key***, u64** *flags***)**

Description
This helper is used in programs implementing policies at the skb socket level. If the sk_buff *skb* is allowed to pass (i.e. if the verdict eBPF program returns **SK_PASS**), redirect it to the socket referenced by *map* (of type **BPF_MAP_TYPE_SOCKHASH**) using hash *key*. Both ingress and egress interfaces can be used for redirection. The **BPF_F_INGRESS** value in *flags* is used to make the distinction (ingress path is selected if the flag is present, egress otherwise). This is the only flag supported for now.

Return **SK_PASS** on success, or **SK_DROP** on error.

long bpf_lwt_push_encap(struct sk_buff ****skb*, u32** *type***, void ****hdr***, u32** *len***)**

Description
Encapsulate the packet associated to *skb* within a Layer 3 protocol header. This header is provided in the buffer at address *hdr*, with *len* its size in bytes. *type* indicates the protocol of the header and can be one of:

BPF_LWT_ENCAP_SEG6
IPv6 encapsulation with Segment Routing Header (**struct ipv6_sr_hdr**). *hdr* only contains the SRH, the IPv6 header is computed by the kernel.

BPF_LWT_ENCAP_SEG6_INLINE
Only works if *skb* contains an IPv6 packet. Insert a Segment Routing Header (**struct ipv6_sr_hdr**) inside the IPv6 header.

BPF_LWT_ENCAP_IP
IP encapsulation (GRE/GUE/IPIP/etc). The outer header must be IPv4 or IPv6, followed by zero or more additional headers, up to **LWT_BPF_MAX_HEADROOM** total bytes in all prepended headers. Please note that if **skb_is_gso**(*skb*) is true, no more than two headers can be prepended, and the inner header, if present, should be either GRE or UDP/GUE.

BPF_LWT_ENCAP_SEG6* types can be called by BPF programs of type **BPF_PROG_TYPE_LWT_IN**; **BPF_LWT_ENCAP_IP** type can be called by bpf programs of types **BPF_PROG_TYPE_LWT_IN** and

BPF_PROG_TYPE_LWT_XMIT.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_lwt_seg6_store_bytes(struct sk_buff ****skb*, u32** *offset***, const void *** *from***, u32** *len***)**

Description

Store *len* bytes from address *from* into the packet associated to *skb*, at *offset*. Only the flags, tag and TLVs inside the outermost IPv6 Segment Routing Header can be modified through this helper.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_lwt_seg6_adjust_srh(struct sk_buff * *skb***, u32** *offset***, s32** *delta***)**

Description

Adjust the size allocated to TLVs in the outermost IPv6 Segment Routing Header contained in the packet associated to *skb*, at position *offset* by *delta* bytes. Only offsets after the segments are accepted. *delta* can be as well positive (growing) as negative (shrinking).

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_lwt_seg6_action(struct sk_buff * *skb***, u32** *action***, void *** *param***, u32** *param_len***)**

Description

Apply an IPv6 Segment Routing action of type *action* to the packet associated to *skb*. Each action takes a parameter contained at address *param*, and of length *param_len* bytes. *action* can be one of:

SEG6_LOCAL_ACTION_END_X
: End.X action: Endpoint with Layer−3 cross−connect. Type of *param*: **struct in6_addr**.

SEG6_LOCAL_ACTION_END_T
: End.T action: Endpoint with specific IPv6 table lookup. Type of *param*: **int**.

SEG6_LOCAL_ACTION_END_B6
: End.B6 action: Endpoint bound to an SRv6 policy. Type of *param*: **struct ipv6_sr_hdr**.

SEG6_LOCAL_ACTION_END_B6_ENCAP
: End.B6.Encap action: Endpoint bound to an SRv6 encapsulation policy. Type of *param*: **struct ipv6_sr_hdr**.

A call to this helper is susceptible to change the underlying packet buffer. Therefore, at load time, all checks on pointers previously done by the verifier are invalidated and must be performed again, if the helper is used in combination with direct packet access.

Return 0 on success, or a negative error in case of failure.

long bpf_rc_repeat(void ****ctx*)**

Description

This helper is used in programs implementing IR decoding, to report a successfully decoded repeat key message. This delays the generation of a key up event for previously generated key down event.

Some IR protocols like NEC have a special IR message for repeating last button, for when a button is held down.

The *ctx* should point to the lirc sample as passed into the program.

This helper is only available is the kernel was compiled with the **CONFIG_BPF_LIRC_MODE2** configuration option set to "**y**".

Return

long bpf_rc_keydown(void ****ctx*, u32** *protocol***, u64** *scancode***, u32** *toggle***)**

Description

This helper is used in programs implementing IR decoding, to report a successfully decoded key press with *scancode*, *toggle* value in the given *protocol*. The scancode will be translated to a keycode using the rc keymap, and reported as an input key down event. After a period a key up event is generated. This period can be extended by calling either **bpf_rc_keydown**() again with the same values, or calling **bpf_rc_repeat**().

Some protocols include a toggle bit, in case the button was released and pressed again between consecutive scancodes.

The *ctx* should point to the lirc sample as passed into the program.

The *protocol* is the decoded protocol number (see **enum rc_proto** for some predefined values).

This helper is only available is the kernel was compiled with the **CONFIG_BPF_LIRC_MODE2** configuration option set to "**y**".

Return

u64 bpf_skb_cgroup_id(struct sk_buff ****skb*)**

Description

Return the cgroup v2 id of the socket associated with the *skb*. This is roughly similar to the **bpf_get_cgroup_classid**() helper for cgroup v1 by providing a tag resp. identifier that can be matched on or used for map lookups e.g. to implement policy. The cgroup v2 id of a given path in the hierarchy is exposed in user space through the f_handle API in order to get to the same 64−bit id.

This helper can be used on TC egress path, but not on ingress, and is available only if the kernel was compiled with the **CONFIG_SOCK_CGROUP_DATA** configuration option.

Return The id is returned or 0 in case the id could not be retrieved.

u64 bpf_get_current_cgroup_id(void)

Description

Get the current cgroup id based on the cgroup within which the current task is running.

Return A 64−bit integer containing the current cgroup id based on the cgroup within which the current task is running.

void *bpf_get_local_storage(void ***map*, u64** *flags***)**

Description

Get the pointer to the local storage area. The type and the size of the local storage is defined by the *map* argument. The *flags* meaning is specific for each map type, and has to be 0 for cgroup local storage.

Depending on the BPF program type, a local storage area can be shared between multiple instances of the BPF program, running simultaneously.

A user should care about the synchronization by himself. For example, by using the **BPF_ATOMIC** instructions to alter the shared data.

Return A pointer to the local storage area.

long bpf_sk_select_reuseport(struct sk_reuseport_md ***reuse*, struct bpf_map ***map***, void ***key***, u64** *flags***)**

Description

Select a **SO_REUSEPORT** socket from a **BPF_MAP_TYPE_REUSEPORT_SOCKARRAY** *map*. It checks the selected socket is matching the incoming request in the socket buffer.

Return 0 on success, or a negative error in case of failure.

u64 bpf_skb_ancestor_cgroup_id(struct sk_buff ***skb*, int** *ancestor_level***)**

Description

Return id of cgroup v2 that is ancestor of cgroup associated with the *skb* at the *ancestor_level*. The root cgroup is at *ancestor_level* zero and each step down the hierarchy increments the level. If *ancestor_level* == level of cgroup associated with *skb*, then return value will be same as that of **bpf_skb_cgroup_id**().

The helper is useful to implement policies based on cgroups that are upper in hierarchy than immediate cgroup associated with *skb*.

The format of returned id and helper limitations are same as in **bpf_skb_cgroup_id**().

Return The id is returned or 0 in case the id could not be retrieved.

struct bpf_sock *bpf_sk_lookup_tcp(void ***ctx*, struct bpf_sock_tuple ***tuple***, u32** *tuple_size***, u64** *netns***, u64** *flags***)**

Description

Look for TCP socket matching *tuple*, optionally in a child network namespace *netns*. The return value must be checked, and if non−**NULL**, released via **bpf_sk_release**().

The *ctx* should point to the context of the program, such as the skb or socket (depending on the hook in use). This is used to determine the base network namespace for the lookup.

tuple_size must be one of:

sizeof(*tuple***−>ipv4)**
Look for an IPv4 socket.

sizeof(*tuple***−>ipv6)**
Look for an IPv6 socket.

If the *netns* is a negative signed 32−bit integer, then the socket lookup table in the netns associated with the *ctx* will be used. For the TC hooks, this is the netns of the device in the skb. For socket hooks, this is the netns of the socket. If *netns* is any other signed 32−bit value greater than or equal to zero then it specifies the ID of the netns relative to the netns associated with the *ctx*. *netns* values beyond the range of 32−bit integers are reserved for future use.

All values for *flags* are reserved for future usage, and must be left at zero.

This helper is available only if the kernel was compiled with **CONFIG_NET** configuration option.

Return Pointer to **struct bpf_sock**, or **NULL** in case of failure. For sockets with reuseport option, the **struct bpf_sock** result is from *reuse*->**socks**[] using the hash of the tuple.

struct bpf_sock *bpf_sk_lookup_udp(void *_ctx_, struct bpf_sock_tuple *_tuple_, u32 _tuple_size_, u64 _netns_, u64 _flags_)

Description

Look for UDP socket matching *tuple*, optionally in a child network namespace *netns*. The return value must be checked, and if non−**NULL**, released via **bpf_sk_release**().

The *ctx* should point to the context of the program, such as the skb or socket (depending on the hook in use). This is used to determine the base network namespace for the lookup.

tuple_size must be one of:

sizeof(_tuple_->**ipv4)**
Look for an IPv4 socket.

sizeof(_tuple_->**ipv6)**
Look for an IPv6 socket.

If the *netns* is a negative signed 32−bit integer, then the socket lookup table in the netns associated with the *ctx* will be used. For the TC hooks, this is the netns of the device in the skb. For socket hooks, this is the netns of the socket. If *netns* is any other signed 32−bit value greater than or equal to zero then it specifies the ID of the netns relative to the netns associated with the *ctx*. *netns* values beyond the range of 32−bit integers are reserved for future use.

All values for *flags* are reserved for future usage, and must be left at zero.

This helper is available only if the kernel was compiled with **CONFIG_NET** configuration option.

Return Pointer to **struct bpf_sock**, or **NULL** in case of failure. For sockets with reuseport option, the **struct bpf_sock** result is from *reuse*->**socks**[] using the hash of the tuple.

long bpf_sk_release(void *_sock_)

Description

Release the reference held by *sock*. *sock* must be a non−**NULL** pointer that was returned from **bpf_sk_lookup_xxx**().

Return 0 on success, or a negative error in case of failure.

long bpf_map_push_elem(struct bpf_map *_map_, const void *_value_, u64 _flags_)

Description

Push an element *value* in *map*. *flags* is one of:

BPF_EXIST
If the queue/stack is full, the oldest element is removed to make room for this.

Return 0 on success, or a negative error in case of failure.

long bpf_map_pop_elem(struct bpf_map *_map_, void *_value_)

Description

Pop an element from *map*.

Return 0 on success, or a negative error in case of failure.

long bpf_map_peek_elem(struct bpf_map *_map_, void *_value_)

Description

Get an element from *map* without removing it.

Return 0 on success, or a negative error in case of failure.

long bpf_msg_push_data(struct sk_msg_buff *_msg_, u32 _start_, u32 _len_, u64 _flags_)

Description

For socket policies, insert *len* bytes into *msg* at offset *start*.

If a program of type **BPF_PROG_TYPE_SK_MSG** is run on a *msg* it may want to insert metadata or options into the *msg*. This can later be read and used by any of the lower layer BPF hooks.

This helper may fail if under memory pressure (a malloc fails) in these cases BPF programs will get an appropriate error and BPF programs will need to handle them.

Return 0 on success, or a negative error in case of failure.

long bpf_msg_pop_data(struct sk_msg_buff *_msg_, u32 _start_, u32 _len_, u64 _flags_)

Description

Will remove *len* bytes from a *msg* starting at byte *start*. This may result in **ENOMEM** errors under certain situations if an allocation and copy are required due to a full ring buffer. However, the helper will try to avoid doing the allocation if possible. Other errors can occur if input parameters are invalid either due to *start* byte not being valid part of *msg* payload and/or *pop* value being to large.

Return 0 on success, or a negative error in case of failure.

long bpf_rc_pointer_rel(void *_ctx_, s32 _rel_x_, s32 _rel_y_)

Description

This helper is used in programs implementing IR decoding, to report a successfully decoded pointer movement.

The *ctx* should point to the lirc sample as passed into the program.

This helper is only available is the kernel was compiled with the **CONFIG_BPF_LIRC_MODE2** configuration option set to "**y**".

Return

long bpf_spin_lock(struct bpf_spin_lock *_lock_)

Description

Acquire a spinlock represented by the pointer *lock*, which is stored as part of a value of a map. Taking the lock allows to safely update the rest of the fields in that value. The spinlock can (and must) later be released with a call to **bpf_spin_unlock**(*lock*).

Spinlocks in BPF programs come with a number of restrictions and constraints:

- **bpf_spin_lock** objects are only allowed inside maps of types **BPF_MAP_TYPE_HASH** and **BPF_MAP_TYPE_ARRAY** (this list could be extended in the future).
- BTF description of the map is mandatory.
- The BPF program can take ONE lock at a time, since taking two or more could cause dead locks.
- Only one **struct bpf_spin_lock** is allowed per map element.
- When the lock is taken, calls (either BPF to BPF or helpers) are not allowed.

- The **BPF_LD_ABS** and **BPF_LD_IND** instructions are not allowed inside a spin-lock−ed region.
- The BPF program MUST call **bpf_spin_unlock**() to release the lock, on all execution paths, before it returns.
- The BPF program can access **struct bpf_spin_lock** only via the **bpf_spin_lock**() and **bpf_spin_unlock**() helpers. Loading or storing data into the **struct bpf_spin_lock** *lock***;** field of a map is not allowed.
- To use the **bpf_spin_lock**() helper, the BTF description of the map value must be a struct and have **struct bpf_spin_lock** *anyname***;** field at the top level. Nested lock inside another struct is not allowed.
- The **struct bpf_spin_lock** *lock* field in a map value must be aligned on a multiple of 4 bytes in that value.
- Syscall with command **BPF_MAP_LOOKUP_ELEM** does not copy the **bpf_spin_lock** field to user space.
- Syscall with command **BPF_MAP_UPDATE_ELEM**, or update from a BPF program, do not update the **bpf_spin_lock** field.
- **bpf_spin_lock** cannot be on the stack or inside a networking packet (it can only be inside of a map values).
- **bpf_spin_lock** is available to root only.
- Tracing programs and socket filter programs cannot use **bpf_spin_lock**() due to insufficient preemption checks (but this may change in the future).
- **bpf_spin_lock** is not allowed in inner maps of map−in−map.

Return

long bpf_spin_unlock(struct bpf_spin_lock ***_lock_)**

Description

Release the *lock* previously locked by a call to **bpf_spin_lock**(*lock*).

Return

struct bpf_sock *bpf_sk_fullsock(struct bpf_sock ***_sk_)**

Description

This helper gets a **struct bpf_sock** pointer such that all the fields in this **bpf_sock** can be accessed.

Return A **struct bpf_sock** pointer on success, or **NULL** in case of failure.

struct bpf_tcp_sock *bpf_tcp_sock(struct bpf_sock ***_sk_)**

Description

This helper gets a **struct bpf_tcp_sock** pointer from a **struct bpf_sock** pointer.

Return A **struct bpf_tcp_sock** pointer on success, or **NULL** in case of failure.

long bpf_skb_ecn_set_ce(struct sk_buff ***_skb_)**

Description

Set ECN (Explicit Congestion Notification) field of IP header to **CE** (Congestion Encountered) if current value is **ECT** (ECN Capable Transport). Otherwise, do nothing. Works with IPv6 and IPv4.

Return 1 if the **CE** flag is set (either by the current helper call or because it was already present), 0 if it is not set.

struct bpf_sock *bpf_get_listener_sock(struct bpf_sock ***_sk_)**

Description

Return a **struct bpf_sock** pointer in **TCP_LISTEN** state. **bpf_sk_release**() is unnecessary and not allowed.

Return A **struct bpf_sock** pointer on success, or **NULL** in case of failure.

struct bpf_sock *bpf_skc_lookup_tcp(void *_ctx_, struct bpf_sock_tuple *_tuple_, u32 _tuple_size_, u64 _netns_, u64 _flags_)

Description

Look for TCP socket matching *tuple*, optionally in a child network namespace *netns*. The return value must be checked, and if non−**NULL**, released via **bpf_sk_release**().

This function is identical to **bpf_sk_lookup_tcp**(), except that it also returns timewait or request sockets. Use **bpf_sk_fullsock**() or **bpf_tcp_sock**() to access the full structure.

This helper is available only if the kernel was compiled with **CONFIG_NET** configuration option.

Return Pointer to **struct bpf_sock**, or **NULL** in case of failure. For sockets with reuseport option, the **struct bpf_sock** result is from *reuse*−>**socks**[] using the hash of the tuple.

long bpf_tcp_check_syncookie(void *_sk_, void *_iph_, u32 _iph_len_, struct tcphdr *_th_, u32 _th_len_)

Description

Check whether *iph* and *th* contain a valid SYN cookie ACK for the listening socket in *sk*.

iph points to the start of the IPv4 or IPv6 header, while *iph_len* contains **sizeof**(**struct iphdr**) or **sizeof**(**struct ipv6hdr**).

th points to the start of the TCP header, while *th_len* contains the length of the TCP header (at least **sizeof**(**struct tcphdr**)).

Return 0 if *iph* and *th* are a valid SYN cookie ACK, or a negative error otherwise.

long bpf_sysctl_get_name(struct bpf_sysctl *_ctx_, char *_buf_, size_t _buf_len_, u64 _flags_)

Description

Get name of sysctl in /proc/sys/ and copy it into provided by program buffer *buf* of size *buf_len*.

The buffer is always NUL terminated, unless it's zero−sized.

If *flags* is zero, full name (e.g. "net/ipv4/tcp_mem") is copied. Use **BPF_F_SYSCTL_BASE_NAME** flag to copy base name only (e.g. "tcp_mem").

Return Number of character copied (not including the trailing NUL).

−E2BIG if the buffer wasn't big enough (*buf* will contain truncated name in this case).

long bpf_sysctl_get_current_value(struct bpf_sysctl *_ctx_, char *_buf_, size_t _buf_len_)

Description

Get current value of sysctl as it is presented in /proc/sys (incl. newline, etc), and copy it as a string into provided by program buffer *buf* of size *buf_len*.

The whole value is copied, no matter what file position user space issued e.g. sys_read at.

The buffer is always NUL terminated, unless it's zero−sized.

Return Number of character copied (not including the trailing NUL).

−E2BIG if the buffer wasn't big enough (*buf* will contain truncated name in this case).

−EINVAL if current value was unavailable, e.g. because sysctl is uninitialized and

read returns −EIO for it.

long bpf_sysctl_get_new_value(struct bpf_sysctl ****ctx*, char ****buf***, size_t** *buf_len***)**

Description

Get new value being written by user space to sysctl (before the actual write happens) and copy it as a string into provided by program buffer *buf* of size *buf_len*.

User space may write new value at file position > 0.

The buffer is always NUL terminated, unless it's zero−sized.

Return Number of character copied (not including the trailing NUL).

−**E2BIG** if the buffer wasn't big enough (*buf* will contain truncated name in this case).

−**EINVAL** if sysctl is being read.

long bpf_sysctl_set_new_value(struct bpf_sysctl ****ctx*, const char ****buf***, size_t** *buf_len***)**

Description

Override new value being written by user space to sysctl with value provided by program in buffer *buf* of size *buf_len*.

buf should contain a string in same form as provided by user space on sysctl write.

User space may write new value at file position > 0. To override the whole sysctl value file position should be set to zero.

Return 0 on success.

−**E2BIG** if the *buf_len* is too big.

−**EINVAL** if sysctl is being read.

long bpf_strtol(const char ****buf*, size_t** *buf_len***, u64** *flags***, long ****res***)**

Description

Convert the initial part of the string from buffer *buf* of size *buf_len* to a long integer according to the given base and save the result in *res*.

The string may begin with an arbitrary amount of white space (as determined by **isspace**(3)) followed by a single optional '−' sign.

Five least significant bits of *flags* encode base, other bits are currently unused.

Base must be either 8, 10, 16 or 0 to detect it automatically similar to user space **strtol**(3).

Return Number of characters consumed on success. Must be positive but no more than *buf_len*.

−**EINVAL** if no valid digits were found or unsupported base was provided.

−**ERANGE** if resulting value was out of range.

long bpf_strtoul(const char ****buf*, size_t** *buf_len***, u64** *flags***, unsigned long ****res***)**

Description

Convert the initial part of the string from buffer *buf* of size *buf_len* to an unsigned long integer according to the given base and save the result in *res*.

The string may begin with an arbitrary amount of white space (as determined by **isspace**(3)).

Five least significant bits of *flags* encode base, other bits are currently unused.

Base must be either 8, 10, 16 or 0 to detect it automatically similar to user space **strtoul**(3).

Return Number of characters consumed on success. Must be positive but no more than *buf_len*.

−**EINVAL** if no valid digits were found or unsupported base was provided.

−**ERANGE** if resulting value was out of range.

void *bpf_sk_storage_get(struct bpf_map ****map*, void ****sk***, void ****value***, u64** *flags***)**

Description

Get a bpf−local−storage from a *sk*.

Logically, it could be thought of getting the value from a *map* with *sk* as the **key**. From this perspective, the usage is not much different from **bpf_map_lookup_elem**(*map*, **&***sk*) except this helper enforces the key must be a full socket and the map must be a **BPF_MAP_TYPE_SK_STORAGE** also.

Underneath, the value is stored locally at *sk* instead of the *map*. The *map* is used as the bpf−local−storage "type". The bpf−local−storage "type" (i.e. the *map*) is searched against all bpf−local−storages residing at *sk*.

sk is a kernel **struct sock** pointer for LSM program. *sk* is a **struct bpf_sock** pointer for other program types.

An optional *flags* (**BPF_SK_STORAGE_GET_F_CREATE**) can be used such that a new bpf−local−storage will be created if one does not exist. *value* can be used together with **BPF_SK_STORAGE_GET_F_CREATE** to specify the initial value of a bpf−local−storage. If *value* is **NULL**, the new bpf−local−storage will be zero initialized.

Return A bpf−local−storage pointer is returned on success.

NULL if not found or there was an error in adding a new bpf−local−storage.

long bpf_sk_storage_delete(struct bpf_map ****map*, void ****sk***)**

Description

Delete a bpf−local−storage from a *sk*.

Return 0 on success.

−**ENOENT** if the bpf−local−storage cannot be found. −**EINVAL** if sk is not a fullsock (e.g. a request_sock).

long bpf_send_signal(u32 *sig***)**

Description

Send signal *sig* to the process of the current task. The signal may be delivered to any of this process's threads.

Return 0 on success or successfully queued.

−**EBUSY** if work queue under nmi is full.

−**EINVAL** if *sig* is invalid.

−**EPERM** if no permission to send the *sig*.

−**EAGAIN** if bpf program can try again.

s64 bpf_tcp_gen_syncookie(void *_sk_, void *_iph_, u32 _iph_len_, struct tcphdr *_th_, u32 _th_len_)

Description

Try to issue a SYN cookie for the packet with corresponding IP/TCP headers, *iph* and *th*, on the listening socket in *sk*.

iph points to the start of the IPv4 or IPv6 header, while *iph_len* contains **sizeof**(**struct iphdr**) or **sizeof**(**struct ipv6hdr**).

th points to the start of the TCP header, while *th_len* contains the length of the TCP header with options (at least **sizeof**(**struct tcphdr**)).

Return On success, lower 32 bits hold the generated SYN cookie in followed by 16 bits which hold the MSS value for that cookie, and the top 16 bits are unused.

On failure, the returned value is one of the following:

−**EINVAL** SYN cookie cannot be issued due to error

−**ENOENT** SYN cookie should not be issued (no SYN flood)

−**EOPNOTSUPP** kernel configuration does not enable SYN cookies

−**EPROTONOSUPPORT** IP packet version is not 4 or 6

long bpf_skb_output(void *_ctx_, struct bpf_map *_map_, u64 _flags_, void *_data_, u64 _size_)

Description

Write raw *data* blob into a special BPF perf event held by *map* of type **BPF_MAP_TYPE_PERF_EVENT_ARRAY**. This perf event must have the following attributes: **PERF_SAMPLE_RAW** as **sample_type**, **PERF_TYPE_SOFTWARE** as **type**, and **PERF_COUNT_SW_BPF_OUTPUT** as **config**.

The *flags* are used to indicate the index in *map* for which the value must be put, masked with **BPF_F_INDEX_MASK**. Alternatively, *flags* can be set to **BPF_F_CURRENT_CPU** to indicate that the index of the current CPU core should be used.

The value to write, of *size*, is passed through eBPF stack and pointed by *data*.

ctx is a pointer to in−kernel struct sk_buff.

This helper is similar to **bpf_perf_event_output**() but restricted to raw_tracepoint bpf programs.

Return 0 on success, or a negative error in case of failure.

long bpf_probe_read_user(void *_dst_, u32 _size_, const void *_unsafe_ptr_)

Description

Safely attempt to read *size* bytes from user space address *unsafe_ptr* and store the data in *dst*.

Return 0 on success, or a negative error in case of failure.

long bpf_probe_read_kernel(void *_dst_, u32 _size_, const void *_unsafe_ptr_)

Description

Safely attempt to read *size* bytes from kernel space address *unsafe_ptr* and store the data in *dst*.

Return 0 on success, or a negative error in case of failure.

long bpf_probe_read_user_str(void *_dst_, u32 _size_, const void *_unsafe_ptr_)

Description

Copy a NUL terminated string from an unsafe user address *unsafe_ptr* to *dst*. The *size* should include the terminating NUL byte. In case the string length is smaller than *size*, the target is not padded with further NUL bytes. If the string length is larger than *size*, just *size*−1 bytes are copied and the last byte is set to NUL.

On success, returns the number of bytes that were written, including the terminal NUL. This makes this helper useful in tracing programs for reading strings, and more importantly to get its length at runtime. See the following snippet:

```
SEC("kprobe/sys_open")
void bpf_sys_open(struct pt_regs *ctx)
{
        char buf[PATHLEN]; // PATHLEN is defined to 256
        int res = bpf_probe_read_user_str(buf, sizeof(buf),
                                          ctx->di);
        // Consume buf, for example push it to
        // userspace via bpf_perf_event_output(); we
        // can use res (the string length) as event
        // size, after checking its boundaries.
}
```

In comparison, using **bpf_probe_read_user**() helper here instead to read the string would require to estimate the length at compile time, and would often result in copying more memory than necessary.

Another useful use case is when parsing individual process arguments or individual environment variables navigating *current***->mm->arg_start** and *current*−**>mm−>env_start**: using this helper and the return value, one can quickly iterate at the right offset of the memory area.

Return On success, the strictly positive length of the output string, including the trailing NUL character. On error, a negative value.

long bpf_probe_read_kernel_str(void *****dst*, **u32 *size*, **const void *****unsafe_ptr*)

Description

Copy a NUL terminated string from an unsafe kernel address *unsafe_ptr* to *dst*. Same semantics as with **bpf_probe_read_user_str**() apply.

Return On success, the strictly positive length of the string, including the trailing NUL character. On error, a negative value.

long bpf_tcp_send_ack(void *****tp*, **u32 *rcv_nxt*)

Description

Send out a tcp−ack. *tp* is the in−kernel struct **tcp_sock**. *rcv_nxt* is the ack_seq to be sent out.

Return 0 on success, or a negative error in case of failure.

long bpf_send_signal_thread(u32 *sig*)

Description

Send signal *sig* to the thread corresponding to the current task.

Return 0 on success or successfully queued.

−**EBUSY** if work queue under nmi is full.

−**EINVAL** if *sig* is invalid.

−**EPERM** if no permission to send the *sig*.

−**EAGAIN** if bpf program can try again.

u64 bpf_jiffies64(void)

Description

Obtain the 64bit jiffies

Return The 64 bit jiffies

long bpf_read_branch_records(struct bpf_perf_event_data *_ctx_, void *_buf_, u32 _size_, u64 _flags_)

Description

For an eBPF program attached to a perf event, retrieve the branch records (**struct perf_branch_entry**) associated to *ctx* and store it in the buffer pointed by *buf* up to size *size* bytes.

Return On success, number of bytes written to *buf*. On error, a negative value.

The *flags* can be set to **BPF_F_GET_BRANCH_RECORDS_SIZE** to instead return the number of bytes required to store all the branch entries. If this flag is set, *buf* may be NULL.

−EINVAL if arguments invalid or **size** not a multiple of **sizeof**(**struct perf_branch_entry**).

−ENOENT if architecture does not support branch records.

long bpf_get_ns_current_pid_tgid(u64 _dev_, u64 _ino_, struct bpf_pidns_info *_nsdata_, u32 _size_)

Description

Returns 0 on success, values for *pid* and *tgid* as seen from the current *namespace* will be returned in *nsdata*.

Return 0 on success, or one of the following in case of failure:

−EINVAL if dev and inum supplied don't match dev_t and inode number with nsfs of current task, or if dev conversion to dev_t lost high bits.

−ENOENT if pidns does not exists for the current task.

long bpf_xdp_output(void *_ctx_, struct bpf_map *_map_, u64 _flags_, void *_data_, u64 _size_)

Description

Write raw *data* blob into a special BPF perf event held by *map* of type **BPF_MAP_TYPE_PERF_EVENT_ARRAY**. This perf event must have the following attributes: **PERF_SAMPLE_RAW** as **sample_type**, **PERF_TYPE_SOFTWARE** as **type**, and **PERF_COUNT_SW_BPF_OUTPUT** as **config**.

The *flags* are used to indicate the index in *map* for which the value must be put, masked with **BPF_F_INDEX_MASK**. Alternatively, *flags* can be set to **BPF_F_CURRENT_CPU** to indicate that the index of the current CPU core should be used.

The value to write, of *size*, is passed through eBPF stack and pointed by *data*.

ctx is a pointer to in−kernel struct xdp_buff.

This helper is similar to **bpf_perf_eventoutput**() but restricted to raw_tracepoint bpf programs.

Return 0 on success, or a negative error in case of failure.

u64 bpf_get_netns_cookie(void *_ctx_)

Description

Retrieve the cookie (generated by the kernel) of the network namespace the input *ctx* is associated with. The network namespace cookie remains stable for its lifetime and provides a global identifier that can be assumed unique. If *ctx* is NULL, then the

helper returns the cookie for the initial network namespace. The cookie itself is very similar to that of **bpf_get_socket_cookie**() helper, but for network namespaces instead of sockets.

Return A 8−byte long opaque number.

u64 bpf_get_current_ancestor_cgroup_id(int *ancestor_level***)**

Description

Return id of cgroup v2 that is ancestor of the cgroup associated with the current task at the *ancestor_level*. The root cgroup is at *ancestor_level* zero and each step down the hierarchy increments the level. If *ancestor_level* == level of cgroup associated with the current task, then return value will be the same as that of **bpf_get_current_cgroup_id**().

The helper is useful to implement policies based on cgroups that are upper in hierarchy than immediate cgroup associated with the current task.

The format of returned id and helper limitations are same as in **bpf_get_current_cgroup_id**().

Return The id is returned or 0 in case the id could not be retrieved.

long bpf_sk_assign(struct sk_buff ***skb*, void ***sk***, u64** *flags***)**

Description

Helper is overloaded depending on BPF program type. This description applies to **BPF_PROG_TYPE_SCHED_CLS** and **BPF_PROG_TYPE_SCHED_ACT** programs.

Assign the *sk* to the *skb*. When combined with appropriate routing configuration to receive the packet towards the socket, will cause *skb* to be delivered to the specified socket. Subsequent redirection of *skb* via **bpf_redirect**(), **bpf_clone_redirect**() or other methods outside of BPF may interfere with successful delivery to the socket.

This operation is only valid from TC ingress path.

The *flags* argument must be zero.

Return 0 on success, or a negative error in case of failure:

−**EINVAL** if specified *flags* are not supported.

−**ENOENT** if the socket is unavailable for assignment.

−**ENETUNREACH** if the socket is unreachable (wrong netns).

−**EOPNOTSUPP** if the operation is not supported, for example a call from outside of TC ingress.

long bpf_sk_assign(struct bpf_sk_lookup ***ctx*, struct bpf_sock ***sk***, u64** *flags***)**

Description

Helper is overloaded depending on BPF program type. This description applies to **BPF_PROG_TYPE_SK_LOOKUP** programs.

Select the *sk* as a result of a socket lookup.

For the operation to succeed passed socket must be compatible with the packet description provided by the *ctx* object.

L4 protocol (**IPPROTO_TCP** or **IPPROTO_UDP**) must be an exact match. While IP family (**AF_INET** or **AF_INET6**) must be compatible, that is IPv6 sockets that are not v6−only can be selected for IPv4 packets.

Only TCP listeners and UDP unconnected sockets can be selected. *sk* can also be NULL to reset any previous selection.

flags argument can combination of following values:

- **BPF_SK_LOOKUP_F_REPLACE** to override the previous socket selection, potentially done by a BPF program that ran before us.
- **BPF_SK_LOOKUP_F_NO_REUSEPORT** to skip load−balancing within reuseport group for the socket being selected.

On success *ctx−>sk* will point to the selected socket.

Return 0 on success, or a negative errno in case of failure.

- **−EAFNOSUPPORT** if socket family (*sk−>family*) is not compatible with packet family (*ctx−>family*).
- **−EEXIST** if socket has been already selected, potentially by another program, and **BPF_SK_LOOKUP_F_REPLACE** flag was not specified.
- **−EINVAL** if unsupported flags were specified.
- **−EPROTOTYPE** if socket L4 protocol (*sk−>protocol*) doesn't match packet protocol (*ctx−>protocol*).
- **−ESOCKTNOSUPPORT** if socket is not in allowed state (TCP listening or UDP unconnected).

u64 bpf_ktime_get_boot_ns(void)

Description

Return the time elapsed since system boot, in nanoseconds. Does include the time the system was suspended. See: **clock_gettime**(**CLOCK_BOOTTIME**)

Return Current *ktime*.

long bpf_seq_printf(struct seq_file *_m_, const char *_fmt_, u32 _fmt_size_, const void *_data_, u32 _data_len_)

Description

bpf_seq_printf() uses seq_file **seq_printf**() to print out the format string. The *m* represents the seq_file. The *fmt* and *fmt_size* are for the format string itself. The *data* and *data_len* are format string arguments. The *data* are a **u64** array and corresponding format string values are stored in the array. For strings and pointers where pointees are accessed, only the pointer values are stored in the *data* array. The *data_len* is the size of *data* in bytes − must be a multiple of 8.

Formats **%s**, **%p{i,I}{4,6}** requires to read kernel memory. Reading kernel memory may fail due to either invalid address or valid address but requiring a major memory fault. If reading kernel memory fails, the string for **%s** will be an empty string, and the ip address for **%p{i,I}{4,6}** will be 0. Not returning error to bpf program is consistent with what **bpf_trace_printk**() does for now.

Return 0 on success, or a negative error in case of failure:

−EBUSY if per−CPU memory copy buffer is busy, can try again by returning 1 from bpf program.

−EINVAL if arguments are invalid, or if *fmt* is invalid/unsupported.

−E2BIG if *fmt* contains too many format specifiers.

−EOVERFLOW if an overflow happened: The same object will be tried again.

long bpf_seq_write(struct seq_file *_m_, const void *_data_, u32 _len_)

Description

bpf_seq_write() uses seq_file **seq_write**() to write the data. The *m* represents the seq_file. The *data* and *len* represent the data to write in bytes.

Return 0 on success, or a negative error in case of failure:

−**EOVERFLOW** if an overflow happened: The same object will be tried again.

u64 bpf_sk_cgroup_id(void ***sk*)**

Description

Return the cgroup v2 id of the socket *sk*.

sk must be a non−**NULL** pointer to a socket, e.g. one returned from **bpf_sk_lookup_xxx**(), **bpf_sk_fullsock**(), etc. The format of returned id is same as in **bpf_skb_cgroup_id**().

This helper is available only if the kernel was compiled with the **CONFIG_SOCK_CGROUP_DATA** configuration option.

Return The id is returned or 0 in case the id could not be retrieved.

u64 bpf_sk_ancestor_cgroup_id(void ***sk*, int** *ancestor_level***)**

Description

Return id of cgroup v2 that is ancestor of cgroup associated with the *sk* at the *ancestor_level*. The root cgroup is at *ancestor_level* zero and each step down the hierarchy increments the level. If *ancestor_level* == level of cgroup associated with *sk*, then return value will be same as that of **bpf_sk_cgroup_id**().

The helper is useful to implement policies based on cgroups that are upper in hierarchy than immediate cgroup associated with *sk*.

The format of returned id and helper limitations are same as in **bpf_sk_cgroup_id**().

Return The id is returned or 0 in case the id could not be retrieved.

long bpf_ringbuf_output(void ***ringbuf*, void ***data***, u64** *size***, u64** *flags***)**

Description

Copy *size* bytes from *data* into a ring buffer *ringbuf*. If **BPF_RB_NO_WAKEUP** is specified in *flags*, no notification of new data availability is sent. If **BPF_RB_FORCE_WAKEUP** is specified in *flags*, notification of new data availability is sent unconditionally. If **0** is specified in *flags*, an adaptive notification of new data availability is sent.

An adaptive notification is a notification sent whenever the user−space process has caught up and consumed all available payloads. In case the user−space process is still processing a previous payload, then no notification is needed as it will process the newly added payload automatically.

Return 0 on success, or a negative error in case of failure.

void *bpf_ringbuf_reserve(void ***ringbuf*, u64** *size***, u64** *flags***)**

Description

Reserve *size* bytes of payload in a ring buffer *ringbuf*. *flags* must be 0.

Return Valid pointer with *size* bytes of memory available; NULL, otherwise.

void bpf_ringbuf_submit(void ***data*, u64** *flags***)**

Description

Submit reserved ring buffer sample, pointed to by *data*. If **BPF_RB_NO_WAKEUP** is specified in *flags*, no notification of new data availability is sent. If **BPF_RB_FORCE_WAKEUP** is specified in *flags*, notification of new data availability is sent unconditionally. If **0** is specified in *flags*, an adaptive notification of new data availability is sent.

See 'bpf_ringbuf_output()' for the definition of adaptive notification.

Return Nothing. Always succeeds.

void bpf_ringbuf_discard(void ****data*, u64** *flags***)**

Description

Discard reserved ring buffer sample, pointed to by *data*. If **BPF_RB_NO_WAKEUP** is specified in *flags*, no notification of new data availability is sent. If **BPF_RB_FORCE_WAKEUP** is specified in *flags*, notification of new data availability is sent unconditionally. If **0** is specified in *flags*, an adaptive notification of new data availability is sent.

See 'bpf_ringbuf_output()' for the definition of adaptive notification.

Return Nothing. Always succeeds.

u64 bpf_ringbuf_query(void ****ringbuf*, u64** *flags***)**

Description

Query various characteristics of provided ring buffer. What exactly is queries is determined by *flags*:

- **BPF_RB_AVAIL_DATA**: Amount of data not yet consumed.
- **BPF_RB_RING_SIZE**: The size of ring buffer.
- **BPF_RB_CONS_POS**: Consumer position (can wrap around).
- **BPF_RB_PROD_POS**: Producer(s) position (can wrap around).

Data returned is just a momentary snapshot of actual values and could be inaccurate, so this facility should be used to power heuristics and for reporting, not to make 100% correct calculation.

Return Requested value, or 0, if *flags* are not recognized.

long bpf_csum_level(struct sk_buff ****skb*, u64** *level***)**

Description

Change the skbs checksum level by one layer up or down, or reset it entirely to none in order to have the stack perform checksum validation. The level is applicable to the following protocols: TCP, UDP, GRE, SCTP, FCOE. For example, a decap of | ETH | IP | UDP | GUE | IP | TCP | into | ETH | IP | TCP | through **bpf_skb_adjust_room**() helper with passing in **BPF_F_ADJ_ROOM_NO_CSUM_RESET** flag would require one call to **bpf_csum_level**() with **BPF_CSUM_LEVEL_DEC** since the UDP header is removed. Similarly, an encap of the latter into the former could be accompanied by a helper call to **bpf_csum_level**() with **BPF_CSUM_LEVEL_INC** if the skb is still intended to be processed in higher layers of the stack instead of just egressing at tc.

There are three supported level settings at this time:

- **BPF_CSUM_LEVEL_INC**: Increases skb−>csum_level for skbs with CHECKSUM_UNNECESSARY.
- **BPF_CSUM_LEVEL_DEC**: Decreases skb−>csum_level for skbs with CHECKSUM_UNNECESSARY.
- **BPF_CSUM_LEVEL_RESET**: Resets skb−>csum_level to 0 and sets CHECKSUM_NONE to force checksum validation by the stack.
- **BPF_CSUM_LEVEL_QUERY**: No−op, returns the current skb−>csum_level.

Return 0 on success, or a negative error in case of failure. In the case of **BPF_CSUM_LEVEL_QUERY**, the current skb−>csum_level is returned or the error code −EACCES in case the skb is not subject to CHECKSUM_UNNECESSARY.

struct tcp6_sock *bpf_skc_to_tcp6_sock(void ***sk*)**

Description
Dynamically cast a *sk* pointer to a *tcp6_sock* pointer.

Return *sk* if casting is valid, or **NULL** otherwise.

struct tcp_sock *bpf_skc_to_tcp_sock(void ***sk*)**

Description
Dynamically cast a *sk* pointer to a *tcp_sock* pointer.

Return *sk* if casting is valid, or **NULL** otherwise.

struct tcp_timewait_sock *bpf_skc_to_tcp_timewait_sock(void ***sk*)**

Description
Dynamically cast a *sk* pointer to a *tcp_timewait_sock* pointer.

Return *sk* if casting is valid, or **NULL** otherwise.

struct tcp_request_sock *bpf_skc_to_tcp_request_sock(void ***sk*)**

Description
Dynamically cast a *sk* pointer to a *tcp_request_sock* pointer.

Return *sk* if casting is valid, or **NULL** otherwise.

struct udp6_sock *bpf_skc_to_udp6_sock(void ***sk*)**

Description
Dynamically cast a *sk* pointer to a *udp6_sock* pointer.

Return *sk* if casting is valid, or **NULL** otherwise.

long bpf_get_task_stack(struct task_struct ***task*, void ***buf***, u32** *size***, u64** *flags***)**

Description
Return a user or a kernel stack in bpf program provided buffer. Note: the user stack will only be populated if the *task* is the current task; all other tasks will return −EOPNOTSUPP. To achieve this, the helper needs *task*, which is a valid pointer to **struct task_struct**. To store the stacktrace, the bpf program provides *buf* with a nonnegative *size*.

The last argument, *flags*, holds the number of stack frames to skip (from 0 to 255), masked with **BPF_F_SKIP_FIELD_MASK**. The next bits can be used to set the following flags:

BPF_F_USER_STACK
Collect a user space stack instead of a kernel stack. The *task* must be the current task.

BPF_F_USER_BUILD_ID
Collect buildid+offset instead of ips for user stack, only valid if **BPF_F_USER_STACK** is also specified.

bpf_get_task_stack() can collect up to **PERF_MAX_STACK_DEPTH** both kernel and user frames, subject to sufficient large buffer size. Note that this limit can be controlled with the **sysctl** program, and that it should be manually increased in order to profile long user stacks (such as stacks for Java programs). To do so, use:

```
# sysctl kernel.perf_event_max_stack=<new value>
```

Return The non−negative copied *buf* length equal to or less than *size* on success, or a negative error in case of failure.

long bpf_load_hdr_opt(struct bpf_sock_ops ***skops*, void ***searchby_res***, u32** *len***, u64** *flags***)**

Description
Load header option. Support reading a particular TCP header option for bpf program (**BPF_PROG_TYPE_SOCK_OPS**).

If *flags* is 0, it will search the option from the *skops*−>**skb_data**. The comment in **struct bpf_sock_ops** has details on what skb_data contains under different *skops*−>**op**.

The first byte of the *searchby_res* specifies the kind that it wants to search.

If the searching kind is an experimental kind (i.e. 253 or 254 according to RFC6994). It also needs to specify the "magic" which is either 2 bytes or 4 bytes. It then also needs to specify the size of the magic by using the 2nd byte which is "kind−length" of a TCP header option and the "kind−length" also includes the first 2 bytes "kind" and "kind−length" itself as a normal TCP header option also does.

For example, to search experimental kind 254 with 2 byte magic 0xeB9F, the searchby_res should be [254, 4, 0xeB, 0x9F, 0, 0, ... 0].

To search for the standard window scale option (3), the *searchby_res* should be [3, 0, 0, ... 0]. Note, kind−length must be 0 for regular option.

Searching for No−Op (0) and End−of−Option−List (1) are not supported.

len must be at least 2 bytes which is the minimal size of a header option.

Supported flags:

- **BPF_LOAD_HDR_OPT_TCP_SYN** to search from the saved_syn packet or the just−received syn packet.

Return > 0 when found, the header option is copied to *searchby_res*. The return value is the total length copied. On failure, a negative error code is returned:

−**EINVAL** if a parameter is invalid.

−**ENOMSG** if the option is not found.

−**ENOENT** if no syn packet is available when **BPF_LOAD_HDR_OPT_TCP_SYN** is used.

−**ENOSPC** if there is not enough space. Only *len* number of bytes are copied.

−**EFAULT** on failure to parse the header options in the packet.

−**EPERM** if the helper cannot be used under the current *skops*−>**op**.

long bpf_store_hdr_opt(struct bpf_sock_ops ***skops*, const void ***from***, u32** *len***, u64** *flags***)**

Description

Store header option. The data will be copied from buffer *from* with length *len* to the TCP header.

The buffer *from* should have the whole option that includes the kind, kind−length, and the actual option data. The *len* must be at least kind−length long. The kind−length does not have to be 4 byte aligned. The kernel will take care of the padding and setting the 4 bytes aligned value to th−>doff.

This helper will check for duplicated option by searching the same option in the outgoing skb.

This helper can only be called during **BPF_SOCK_OPS_WRITE_HDR_OPT_CB**.

Return 0 on success, or negative error in case of failure:

−**EINVAL** If param is invalid.

−**ENOSPC** if there is not enough space in the header. Nothing has been written

−**EEXIST** if the option already exists.

−**EFAULT** on failure to parse the existing header options.

−**EPERM** if the helper cannot be used under the current *skops*−>**op**.

long bpf_reserve_hdr_opt(struct bpf_sock_ops ***skops*, u32** *len***, u64** *flags***)**

Description

Reserve *len* bytes for the bpf header option. The space will be used by **bpf_store_hdr_opt**() later in **BPF_SOCK_OPS_WRITE_HDR_OPT_CB**.

If **bpf_reserve_hdr_opt**() is called multiple times, the total number of bytes will be reserved.

This helper can only be called during **BPF_SOCK_OPS_HDR_OPT_LEN_CB**.

Return 0 on success, or negative error in case of failure:

−**EINVAL** if a parameter is invalid.

−**ENOSPC** if there is not enough space in the header.

−**EPERM** if the helper cannot be used under the current *skops*−>**op**.

void *bpf_inode_storage_get(struct bpf_map ***map*, void *** *inode***, void *** *value***, u64** *flags***)**

Description

Get a bpf_local_storage from an *inode*.

Logically, it could be thought of as getting the value from a *map* with *inode* as the **key**. From this perspective, the usage is not much different from **bpf_map_lookup_elem**(*map*, **&***inode*) except this helper enforces the key must be an inode and the map must also be a **BPF_MAP_TYPE_INODE_STORAGE**.

Underneath, the value is stored locally at *inode* instead of the *map*. The *map* is used as the bpf−local−storage "type". The bpf−local−storage "type" (i.e. the *map*) is searched against all bpf_local_storage residing at *inode*.

An optional *flags* (**BPF_LOCAL_STORAGE_GET_F_CREATE**) can be used such that a new bpf_local_storage will be created if one does not exist. *value* can be used together with **BPF_LOCAL_STORAGE_GET_F_CREATE** to specify the initial value of a bpf_local_storage. If *value* is **NULL**, the new bpf_local_storage will be zero initialized.

Return A bpf_local_storage pointer is returned on success.

NULL if not found or there was an error in adding a new bpf_local_storage.

int bpf_inode_storage_delete(struct bpf_map ***map*, void *** *inode***)**

Description

Delete a bpf_local_storage from an *inode*.

Return 0 on success.

−**ENOENT** if the bpf_local_storage cannot be found.

long bpf_d_path(struct path ***path*, char ***buf***, u32** *sz***)**

Description

Return full path for given **struct path** object, which needs to be the kernel BTF *path* object. The path is returned in the provided buffer *buf* of size *sz* and is zero

terminated.

Return On success, the strictly positive length of the string, including the trailing NUL character. On error, a negative value.

long bpf_copy_from_user(void *_dst_, u32 _size_, const void *_user_ptr_)

Description

Read *size* bytes from user space address *user_ptr* and store the data in *dst*. This is a wrapper of **copy_from_user**().

Return 0 on success, or a negative error in case of failure.

long bpf_snprintf_btf(char *_str_, u32 _str_size_, struct btf_ptr *_ptr_, u32 _btf_ptr_size_, u64 _flags_)

Description

Use BTF to store a string representation of *ptr*->ptr in *str*, using *ptr*->type_id. This value should specify the type that *ptr*->ptr points to. LLVM __builtin_btf_type_id(type, 1) can be used to look up vmlinux BTF type ids. Traversing the data structure using BTF, the type information and values are stored in the first *str_size* - 1 bytes of *str*. Safe copy of the pointer data is carried out to avoid kernel crashes during operation. Smaller types can use string space on the stack; larger programs can use map data to store the string representation.

The string can be subsequently shared with userspace via bpf_perf_event_output() or ring buffer interfaces. bpf_trace_printk() is to be avoided as it places too small a limit on string size to be useful.

flags is a combination of

BTF_F_COMPACT
no formatting around type information

BTF_F_NONAME
no struct/union member names/types

BTF_F_PTR_RAW
show raw (unobfuscated) pointer values; equivalent to printk specifier %px.

BTF_F_ZERO
show zero-valued struct/union members; they are not displayed by default

Return The number of bytes that were written (or would have been written if output had to be truncated due to string size), or a negative error in cases of failure.

long bpf_seq_printf_btf(struct seq_file *_m_, struct btf_ptr *_ptr_, u32 _ptr_size_, u64 _flags_)

Description

Use BTF to write to seq_write a string representation of *ptr*->ptr, using *ptr*->type_id as per bpf_snprintf_btf(). *flags* are identical to those used for bpf_snprintf_btf.

Return 0 on success or a negative error in case of failure.

u64 bpf_skb_cgroup_classid(struct sk_buff *_skb_)

Description

See **bpf_get_cgroup_classid**() for the main description. This helper differs from **bpf_get_cgroup_classid**() in that the cgroup v1 net_cls class is retrieved only from the *skb*'s associated socket instead of the current process.

Return The id is returned or 0 in case the id could not be retrieved.

long bpf_redirect_neigh(u32 _ifindex_, struct bpf_redir_neigh *_params_, int _plen_, u64 _flags_)

Description

Redirect the packet to another net device of index *ifindex* and fill in L2 addresses from neighboring subsystem. This helper is somewhat similar to **bpf_redirect**(), except that it populates L2 addresses as well, meaning, internally, the helper relies on the neighbor lookup for the L2 address of the nexthop.

The helper will perform a FIB lookup based on the skb's networking header to get the address of the next hop, unless this is supplied by the caller in the *params* argument. The *plen* argument indicates the len of *params* and should be set to 0 if *params* is NULL.

The *flags* argument is reserved and must be 0. The helper is currently only supported for tc BPF program types, and enabled for IPv4 and IPv6 protocols.

Return The helper returns **TC_ACT_REDIRECT** on success or **TC_ACT_SHOT** on error.

void *bpf_per_cpu_ptr(const void ****percpu_ptr*, u32** *cpu***)**

Description

Take a pointer to a percpu ksym, *percpu_ptr*, and return a pointer to the percpu kernel variable on *cpu*. A ksym is an extern variable decorated with '__ksym'. For ksym, there is a global var (either static or global) defined of the same name in the kernel. The ksym is percpu if the global var is percpu. The returned pointer points to the global percpu var on *cpu*.

bpf_per_cpu_ptr() has the same semantic as per_cpu_ptr() in the kernel, except that bpf_per_cpu_ptr() may return NULL. This happens if *cpu* is larger than nr_cpu_ids. The caller of bpf_per_cpu_ptr() must check the returned value.

Return A pointer pointing to the kernel percpu variable on *cpu*, or NULL, if *cpu* is invalid.

void *bpf_this_cpu_ptr(const void ****percpu_ptr*)**

Description

Take a pointer to a percpu ksym, *percpu_ptr*, and return a pointer to the percpu kernel variable on this cpu. See the description of 'ksym' in **bpf_per_cpu_ptr**().

bpf_this_cpu_ptr() has the same semantic as this_cpu_ptr() in the kernel. Different from **bpf_per_cpu_ptr**(), it would never return NULL.

Return A pointer pointing to the kernel percpu variable on this cpu.

long bpf_redirect_peer(u32 *ifindex***, u64** *flags***)**

Description

Redirect the packet to another net device of index *ifindex*. This helper is somewhat similar to **bpf_redirect**(), except that the redirection happens to the *ifindex*' peer device and the netns switch takes place from ingress to ingress without going through the CPU's backlog queue.

The *flags* argument is reserved and must be 0. The helper is currently only supported for tc BPF program types at the ingress hook and for veth device types. The peer device must reside in a different network namespace.

Return The helper returns **TC_ACT_REDIRECT** on success or **TC_ACT_SHOT** on error.

void *bpf_task_storage_get(struct bpf_map ****map*, struct task_struct ****task***, void ****value***, u64** *flags***)**

Description

Get a bpf_local_storage from the *task*.

Logically, it could be thought of as getting the value from a *map* with *task* as the **key**. From this perspective, the usage is not much different from **bpf_map_lookup_elem**(*map*, **&***task*) except this helper enforces the key must be a task_struct and the map must also be a **BPF_MAP_TYPE_TASK_STORAGE**.

Underneath, the value is stored locally at *task* instead of the *map*. The *map* is used as the bpf−local−storage "type". The bpf−local−storage "type" (i.e. the *map*) is searched against all bpf_local_storage residing at *task*.

An optional *flags* (**BPF_LOCAL_STORAGE_GET_F_CREATE**) can be used such that a new bpf_local_storage will be created if one does not exist. *value* can be used

together with **BPF_LOCAL_STORAGE_GET_F_CREATE** to specify the initial value of a bpf_local_storage. If *value* is **NULL**, the new bpf_local_storage will be zero initialized.

Return A bpf_local_storage pointer is returned on success.

NULL if not found or there was an error in adding a new bpf_local_storage.

long bpf_task_storage_delete(struct bpf_map ****map*, struct task_struct ****task***)**

Description

Delete a bpf_local_storage from a *task*.

Return 0 on success.

−ENOENT if the bpf_local_storage cannot be found.

struct task_struct *bpf_get_current_task_btf(void)

Description

Return a BTF pointer to the "current" task. This pointer can also be used in helpers that accept an *ARG_PTR_TO_BTF_ID* of type *task_struct*.

Return Pointer to the current task.

long bpf_bprm_opts_set(struct linux_binprm ****bprm*, u64** *flags***)**

Description

Set or clear certain options on *bprm*:

BPF_F_BPRM_SECUREEXEC Set the secureexec bit which sets the **AT_SECURE** auxv for glibc. The bit is cleared if the flag is not specified.

Return **−EINVAL** if invalid *flags* are passed, zero otherwise.

u64 bpf_ktime_get_coarse_ns(void)

Description

Return a coarse−grained version of the time elapsed since system boot, in nanoseconds. Does not include time the system was suspended.

See: **clock_gettime**(**CLOCK_MONOTONIC_COARSE**)

Return Current *ktime*.

long bpf_ima_inode_hash(struct inode ****inode*, void ****dst***, u32** *size***)**

Description

Returns the stored IMA hash of the *inode* (if it's available). If the hash is larger than *size*, then only *size* bytes will be copied to *dst*

Return The **hash_algo** is returned on success, **−EOPNOTSUP** if IMA is disabled or **−EINVAL** if invalid arguments are passed.

struct socket *bpf_sock_from_file(struct file ****file*)**

Description

If the given file represents a socket, returns the associated socket.

Return A pointer to a struct socket on success or NULL if the file is not a socket.

long bpf_check_mtu(void ****ctx*, u32** *ifindex***, u32 ****mtu_len***, s32** *len_diff***, u64** *flags***)**

Description

Check packet size against exceeding MTU of net device (based on *ifindex*). This helper will likely be used in combination with helpers that adjust/change the packet size.

The argument *len_diff* can be used for querying with a planned size change. This allows to check MTU prior to changing packet ctx. Providing a *len_diff* adjustment that is larger than the actual packet size (resulting in negative packet size) will in principle

not exceed the MTU, which is why it is not considered a failure. Other BPF helpers are needed for performing the planned size change; therefore the responsibility for catching a negative packet size belongs in those helpers.

Specifying *ifindex* zero means the MTU check is performed against the current net device. This is practical if this isn't used prior to redirect.

On input *mtu_len* must be a valid pointer, else verifier will reject BPF program. If the value *mtu_len* is initialized to zero then the ctx packet size is use. When value *mtu_len* is provided as input this specify the L3 length that the MTU check is done against. Remember XDP and TC length operate at L2, but this value is L3 as this correlate to MTU and IP−header tot_len values which are L3 (similar behavior as bpf_fib_lookup).

The Linux kernel route table can configure MTUs on a more specific per route level, which is not provided by this helper. For route level MTU checks use the **bpf_fib_lookup**() helper.

ctx is either **struct xdp_md** for XDP programs or **struct sk_buff** for tc cls_act programs.

The *flags* argument can be a combination of one or more of the following values:

BPF_MTU_CHK_SEGS
: This flag will only works for *ctx* **struct sk_buff**. If packet context contains extra packet segment buffers (often knows as GSO skb), then MTU check is harder to check at this point, because in transmit path it is possible for the skb packet to get re−segmented (depending on net device features). This could still be a MTU violation, so this flag enables performing MTU check against segments, with a different violation return code to tell it apart. Check cannot use len_diff.

On return *mtu_len* pointer contains the MTU value of the net device. Remember the net device configured MTU is the L3 size, which is returned here and XDP and TC length operate at L2. Helper take this into account for you, but remember when using MTU value in your BPF−code.

Return

- 0 on success, and populate MTU value in *mtu_len* pointer.
- < 0 if any input argument is invalid (*mtu_len* not updated)

MTU violations return positive values, but also populate MTU value in *mtu_len* pointer, as this can be needed for implementing PMTU handing:

- **BPF_MTU_CHK_RET_FRAG_NEEDED**
- **BPF_MTU_CHK_RET_SEGS_TOOBIG**

long bpf_for_each_map_elem(struct bpf_map ****map*, void ****callback_fn***, void ****callback_ctx***, u64** ***flags*****)**

Description

For each element in **map**, call **callback_fn** function with **map**, **callback_ctx** and other map−specific parameters. The **callback_fn** should be a static function and the **callback_ctx** should be a pointer to the stack. The **flags** is used to control certain aspects of the helper. Currently, the **flags** must be 0.

The following are a list of supported map types and their respective expected callback signatures:

BPF_MAP_TYPE_HASH, BPF_MAP_TYPE_PERCPU_HASH,

BPF_MAP_TYPE_LRU_HASH, BPF_MAP_TYPE_LRU_PERCPU_HASH, BPF_MAP_TYPE_ARRAY, BPF_MAP_TYPE_PERCPU_ARRAY

long (*callback_fn)(struct bpf_map *map, const void *key, void *value, void *ctx);

For per_cpu maps, the map_value is the value on the cpu where the bpf_prog is running.

If **callback_fn** return 0, the helper will continue to the next element. If return value is 1, the helper will skip the rest of elements and return. Other return values are not used now.

Return The number of traversed map elements for success, **−EINVAL** for invalid **flags**.

long bpf_snprintf(char *_str_, u32 _str_size_, const char *_fmt_, u64 *_data_, u32 _data_len_)

Description

Outputs a string into the **str** buffer of size **str_size** based on a format string stored in a read−only map pointed by **fmt**.

Each format specifier in **fmt** corresponds to one u64 element in the **data** array. For strings and pointers where pointees are accessed, only the pointer values are stored in the *data* array. The *data_len* is the size of *data* in bytes − must be a multiple of 8.

Formats **%s** and **%p{i,I}{4,6}** require to read kernel memory. Reading kernel memory may fail due to either invalid address or valid address but requiring a major memory fault. If reading kernel memory fails, the string for **%s** will be an empty string, and the ip address for **%p{i,I}{4,6}** will be 0. Not returning error to bpf program is consistent with what **bpf_trace_printk**() does for now.

Return The strictly positive length of the formatted string, including the trailing zero character. If the return value is greater than **str_size**, **str** contains a truncated string, guaranteed to be zero−terminated except when **str_size** is 0.

Or **−EBUSY** if the per−CPU memory copy buffer is busy.

long bpf_sys_bpf(u32 _cmd_, void *_attr_, u32 _attr_size_)

Description

Execute bpf syscall with given arguments.

Return A syscall result.

long bpf_btf_find_by_name_kind(char *_name_, int _name_sz_, u32 _kind_, int _flags_)

Description

Find BTF type with given name and kind in vmlinux BTF or in module's BTFs.

Return Returns btf_id and btf_obj_fd in lower and upper 32 bits.

long bpf_sys_close(u32 _fd_)

Description

Execute close syscall for given FD.

Return A syscall result.

long bpf_timer_init(struct bpf_timer *_timer_, struct bpf_map *_map_, u64 _flags_)

Description

Initialize the timer. First 4 bits of *flags* specify clockid. Only CLOCK_MONOTONIC, CLOCK_REALTIME, CLOCK_BOOTTIME are allowed. All other bits of *flags* are reserved. The verifier will reject the program if *timer* is not from the same *map*.

Return 0 on success. **−EBUSY** if *timer* is already initialized. **−EINVAL** if invalid *flags* are passed. **−EPERM** if *timer* is in a map that doesn't have any user references. The user space should either hold a file descriptor to a map with timers or pin such map in

bpffs. When map is unpinned or file descriptor is closed all timers in the map will be cancelled and freed.

long bpf_timer_set_callback(struct bpf_timer ****timer*, void ****callback_fn***)**

Description

Configure the timer to call *callback_fn* static function.

Return 0 on success. **−EINVAL** if *timer* was not initialized with bpf_timer_init() earlier. **−EPERM** if *timer* is in a map that doesn't have any user references. The user space should either hold a file descriptor to a map with timers or pin such map in bpffs. When map is unpinned or file descriptor is closed all timers in the map will be cancelled and freed.

long bpf_timer_start(struct bpf_timer ****timer*, u64** *nsecs***, u64** *flags***)**

Description

Set timer expiration N nanoseconds from the current time. The configured callback will be invoked in soft irq context on some cpu and will not repeat unless another bpf_timer_start() is made. In such case the next invocation can migrate to a different cpu. Since struct bpf_timer is a field inside map element the map owns the timer. The bpf_timer_set_callback() will increment refcnt of BPF program to make sure that callback_fn code stays valid. When user space reference to a map reaches zero all timers in a map are cancelled and corresponding program's refcnts are decremented. This is done to make sure that Ctrl−C of a user process doesn't leave any timers running. If map is pinned in bpffs the callback_fn can re−arm itself indefinitely. bpf_map_update/delete_elem() helpers and user space sys_bpf commands cancel and free the timer in the given map element. The map can contain timers that invoke callback_fn−s from different programs. The same callback_fn can serve different timers from different maps if key/value layout matches across maps. Every bpf_timer_set_callback() can have different callback_fn.

flags can be one of:

BPF_F_TIMER_ABS
Start the timer in absolute expire value instead of the default relative one.

BPF_F_TIMER_CPU_PIN
Timer will be pinned to the CPU of the caller.

Return 0 on success. **−EINVAL** if *timer* was not initialized with bpf_timer_init() earlier or invalid *flags* are passed.

long bpf_timer_cancel(struct bpf_timer ****timer*)**

Description

Cancel the timer and wait for callback_fn to finish if it was running.

Return 0 if the timer was not active. 1 if the timer was active. **−EINVAL** if *timer* was not initialized with bpf_timer_init() earlier. **−EDEADLK** if callback_fn tried to call bpf_timer_cancel() on its own timer which would have led to a deadlock otherwise.

u64 bpf_get_func_ip(void ****ctx*)**

Description

Get address of the traced function (for tracing and kprobe programs).

When called for kprobe program attached as uprobe it returns probe address for both entry and return uprobe.

Return Address of the traced function for kprobe. 0 for kprobes placed within the function (not at the entry). Address of the probe for uprobe and return uprobe.

u64 bpf_get_attach_cookie(void ****ctx*)**

Description

Get bpf_cookie value provided (optionally) during the program attachment. It might be different for each individual attachment, even if BPF program itself is the same.

Expects BPF program context *ctx* as a first argument.

Supported for the following program types:

- kprobe/uprobe;
- tracepoint;
- perf_event.

Return Value specified by user at BPF link creation/attachment time or 0, if it was not specified.

long bpf_task_pt_regs(struct task_struct ****task*)**

Description

Get the struct pt_regs associated with **task**.

Return A pointer to struct pt_regs.

long bpf_get_branch_snapshot(void ****entries*, u32** *size***, u64** *flags***)**

Description

Get branch trace from hardware engines like Intel LBR. The hardware engine is stopped shortly after the helper is called. Therefore, the user need to filter branch entries based on the actual use case. To capture branch trace before the trigger point of the BPF program, the helper should be called at the beginning of the BPF program.

The data is stored as struct perf_branch_entry into output buffer *entries*. *size* is the size of *entries* in bytes. *flags* is reserved for now and must be zero.

Return On success, number of bytes written to *buf*. On error, a negative value.

−**EINVAL** if *flags* is not zero.

−**ENOENT** if architecture does not support branch records.

long bpf_trace_vprintk(const char ****fmt*, u32** *fmt_size***, const void ****data***, u32** *data_len***)**

Description

Behaves like **bpf_trace_printk**() helper, but takes an array of u64 to format and can handle more format args as a result.

Arguments are to be used as in **bpf_seq_printf**() helper.

Return The number of bytes written to the buffer, or a negative error in case of failure.

struct unix_sock *bpf_skc_to_unix_sock(void ****sk*)**

Description

Dynamically cast a *sk* pointer to a *unix_sock* pointer.

Return *sk* if casting is valid, or **NULL** otherwise.

long bpf_kallsyms_lookup_name(const char ****name*, int** *name_sz***, int** *flags***, u64 ****res***)**

Description

Get the address of a kernel symbol, returned in *res*. *res* is set to 0 if the symbol is not found.

Return On success, zero. On error, a negative value.

−**EINVAL** if *flags* is not zero.

−**EINVAL** if string *name* is not the same size as *name_sz*.

−**ENOENT** if symbol is not found.

−**EPERM** if caller does not have permission to obtain kernel address.

long bpf_find_vma(struct task_struct ***task*, u64** *addr***, void (***callback_fn***)(struct task_struct ***task***, struct vm_area_struct ***vma***, void ***callback_ctx***), void ***callback_ctx***, u64** *flags***)**

Description

Find vma of *task* that contains *addr*, call *callback_fn* function with *task*, *vma*, and *callback_ctx*. The *callback_fn* should be a static function and the *callback_ctx* should be a pointer to the stack. The *flags* is used to control certain aspects of the helper. Currently, the *flags* must be 0.

The expected callback signature is

long (*callback_fn)(struct task_struct *task, struct vm_area_struct *vma, void *callback_ctx);

Return 0 on success. **−ENOENT** if *task−>mm* is NULL, or no vma contains *addr*. **−EBUSY** if failed to try lock mmap_lock. **−EINVAL** for invalid **flags**.

long bpf_loop(u32 *nr_loops***, void (***callback_fn***)(u32, void ***callback_ctx***), void ***callback_ctx***, u64** *flags***)**

Description

For **nr_loops**, call **callback_fn** function with **callback_ctx** as the context parameter. The **callback_fn** should be a static function and the **callback_ctx** should be a pointer to the stack. The **flags** is used to control certain aspects of the helper. Currently, the **flags** must be 0. Currently, nr_loops is limited to 1 << 23 (˜8 million) loops.

long (*callback_fn)(u32 index, void *ctx);

where **index** is the current index in the loop. The index is zero−indexed.

If **callback_fn** returns 0, the helper will continue to the next loop. If return value is 1, the helper will skip the rest of the loops and return. Other return values are not used now, and will be rejected by the verifier.

Return The number of loops performed, **−EINVAL** for invalid **flags**, **−E2BIG** if **nr_loops** exceeds the maximum number of loops.

long bpf_strncmp(const char ***s1*, u32** *s1_sz***, const char ***s2***)**

Description

Do strncmp() between **s1** and **s2**. **s1** doesn't need to be null−terminated and **s1_sz** is the maximum storage size of **s1**. **s2** must be a read−only string.

Return An integer less than, equal to, or greater than zero if the first **s1_sz** bytes of **s1** is found to be less than, to match, or be greater than **s2**.

long bpf_get_func_arg(void ***ctx*, u32** *n***, u64 ***value***)**

Description

Get **n**−th argument register (zero based) of the traced function (for tracing programs) returned in **value**.

Return 0 on success. **−EINVAL** if n >= argument register count of traced function.

long bpf_get_func_ret(void ***ctx*, u64 ***value***)**

Description

Get return value of the traced function (for tracing programs) in **value**.

Return 0 on success. **−EOPNOTSUPP** for tracing programs other than BPF_TRACE_FEXIT or BPF_MODIFY_RETURN.

long bpf_get_func_arg_cnt(void ***ctx*)**

Description

Get number of registers of the traced function (for tracing programs) where function arguments are stored in these registers.

Return The number of argument registers of the traced function.

int bpf_get_retval(void)

Description

Get the BPF program's return value that will be returned to the upper layers.

This helper is currently supported by cgroup programs and only by the hooks where BPF program's return value is returned to the userspace via errno.

Return The BPF program's return value.

int bpf_set_retval(int *retval***)**

Description

Set the BPF program's return value that will be returned to the upper layers.

This helper is currently supported by cgroup programs and only by the hooks where BPF program's return value is returned to the userspace via errno.

Note that there is the following corner case where the program exports an error via bpf_set_retval but signals success via 'return 1':

bpf_set_retval(−EPERM); return 1;

In this case, the BPF program's return value will use helper's −EPERM. This still holds true for cgroup/bind{4,6} which supports extra 'return 3' success case.

Return 0 on success, or a negative error in case of failure.

u64 bpf_xdp_get_buff_len(struct xdp_buff ***xdp_md*)**

Description

Get the total size of a given xdp buff (linear and paged area)

Return The total size of a given xdp buffer.

long bpf_xdp_load_bytes(struct xdp_buff ***xdp_md*, u32** *offset***, void ***buf***, u32** *len***)**

Description

This helper is provided as an easy way to load data from a xdp buffer. It can be used to load *len* bytes from *offset* from the frame associated to *xdp_md*, into the buffer pointed by *buf*.

Return 0 on success, or a negative error in case of failure.

long bpf_xdp_store_bytes(struct xdp_buff ***xdp_md*, u32** *offset***, void ***buf***, u32** *len***)**

Description

Store *len* bytes from buffer *buf* into the frame associated to *xdp_md*, at *offset*.

Return 0 on success, or a negative error in case of failure.

long bpf_copy_from_user_task(void ***dst*, u32** *size***, const void ***user_ptr***, struct task_struct ***tsk***, u64** *flags***)**

Description

Read *size* bytes from user space address *user_ptr* in *tsk*'s address space, and stores the data in *dst*. *flags* is not used yet and is provided for future extensibility. This helper can only be used by sleepable programs.

Return 0 on success, or a negative error in case of failure. On error *dst* buffer is zeroed out.

long bpf_skb_set_tstamp(struct sk_buff ***skb*, u64** *tstamp***, u32** *tstamp_type***)**

Description

Change the __sk_buff−>tstamp_type to *tstamp_type* and set *tstamp* to the __sk_buff−>tstamp together.

If there is no need to change the __sk_buff−>tstamp_type, the tstamp value can be directly written to __sk_buff−>tstamp instead.

BPF_SKB_TSTAMP_DELIVERY_MONO is the only tstamp that will be kept during bpf_redirect_*(). A non zero *tstamp* must be used with the BPF_SKB_TSTAMP_DELIVERY_MONO *tstamp_type*.

A BPF_SKB_TSTAMP_UNSPEC *tstamp_type* can only be used with a zero *tstamp*.

Only IPv4 and IPv6 skb−>protocol are supported.

This function is most useful when it needs to set a mono delivery time to __sk_buff−>tstamp and then bpf_redirect_*() to the egress of an iface. For example, changing the (rcv) timestamp in __sk_buff−>tstamp at ingress to a mono delivery time and then bpf_redirect_*() to *sch_fq@phy−dev*.

Return 0 on success. **−EINVAL** for invalid input **−EOPNOTSUPP** for unsupported protocol

long bpf_ima_file_hash(struct file *_file_, void *_dst_, u32 _size_)

Description

Returns a calculated IMA hash of the *file*. If the hash is larger than *size*, then only *size* bytes will be copied to *dst*

Return The **hash_algo** is returned on success, **−EOPNOTSUP** if the hash calculation failed or **−EINVAL** if invalid arguments are passed.

void *bpf_kptr_xchg(void *_map_value_, void *_ptr_)

Description

Exchange kptr at pointer *map_value* with *ptr*, and return the old value. *ptr* can be NULL, otherwise it must be a referenced pointer which will be released when this helper is called.

Return The old value of kptr (which can be NULL). The returned pointer if not NULL, is a reference which must be released using its corresponding release function, or moved into a BPF map before program exit.

void *bpf_map_lookup_percpu_elem(struct bpf_map *_map_, const void *_key_, u32 _cpu_)

Description

Perform a lookup in *percpu map* for an entry associated to *key* on *cpu*.

Return Map value associated to *key* on *cpu*, or **NULL** if no entry was found or *cpu* is invalid.

struct mptcp_sock *bpf_skc_to_mptcp_sock(void *_sk_)

Description

Dynamically cast a *sk* pointer to a *mptcp_sock* pointer.

Return *sk* if casting is valid, or **NULL** otherwise.

long bpf_dynptr_from_mem(void *_data_, u32 _size_, u64 _flags_, struct bpf_dynptr *_ptr_)

Description

Get a dynptr to local memory *data*.

data must be a ptr to a map value. The maximum *size* supported is DYNPTR_MAX_SIZE. *flags* is currently unused.

Return 0 on success, −E2BIG if the size exceeds DYNPTR_MAX_SIZE, −EINVAL if flags is not 0.

long bpf_ringbuf_reserve_dynptr(void *_ringbuf_, u32 _size_, u64 _flags_, struct bpf_dynptr *_ptr_)

Description

Reserve *size* bytes of payload in a ring buffer *ringbuf* through the dynptr interface. *flags* must be 0.

Please note that a corresponding bpf_ringbuf_submit_dynptr or bpf_ringbuf_discard_dynptr must be called on *ptr*, even if the reservation fails. This is enforced by

the verifier.

Return 0 on success, or a negative error in case of failure.

void bpf_ringbuf_submit_dynptr(struct bpf_dynptr *_ptr_, u64 _flags_)

Description

Submit reserved ring buffer sample, pointed to by *data*, through the dynptr interface. This is a no−op if the dynptr is invalid/null.

For more information on *flags*, please see 'bpf_ringbuf_submit'.

Return Nothing. Always succeeds.

void bpf_ringbuf_discard_dynptr(struct bpf_dynptr *_ptr_, u64 _flags_)

Description

Discard reserved ring buffer sample through the dynptr interface. This is a no−op if the dynptr is invalid/null.

For more information on *flags*, please see 'bpf_ringbuf_discard'.

Return Nothing. Always succeeds.

long bpf_dynptr_read(void *_dst_, u32 _len_, const struct bpf_dynptr *_src_, u32 _offset_, u64 _flags_)

Description

Read *len* bytes from *src* into *dst*, starting from *offset* into *src*. *flags* is currently unused.

Return 0 on success, −E2BIG if *offset* + *len* exceeds the length of *src*'s data, −EINVAL if *src* is an invalid dynptr or if *flags* is not 0.

long bpf_dynptr_write(const struct bpf_dynptr *_dst_, u32 _offset_, void *_src_, u32 _len_, u64 _flags_)

Description

Write *len* bytes from *src* into *dst*, starting from *offset* into *dst*.

flags must be 0 except for skb−type dynptrs.

For skb−type dynptrs:

- All data slices of the dynptr are automatically invalidated after **bpf_dynptr_write**(). This is because writing may pull the skb and change the underlying packet buffer.
- For *flags*, please see the flags accepted by **bpf_skb_store_bytes**().

Return 0 on success, −E2BIG if *offset* + *len* exceeds the length of *dst*'s data, −EINVAL if *dst* is an invalid dynptr or if *dst* is a read−only dynptr or if *flags* is not correct. For skb−type dynptrs, other errors correspond to errors returned by **bpf_skb_store_bytes**().

void *bpf_dynptr_data(const struct bpf_dynptr *_ptr_, u32 _offset_, u32 _len_)

Description

Get a pointer to the underlying dynptr data.

len must be a statically known value. The returned data slice is invalidated whenever the dynptr is invalidated.

skb and xdp type dynptrs may not use bpf_dynptr_data. They should instead use bpf_dynptr_slice and bpf_dynptr_slice_rdwr.

Return Pointer to the underlying dynptr data, NULL if the dynptr is read−only, if the dynptr is invalid, or if the offset and length is out of bounds.

s64 bpf_tcp_raw_gen_syncookie_ipv4(struct iphdr *_iph_, struct tcphdr *_th_, u32 _th_len_)

Description

Try to issue a SYN cookie for the packet with corresponding IPv4/TCP headers, *iph* and *th*, without depending on a listening socket.

iph points to the IPv4 header.

th points to the start of the TCP header, while *th_len* contains the length of the TCP header (at least **sizeof**(**struct tcphdr**)).

Return On success, lower 32 bits hold the generated SYN cookie in followed by 16 bits which hold the MSS value for that cookie, and the top 16 bits are unused.

On failure, the returned value is one of the following:

−EINVAL if *th_len* is invalid.

s64 bpf_tcp_raw_gen_syncookie_ipv6(struct ipv6hdr ***_iph_, struct tcphdr ***_th_**, u32** _th_len**)**

Description

Try to issue a SYN cookie for the packet with corresponding IPv6/TCP headers, *iph* and *th*, without depending on a listening socket.

iph points to the IPv6 header.

th points to the start of the TCP header, while *th_len* contains the length of the TCP header (at least **sizeof**(**struct tcphdr**)).

Return On success, lower 32 bits hold the generated SYN cookie in followed by 16 bits which hold the MSS value for that cookie, and the top 16 bits are unused.

On failure, the returned value is one of the following:

−EINVAL if *th_len* is invalid.

−EPROTONOSUPPORT if CONFIG_IPV6 is not builtin.

long bpf_tcp_raw_check_syncookie_ipv4(struct iphdr ***_iph_, struct tcphdr ***_th_**)**

Description

Check whether *iph* and *th* contain a valid SYN cookie ACK without depending on a listening socket.

iph points to the IPv4 header.

th points to the TCP header.

Return 0 if *iph* and *th* are a valid SYN cookie ACK.

On failure, the returned value is one of the following:

−EACCES if the SYN cookie is not valid.

long bpf_tcp_raw_check_syncookie_ipv6(struct ipv6hdr ***_iph_, struct tcphdr ***_th_**)**

Description

Check whether *iph* and *th* contain a valid SYN cookie ACK without depending on a listening socket.

iph points to the IPv6 header.

th points to the TCP header.

Return 0 if *iph* and *th* are a valid SYN cookie ACK.

On failure, the returned value is one of the following:

−EACCES if the SYN cookie is not valid.

−EPROTONOSUPPORT if CONFIG_IPV6 is not builtin.

u64 bpf_ktime_get_tai_ns(void)

Description

A nonsettable system−wide clock derived from wall−clock time but ignoring leap seconds. This clock does not experience discontinuities and backwards jumps caused by NTP inserting leap seconds as CLOCK_REALTIME does.

See: **clock_gettime**(**CLOCK_TAI**)

Return Current *ktime*.

long bpf_user_ringbuf_drain(struct bpf_map *_map_, void *_callback_fn_, void *_ctx_, u64 _flags_)

Description

Drain samples from the specified user ring buffer, and invoke the provided callback for each such sample:

long (*callback_fn)(const struct bpf_dynptr *dynptr, void *ctx);

If **callback_fn** returns 0, the helper will continue to try and drain the next sample, up to a maximum of BPF_MAX_USER_RINGBUF_SAMPLES samples. If the return value is 1, the helper will skip the rest of the samples and return. Other return values are not used now, and will be rejected by the verifier.

Return The number of drained samples if no error was encountered while draining samples, or 0 if no samples were present in the ring buffer. If a user−space producer was epoll−waiting on this map, and at least one sample was drained, they will receive an event notification notifying them of available space in the ring buffer. If the BPF_RB_NO_WAKEUP flag is passed to this function, no wakeup notification will be sent. If the BPF_RB_FORCE_WAKEUP flag is passed, a wakeup notification will be sent even if no sample was drained.

On failure, the returned value is one of the following:

−EBUSY if the ring buffer is contended, and another calling context was concurrently draining the ring buffer.

−EINVAL if user−space is not properly tracking the ring buffer due to the producer position not being aligned to 8 bytes, a sample not being aligned to 8 bytes, or the producer position not matching the advertised length of a sample.

−E2BIG if user−space has tried to publish a sample which is larger than the size of the ring buffer, or which cannot fit within a struct bpf_dynptr.

void *bpf_cgrp_storage_get(struct bpf_map *_map_, struct cgroup *_cgroup_, void *_value_, u64 _flags_)

Description

Get a bpf_local_storage from the *cgroup*.

Logically, it could be thought of as getting the value from a *map* with *cgroup* as the **key**. From this perspective, the usage is not much different from **bpf_map_lookup_elem**(*map*, **&***cgroup*) except this helper enforces the key must be a cgroup struct and the map must also be a **BPF_MAP_TYPE_CGRP_STORAGE**.

In reality, the local−storage value is embedded directly inside of the *cgroup* object itself, rather than being located in the **BPF_MAP_TYPE_CGRP_STORAGE** map. When the local−storage value is queried for some *map* on a *cgroup* object, the kernel will perform an O(n) iteration over all of the live local−storage values for that *cgroup* object until the local−storage value for the *map* is found.

An optional *flags* (**BPF_LOCAL_STORAGE_GET_F_CREATE**) can be used such that a new bpf_local_storage will be created if one does not exist. *value* can be used together with **BPF_LOCAL_STORAGE_GET_F_CREATE** to specify the initial value of a bpf_local_storage. If *value* is **NULL**, the new bpf_local_storage will be zero initialized.

Return A bpf_local_storage pointer is returned on success.

NULL if not found or there was an error in adding a new bpf_local_storage.

long bpf_cgrp_storage_delete(struct bpf_map ****map*, struct cgroup ****cgroup***)**

Description

Delete a bpf_local_storage from a *cgroup*.

Return 0 on success.

−ENOENT if the bpf_local_storage cannot be found.

EXAMPLES

Example usage for most of the eBPF helpers listed in this manual page are available within the Linux kernel sources, at the following locations:

- *samples/bpf/*
- *tools/testing/selftests/bpf/*

LICENSE

eBPF programs can have an associated license, passed along with the bytecode instructions to the kernel when the programs are loaded. The format for that string is identical to the one in use for kernel modules (Dual licenses, such as "Dual BSD/GPL", may be used). Some helper functions are only accessible to programs that are compatible with the GNU General Public License (GNU GPL).

In order to use such helpers, the eBPF program must be loaded with the correct license string passed (via **attr**) to the **bpf**() system call, and this generally translates into the C source code of the program containing a line similar to the following:

```
char ____license[] __attribute__((section("license"), used)) = "GPL";
```

IMPLEMENTATION

This manual page is an effort to document the existing eBPF helper functions. But as of this writing, the BPF sub−system is under heavy development. New eBPF program or map types are added, along with new helper functions. Some helpers are occasionally made available for additional program types. So in spite of the efforts of the community, this page might not be up−to−date. If you want to check by yourself what helper functions exist in your kernel, or what types of programs they can support, here are some files among the kernel tree that you may be interested in:

- *include/uapi/linux/bpf.h* is the main BPF header. It contains the full list of all helper functions, as well as many other BPF definitions including most of the flags, structs or constants used by the helpers.
- *net/core/filter.c* contains the definition of most network−related helper functions, and the list of program types from which they can be used.
- *kernel/trace/bpf_trace.c* is the equivalent for most tracing program−related helpers.
- *kernel/bpf/verifier.c* contains the functions used to check that valid types of eBPF maps are used with a given helper function.
- *kernel/bpf/* directory contains other files in which additional helpers are defined (for cgroups, sockmaps, etc.).
- The bpftool utility can be used to probe the availability of helper functions on the system (as well as supported program and map types, and a number of other parameters). To do so, run **bpftool feature probe** (see **bpftool−feature**(8) for details). Add the **unprivileged** keyword to list features available to unprivileged users.

Compatibility between helper functions and program types can generally be found in the files where

helper functions are defined. Look for the **struct bpf_func_proto** objects and for functions returning them: these functions contain a list of helpers that a given program type can call. Note that the **default:** label of the **switch ... case** used to filter helpers can call other functions, themselves allowing access to additional helpers. The requirement for GPL license is also in those **struct bpf_func_proto**.

Compatibility between helper functions and map types can be found in the **check_map_func_compatibility**() function in file *kernel/bpf/verifier.c*.

Helper functions that invalidate the checks on **data** and **data_end** pointers for network processing are listed in function **bpf_helper_changes_pkt_data**() in file *net/core/filter.c*.

NAME

capabilities − overview of Linux capabilities

DESCRIPTION

For the purpose of performing permission checks, traditional UNIX implementations distinguish two categories of processes: *privileged* processes (whose effective user ID is 0, referred to as superuser or root), and *unprivileged* processes (whose effective UID is nonzero). Privileged processes bypass all kernel permission checks, while unprivileged processes are subject to full permission checking based on the process's credentials (usually: effective UID, effective GID, and supplementary group list).

Starting with Linux 2.2, Linux divides the privileges traditionally associated with superuser into distinct units, known as *capabilities*, which can be independently enabled and disabled. Capabilities are a per-thread attribute.

Capabilities list

The following list shows the capabilities implemented on Linux, and the operations or behaviors that each capability permits:

CAP_AUDIT_CONTROL (since Linux 2.6.11)
Enable and disable kernel auditing; change auditing filter rules; retrieve auditing status and filtering rules.

CAP_AUDIT_READ (since Linux 3.16)
Allow reading the audit log via a multicast netlink socket.

CAP_AUDIT_WRITE (since Linux 2.6.11)
Write records to kernel auditing log.

CAP_BLOCK_SUSPEND (since Linux 3.5)
Employ features that can block system suspend (**epoll**(7) **EPOLLWAKEUP**, */proc/sys/wake_lock*).

CAP_BPF (since Linux 5.8)
Employ privileged BPF operations; see *bpf*(2) and *bpf-helpers*(7).

This capability was added in Linux 5.8 to separate out BPF functionality from the overloaded **CAP_SYS_ADMIN** capability.

CAP_CHECKPOINT_RESTORE (since Linux 5.9)
- Update */proc/sys/kernel/ns_last_pid* (see *pid_namespaces*(7));
- employ the *set_tid* feature of *clone3*(2);
- read the contents of the symbolic links in */proc/*pid*/map_files* for other processes.

This capability was added in Linux 5.9 to separate out checkpoint/restore functionality from the overloaded **CAP_SYS_ADMIN** capability.

CAP_CHOWN
Make arbitrary changes to file UIDs and GIDs (see *chown*(2)).

CAP_DAC_OVERRIDE
Bypass file read, write, and execute permission checks. (DAC is an abbreviation of "discretionary access control".)

CAP_DAC_READ_SEARCH
- Bypass file read permission checks and directory read and execute permission checks;
- invoke *open_by_handle_at*(2);
- use the *linkat*(2) **AT_EMPTY_PATH** flag to create a link to a file referred to by a file descriptor.

CAP_FOWNER
- Bypass permission checks on operations that normally require the filesystem UID of the process to match the UID of the file (e.g., *chmod*(2), *utime*(2)), excluding those operations covered by **CAP_DAC_OVERRIDE** and **CAP_DAC_READ_SEARCH**;
- set inode flags (see *ioctl_iflags*(2)) on arbitrary files;
- set Access Control Lists (ACLs) on arbitrary files;
- ignore directory sticky bit on file deletion;

- modify *user* extended attributes on sticky directory owned by any user;
- specify **O_NOATIME** for arbitrary files in *open*(2) and *fcntl*(2).

CAP_FSETID
- Don't clear set-user-ID and set-group-ID mode bits when a file is modified;
- set the set-group-ID bit for a file whose GID does not match the filesystem or any of the supplementary GIDs of the calling process.

CAP_IPC_LOCK
- Lock memory (**mlock**(2), *mlockall*(2), *mmap*(2), *shmctl*(2));
- Allocate memory using huge pages (**memfd_create**(2), *mmap*(2), *shmctl*(2)).

CAP_IPC_OWNER
Bypass permission checks for operations on System V IPC objects.

CAP_KILL
Bypass permission checks for sending signals (see *kill*(2)). This includes use of the *ioctl*(2) **KDSIGACCEPT** operation.

CAP_LEASE (since Linux 2.4)
Establish leases on arbitrary files (see *fcntl*(2)).

CAP_LINUX_IMMUTABLE
Set the **FS_APPEND_FL** and **FS_IMMUTABLE_FL** inode flags (see *ioctl_iflags*(2)).

CAP_MAC_ADMIN (since Linux 2.6.25)
Allow MAC configuration or state changes. Implemented for the Smack Linux Security Module (LSM).

CAP_MAC_OVERRIDE (since Linux 2.6.25)
Override Mandatory Access Control (MAC). Implemented for the Smack LSM.

CAP_MKNOD (since Linux 2.4)
Create special files using *mknod*(2).

CAP_NET_ADMIN
Perform various network-related operations:
- interface configuration;
- administration of IP firewall, masquerading, and accounting;
- modify routing tables;
- bind to any address for transparent proxying;
- set type-of-service (TOS);
- clear driver statistics;
- set promiscuous mode;
- enabling multicasting;
- use *setsockopt*(2) to set the following socket options: **SO_DEBUG**, **SO_MARK**, **SO_PRIORITY** (for a priority outside the range 0 to 6), **SO_RCVBUFFORCE**, and **SO_SNDBUFFORCE**.

CAP_NET_BIND_SERVICE
Bind a socket to Internet domain privileged ports (port numbers less than 1024).

CAP_NET_BROADCAST
(Unused) Make socket broadcasts, and listen to multicasts.

CAP_NET_RAW
- Use RAW and PACKET sockets;
- bind to any address for transparent proxying.

CAP_PERFMON (since Linux 5.8)
Employ various performance-monitoring mechanisms, including:

- call *perf_event_open*(2);
- employ various BPF operations that have performance implications.

This capability was added in Linux 5.8 to separate out performance monitoring functionality from the overloaded **CAP_SYS_ADMIN** capability. See also the kernel source file *Documentation/admin−guide/perf−security.rst*.

CAP_SETGID
- Make arbitrary manipulations of process GIDs and supplementary GID list;
- forge GID when passing socket credentials via UNIX domain sockets;
- write a group ID mapping in a user namespace (see *user_namespaces*(7)).

CAP_SETFCAP (since Linux 2.6.24)
Set arbitrary capabilities on a file.

Since Linux 5.12, this capability is also needed to map user ID 0 in a new user namespace; see *user_namespaces*(7) for details.

CAP_SETPCAP
If file capabilities are supported (i.e., since Linux 2.6.24): add any capability from the calling thread's bounding set to its inheritable set; drop capabilities from the bounding set (via *prctl*(2) **PR_CAPBSET_DROP**); make changes to the *securebits* flags.

If file capabilities are not supported (i.e., before Linux 2.6.24): grant or remove any capability in the caller's permitted capability set to or from any other process. (This property of **CAP_SETPCAP** is not available when the kernel is configured to support file capabilities, since **CAP_SETPCAP** has entirely different semantics for such kernels.)

CAP_SETUID
- Make arbitrary manipulations of process UIDs (**setuid**(2), *setreuid*(2), *setresuid*(2), *setfsuid*(2));
- forge UID when passing socket credentials via UNIX domain sockets;
- write a user ID mapping in a user namespace (see *user_namespaces*(7)).

CAP_SYS_ADMIN
Note: this capability is overloaded; see *Notes to kernel developers* below.

- Perform a range of system administration operations including: *quotactl*(2), *mount*(2), *umount*(2), *pivot_root*(2), *swapon*(2), *swapoff*(2), *sethostname*(2), and *setdomainname*(2);
- perform privileged *syslog*(2) operations (since Linux 2.6.37, **CAP_SYSLOG** should be used to permit such operations);
- perform **VM86_REQUEST_IRQ** *vm86*(2) command;
- access the same checkpoint/restore functionality that is governed by **CAP_CHECKPOINT_RESTORE** (but the latter, weaker capability is preferred for accessing that functionality).
- perform the same BPF operations as are governed by **CAP_BPF** (but the latter, weaker capability is preferred for accessing that functionality).
- employ the same performance monitoring mechanisms as are governed by **CAP_PERFMON** (but the latter, weaker capability is preferred for accessing that functionality).
- perform **IPC_SET** and **IPC_RMID** operations on arbitrary System V IPC objects;
- override **RLIMIT_NPROC** resource limit;
- perform operations on *trusted* and *security* extended attributes (see *xattr*(7));
- use *lookup_dcookie*(2);
- use *ioprio_set*(2) to assign **IOPRIO_CLASS_RT** and (before Linux 2.6.25) **IOPRIO_CLASS_IDLE** I/O scheduling classes;
- forge PID when passing socket credentials via UNIX domain sockets;
- exceed */proc/sys/fs/file−max*, the system-wide limit on the number of open files, in system calls that open files (e.g., *accept*(2), *execve*(2), *open*(2), *pipe*(2));
- employ **CLONE_*** flags that create new namespaces with *clone*(2) and *unshare*(2) (but, since Linux 3.8, creating user namespaces does not require any capability);
- access privileged *perf* event information;
- call *setns*(2) (requires **CAP_SYS_ADMIN** in the *target* namespace);
- call *fanotify_init*(2);
- perform privileged **KEYCTL_CHOWN** and **KEYCTL_SETPERM** *keyctl*(2) operations;
- perform *madvise*(2) **MADV_HWPOISON** operation;
- employ the **TIOCSTI** *ioctl*(2) to insert characters into the input queue of a terminal other than the caller's controlling terminal;
- employ the obsolete *nfsservctl*(2) system call;

- employ the obsolete *bdflush*(2) system call;
- perform various privileged block-device *ioctl*(2) operations;
- perform various privileged filesystem *ioctl*(2) operations;
- perform privileged *ioctl*(2) operations on the */dev/random* device (see *random*(4));
- install a *seccomp*(2) filter without first having to set the *no_new_privs* thread attribute;
- modify allow/deny rules for device control groups;
- employ the *ptrace*(2) **PTRACE_SECCOMP_GET_FILTER** operation to dump tracee's seccomp filters;
- employ the *ptrace*(2) **PTRACE_SETOPTIONS** operation to suspend the tracee's seccomp protections (i.e., the **PTRACE_O_SUSPEND_SECCOMP** flag);
- perform administrative operations on many device drivers;
- modify autogroup nice values by writing to */proc/*pid*/autogroup* (see *sched*(7)).

CAP_SYS_BOOT

Use *reboot*(2) and *kexec_load*(2).

CAP_SYS_CHROOT

- Use *chroot*(2);
- change mount namespaces using *setns*(2).

CAP_SYS_MODULE

- Load and unload kernel modules (see *init_module*(2) and *delete_module*(2));
- before Linux 2.6.25: drop capabilities from the system-wide capability bounding set.

CAP_SYS_NICE

- Lower the process nice value (**nice**(2), *setpriority*(2)) and change the nice value for arbitrary processes;
- set real-time scheduling policies for calling process, and set scheduling policies and priorities for arbitrary processes (**sched_setscheduler**(2), *sched_setparam*(2), *sched_setattr*(2));
- set CPU affinity for arbitrary processes (**sched_setaffinity**(2));
- set I/O scheduling class and priority for arbitrary processes (**ioprio_set**(2));
- apply *migrate_pages*(2) to arbitrary processes and allow processes to be migrated to arbitrary nodes;
- apply *move_pages*(2) to arbitrary processes;
- use the **MPOL_MF_MOVE_ALL** flag with *mbind*(2) and *move_pages*(2).

CAP_SYS_PACCT

Use *acct*(2).

CAP_SYS_PTRACE

- Trace arbitrary processes using *ptrace*(2);
- apply *get_robust_list*(2) to arbitrary processes;
- transfer data to or from the memory of arbitrary processes using *process_vm_readv*(2) and *process_vm_writev*(2);
- inspect processes using *kcmp*(2).

CAP_SYS_RAWIO

- Perform I/O port operations (**iopl**(2) and *ioperm*(2));
- access */proc/kcore*;
- employ the **FIBMAP** *ioctl*(2) operation;
- open devices for accessing x86 model-specific registers (MSRs, see *msr*(4));
- update */proc/sys/vm/mmap_min_addr*;
- create memory mappings at addresses below the value specified by */proc/sys/vm/mmap_min_addr*;
- map files in */proc/bus/pci*;
- open */dev/mem* and */dev/kmem*;
- perform various SCSI device commands;
- perform certain operations on *hpsa*(4) and *cciss*(4) devices;
- perform a range of device-specific operations on other devices.

CAP_SYS_RESOURCE

- Use reserved space on ext2 filesystems;
- make *ioctl*(2) calls controlling ext3 journaling;
- override disk quota limits;
- increase resource limits (see *setrlimit*(2));
- override **RLIMIT_NPROC** resource limit;
- override maximum number of consoles on console allocation;
- override maximum number of keymaps;
- allow more than 64hz interrupts from the real-time clock;
- raise *msg_qbytes* limit for a System V message queue above the limit in */proc/sys/kernel/msgmnb* (see *msgop*(2) and *msgctl*(2));
- allow the **RLIMIT_NOFILE** resource limit on the number of "in-flight" file descriptors to be bypassed when passing file descriptors to another process via a UNIX domain socket (see *unix*(7));
- override the */proc/sys/fs/pipe-size-max* limit when setting the capacity of a pipe using the **F_SETPIPE_SZ** *fcntl*(2) command;
- use **F_SETPIPE_SZ** to increase the capacity of a pipe above the limit specified by */proc/sys/fs/pipe-max-size*;
- override */proc/sys/fs/mqueue/queues_max*, */proc/sys/fs/mqueue/msg_max*, and */proc/sys/fs/mqueue/msgsize_max* limits when creating POSIX message queues (see *mq_overview*(7));
- employ the *prctl*(2) **PR_SET_MM** operation;
- set */proc/*pid*/oom_score_adj* to a value lower than the value last set by a process with **CAP_SYS_RESOURCE**.

CAP_SYS_TIME
Set system clock (**settimeofday**(2), *stime*(2), *adjtimex*(2)); set real-time (hardware) clock.

CAP_SYS_TTY_CONFIG
Use *vhangup*(2); employ various privileged *ioctl*(2) operations on virtual terminals.

CAP_SYSLOG (since Linux 2.6.37)
- Perform privileged *syslog*(2) operations. See *syslog*(2) for information on which operations require privilege.
- View kernel addresses exposed via */proc* and other interfaces when */proc/sys/kernel/kptr_restrict* has the value 1. (See the discussion of the *kptr_restrict* in *proc*(5).)

CAP_WAKE_ALARM (since Linux 3.0)
Trigger something that will wake up the system (set **CLOCK_REALTIME_ALARM** and **CLOCK_BOOTTIME_ALARM** timers).

Past and current implementation

A full implementation of capabilities requires that:

- For all privileged operations, the kernel must check whether the thread has the required capability in its effective set.
- The kernel must provide system calls allowing a thread's capability sets to be changed and retrieved.
- The filesystem must support attaching capabilities to an executable file, so that a process gains those capabilities when the file is executed.

Before Linux 2.6.24, only the first two of these requirements are met; since Linux 2.6.24, all three requirements are met.

Notes to kernel developers

When adding a new kernel feature that should be governed by a capability, consider the following points.

- The goal of capabilities is divide the power of superuser into pieces, such that if a program that has one or more capabilities is compromised, its power to do damage to the system would be less than the same program running with root privilege.
- You have the choice of either creating a new capability for your new feature, or associating the feature with one of the existing capabilities. In order to keep the set of capabilities to a manageable size, the latter option is preferable, unless there are compelling reasons to take the former option.

(There is also a technical limit: the size of capability sets is currently limited to 64 bits.)

- To determine which existing capability might best be associated with your new feature, review the list of capabilities above in order to find a "silo" into which your new feature best fits. One approach to take is to determine if there are other features requiring capabilities that will always be used along with the new feature. If the new feature is useless without these other features, you should use the same capability as the other features.
- *Don't* choose **CAP_SYS_ADMIN** if you can possibly avoid it! A vast proportion of existing capability checks are associated with this capability (see the partial list above). It can plausibly be called "the new root", since on the one hand, it confers a wide range of powers, and on the other hand, its broad scope means that this is the capability that is required by many privileged programs. Don't make the problem worse. The only new features that should be associated with **CAP_SYS_ADMIN** are ones that *closely* match existing uses in that silo.
- If you have determined that it really is necessary to create a new capability for your feature, don't make or name it as a "single-use" capability. Thus, for example, the addition of the highly specific **CAP_SYS_PACCT** was probably a mistake. Instead, try to identify and name your new capability as a broader silo into which other related future use cases might fit.

Thread capability sets

Each thread has the following capability sets containing zero or more of the above capabilities:

Permitted

This is a limiting superset for the effective capabilities that the thread may assume. It is also a limiting superset for the capabilities that may be added to the inheritable set by a thread that does not have the **CAP_SETPCAP** capability in its effective set.

If a thread drops a capability from its permitted set, it can never reacquire that capability (unless it *execve*(2)s either a set-user-ID-root program, or a program whose associated file capabilities grant that capability).

Inheritable

This is a set of capabilities preserved across an *execve*(2). Inheritable capabilities remain inheritable when executing any program, and inheritable capabilities are added to the permitted set when executing a program that has the corresponding bits set in the file inheritable set.

Because inheritable capabilities are not generally preserved across *execve*(2) when running as a non-root user, applications that wish to run helper programs with elevated capabilities should consider using ambient capabilities, described below.

Effective

This is the set of capabilities used by the kernel to perform permission checks for the thread.

Bounding (per-thread since Linux 2.6.25)

The capability bounding set is a mechanism that can be used to limit the capabilities that are gained during *execve*(2).

Since Linux 2.6.25, this is a per-thread capability set. In older kernels, the capability bounding set was a system wide attribute shared by all threads on the system.

For more details, see *Capability bounding set* below.

Ambient (since Linux 4.3)

This is a set of capabilities that are preserved across an *execve*(2) of a program that is not privileged. The ambient capability set obeys the invariant that no capability can ever be ambient if it is not both permitted and inheritable.

The ambient capability set can be directly modified using *prctl*(2). Ambient capabilities are automatically lowered if either of the corresponding permitted or inheritable capabilities is lowered.

Executing a program that changes UID or GID due to the set-user-ID or set-group-ID bits or executing a program that has any file capabilities set will clear the ambient set. Ambient capabilities are added to the permitted set and assigned to the effective set when *execve*(2) is called. If ambient capabilities cause a process's permitted and effective capabilities to increase during an *execve*(2), this does not trigger the secure-execution mode described in *ld.so*(8).

A child created via *fork*(2) inherits copies of its parent's capability sets. For details on how *execve*(2) affects capabilities, see *Transformation of capabilities during execve()* below.

Using *capset*(2), a thread may manipulate its own capability sets; see *Programmatically adjusting capability sets* below.

Since Linux 3.2, the file */proc/sys/kernel/cap_last_cap* exposes the numerical value of the highest capability supported by the running kernel; this can be used to determine the highest bit that may be set in a capability set.

File capabilities

Since Linux 2.6.24, the kernel supports associating capability sets with an executable file using *setcap*(8)The file capability sets are stored in an extended attribute (see *setxattr*(2) and *xattr*(7)) named *security.capability*. Writing to this extended attribute requires the **CAP_SETFCAP** capability. The file capability sets, in conjunction with the capability sets of the thread, determine the capabilities of a thread after an *execve*(2).

The three file capability sets are:

Permitted (formerly known as *forced*):
: These capabilities are automatically permitted to the thread, regardless of the thread's inheritable capabilities.

Inheritable (formerly known as *allowed*):
: This set is ANDed with the thread's inheritable set to determine which inheritable capabilities are enabled in the permitted set of the thread after the *execve*(2).

Effective:
: This is not a set, but rather just a single bit. If this bit is set, then during an *execve*(2) all of the new permitted capabilities for the thread are also raised in the effective set. If this bit is not set, then after an *execve*(2), none of the new permitted capabilities is in the new effective set.

  Enabling the file effective capability bit implies that any file permitted or inheritable capability that causes a thread to acquire the corresponding permitted capability during an *execve*(2) (see *Transformation of capabilities during execve()* below) will also acquire that capability in its effective set. Therefore, when assigning capabilities to a file (**setcap**(8), *cap_set_file*(3), *cap_set_fd*(3)), if we specify the effective flag as being enabled for any capability, then the effective flag must also be specified as enabled for all other capabilities for which the corresponding permitted or inheritable flag is enabled.

File capability extended attribute versioning

To allow extensibility, the kernel supports a scheme to encode a version number inside the *security.capability* extended attribute that is used to implement file capabilities. These version numbers are internal to the implementation, and not directly visible to user-space applications. To date, the following versions are supported:

VFS_CAP_REVISION_1
: This was the original file capability implementation, which supported 32-bit masks for file capabilities.

VFS_CAP_REVISION_2 (since Linux 2.6.25)
: This version allows for file capability masks that are 64 bits in size, and was necessary as the number of supported capabilities grew beyond 32. The kernel transparently continues to support the execution of files that have 32-bit version 1 capability masks, but when adding capabilities to files that did not previously have capabilities, or modifying the capabilities of existing files, it automatically uses the version 2 scheme (or possibly the version 3 scheme, as described below).

VFS_CAP_REVISION_3 (since Linux 4.14)
: Version 3 file capabilities are provided to support namespaced file capabilities (described below).

  As with version 2 file capabilities, version 3 capability masks are 64 bits in size. But in addition, the root user ID of namespace is encoded in the *security.capability* extended attribute. (A namespace's root user ID is the value that user ID 0 inside that namespace maps to in the initial user namespace.)

Version 3 file capabilities are designed to coexist with version 2 capabilities; that is, on a modern Linux system, there may be some files with version 2 capabilities while others have version 3 capabilities.

Before Linux 4.14, the only kind of file capability extended attribute that could be attached to a file was a **VFS_CAP_REVISION_2** attribute. Since Linux 4.14, the version of the *security.capability* extended attribute that is attached to a file depends on the circumstances in which the attribute was created.

Starting with Linux 4.14, a *security.capability* extended attribute is automatically created as (or converted to) a version 3 (**VFS_CAP_REVISION_3**) attribute if both of the following are true:

- The thread writing the attribute resides in a noninitial user namespace. (More precisely: the thread resides in a user namespace other than the one from which the underlying filesystem was mounted.)
- The thread has the **CAP_SETFCAP** capability over the file inode, meaning that (a) the thread has the **CAP_SETFCAP** capability in its own user namespace; and (b) the UID and GID of the file inode have mappings in the writer's user namespace.

When a **VFS_CAP_REVISION_3** *security.capability* extended attribute is created, the root user ID of the creating thread's user namespace is saved in the extended attribute.

By contrast, creating or modifying a *security.capability* extended attribute from a privileged (**CAP_SETFCAP**) thread that resides in the namespace where the underlying filesystem was mounted (this normally means the initial user namespace) automatically results in the creation of a version 2 (**VFS_CAP_REVISION_2**) attribute.

Note that the creation of a version 3 *security.capability* extended attribute is automatic. That is to say, when a user-space application writes (**setxattr**(2)) a *security.capability* attribute in the version 2 format, the kernel will automatically create a version 3 attribute if the attribute is created in the circumstances described above. Correspondingly, when a version 3 *security.capability* attribute is retrieved (**getxattr**(2)) by a process that resides inside a user namespace that was created by the root user ID (or a descendant of that user namespace), the returned attribute is (automatically) simplified to appear as a version 2 attribute (i.e., the returned value is the size of a version 2 attribute and does not include the root user ID). These automatic translations mean that no changes are required to user-space tools (e.g., *setcap*(1) and *getcap*(1)) in order for those tools to be used to create and retrieve version 3 *security.capability* attributes.

Note that a file can have either a version 2 or a version 3 *security.capability* extended attribute associated with it, but not both: creation or modification of the *security.capability* extended attribute will automatically modify the version according to the circumstances in which the extended attribute is created or modified.

Transformation of capabilities during execve()

During an *execve*(2), the kernel calculates the new capabilities of the process using the following algorithm:

```
P'(ambient)     = (file is privileged) ? 0 : P(ambient)

P'(permitted)   = (P(inheritable) & F(inheritable)) |
                  (F(permitted) & P(bounding)) | P'(ambient)

P'(effective)   = F(effective) ? P'(permitted) : P'(ambient)

P'(inheritable) = P(inheritable)    [i.e., unchanged]

P'(bounding)    = P(bounding)       [i.e., unchanged]
```

where:

P() denotes the value of a thread capability set before the *execve*(2)

P'() denotes the value of a thread capability set after the *execve*(2)

F() denotes a file capability set

Note the following details relating to the above capability transformation rules:

- The ambient capability set is present only since Linux 4.3. When determining the transformation of the ambient set during *execve*(2), a privileged file is one that has capabilities or has the set-user-ID or set-group-ID bit set.
- Prior to Linux 2.6.25, the bounding set was a system-wide attribute shared by all threads. That system-wide value was employed to calculate the new permitted set during *execve*(2) in the same manner as shown above for *P(bounding)*.

Note: during the capability transitions described above, file capabilities may be ignored (treated as empty) for the same reasons that the set-user-ID and set-group-ID bits are ignored; see *execve*(2). File capabilities are similarly ignored if the kernel was booted with the *no_file_caps* option.

Note: according to the rules above, if a process with nonzero user IDs performs an *execve*(2) then any capabilities that are present in its permitted and effective sets will be cleared. For the treatment of capabilities when a process with a user ID of zero performs an *execve*(2), see *Capabilities and execution of programs by root* below.

Safety checking for capability-dumb binaries

A capability-dumb binary is an application that has been marked to have file capabilities, but has not been converted to use the *libcap*(3) API to manipulate its capabilities. (In other words, this is a traditional set-user-ID-root program that has been switched to use file capabilities, but whose code has not been modified to understand capabilities.) For such applications, the effective capability bit is set on the file, so that the file permitted capabilities are automatically enabled in the process effective set when executing the file. The kernel recognizes a file which has the effective capability bit set as capability-dumb for the purpose of the check described here.

When executing a capability-dumb binary, the kernel checks if the process obtained all permitted capabilities that were specified in the file permitted set, after the capability transformations described above have been performed. (The typical reason why this might *not* occur is that the capability bounding set masked out some of the capabilities in the file permitted set.) If the process did not obtain the full set of file permitted capabilities, then *execve*(2) fails with the error **EPERM**. This prevents possible security risks that could arise when a capability-dumb application is executed with less privilege than it needs. Note that, by definition, the application could not itself recognize this problem, since it does not employ the *libcap*(3) API.

Capabilities and execution of programs by root

In order to mirror traditional UNIX semantics, the kernel performs special treatment of file capabilities when a process with UID 0 (root) executes a program and when a set-user-ID-root program is executed.

After having performed any changes to the process effective ID that were triggered by the set-user-ID mode bit of the binary—e.g., switching the effective user ID to 0 (root) because a set-user-ID-root program was executed—the kernel calculates the file capability sets as follows:

(1) If the real or effective user ID of the process is 0 (root), then the file inheritable and permitted sets are ignored; instead they are notionally considered to be all ones (i.e., all capabilities enabled). (There is one exception to this behavior, described in *Set-user-ID-root programs that have file capabilities* below.)

(2) If the effective user ID of the process is 0 (root) or the file effective bit is in fact enabled, then the file effective bit is notionally defined to be one (enabled).

These notional values for the file's capability sets are then used as described above to calculate the transformation of the process's capabilities during *execve*(2).

Thus, when a process with nonzero UIDs *execve*(2)s a set-user-ID-root program that does not have capabilities attached, or when a process whose real and effective UIDs are zero *execve*(2)s a program, the calculation of the process's new permitted capabilities simplifies to:

```
P'(permitted)   = P(inheritable) | P(bounding)

P'(effective)   = P'(permitted)
```

Consequently, the process gains all capabilities in its permitted and effective capability sets, except those masked out by the capability bounding set. (In the calculation of P'(permitted), the P'(ambient) term can be simplified away because it is by definition a proper subset of P(inheritable).)

The special treatments of user ID 0 (root) described in this subsection can be disabled using the

securebits mechanism described below.

Set-user-ID-root programs that have file capabilities

There is one exception to the behavior described in *Capabilities and execution of programs by root* above. If (a) the binary that is being executed has capabilities attached and (b) the real user ID of the process is *not* 0 (root) and (c) the effective user ID of the process *is* 0 (root), then the file capability bits are honored (i.e., they are not notionally considered to be all ones). The usual way in which this situation can arise is when executing a set-UID-root program that also has file capabilities. When such a program is executed, the process gains just the capabilities granted by the program (i.e., not all capabilities, as would occur when executing a set-user-ID-root program that does not have any associated file capabilities).

Note that one can assign empty capability sets to a program file, and thus it is possible to create a set-user-ID-root program that changes the effective and saved set-user-ID of the process that executes the program to 0, but confers no capabilities to that process.

Capability bounding set

The capability bounding set is a security mechanism that can be used to limit the capabilities that can be gained during an *execve*(2). The bounding set is used in the following ways:

- During an *execve*(2), the capability bounding set is ANDed with the file permitted capability set, and the result of this operation is assigned to the thread's permitted capability set. The capability bounding set thus places a limit on the permitted capabilities that may be granted by an executable file.
- (Since Linux 2.6.25) The capability bounding set acts as a limiting superset for the capabilities that a thread can add to its inheritable set using *capset*(2). This means that if a capability is not in the bounding set, then a thread can't add this capability to its inheritable set, even if it was in its permitted capabilities, and thereby cannot have this capability preserved in its permitted set when it *execve*(2)s a file that has the capability in its inheritable set.

Note that the bounding set masks the file permitted capabilities, but not the inheritable capabilities. If a thread maintains a capability in its inheritable set that is not in its bounding set, then it can still gain that capability in its permitted set by executing a file that has the capability in its inheritable set.

Depending on the kernel version, the capability bounding set is either a system-wide attribute, or a per-process attribute.

Capability bounding set from Linux 2.6.25 onward

From Linux 2.6.25, the *capability bounding set* is a per-thread attribute. (The system-wide capability bounding set described below no longer exists.)

The bounding set is inherited at *fork*(2) from the thread's parent, and is preserved across an *execve*(2).

A thread may remove capabilities from its capability bounding set using the *prctl*(2) **PR_CAPBSET_DROP** operation, provided it has the **CAP_SETPCAP** capability. Once a capability has been dropped from the bounding set, it cannot be restored to that set. A thread can determine if a capability is in its bounding set using the *prctl*(2) **PR_CAPBSET_READ** operation.

Removing capabilities from the bounding set is supported only if file capabilities are compiled into the kernel. Before Linux 2.6.33, file capabilities were an optional feature configurable via the **CONFIG_SECURITY_FILE_CAPABILITIES** option. Since Linux 2.6.33, the configuration option has been removed and file capabilities are always part of the kernel. When file capabilities are compiled into the kernel, the **init** process (the ancestor of all processes) begins with a full bounding set. If file capabilities are not compiled into the kernel, then **init** begins with a full bounding set minus **CAP_SETPCAP**, because this capability has a different meaning when there are no file capabilities.

Removing a capability from the bounding set does not remove it from the thread's inheritable set. However it does prevent the capability from being added back into the thread's inheritable set in the future.

Capability bounding set prior to Linux 2.6.25

Before Linux 2.6.25, the capability bounding set is a system-wide attribute that affects all threads on the system. The bounding set is accessible via the file */proc/sys/kernel/cap−bound*. (Confusingly, this bit mask parameter is expressed as a signed decimal number in */proc/sys/kernel/cap−bound*.)

Only the **init** process may set capabilities in the capability bounding set; other than that, the superuser (more precisely: a process with the **CAP_SYS_MODULE** capability) may only clear capabilities from this set.

On a standard system the capability bounding set always masks out the **CAP_SETPCAP** capability. To remove this restriction (dangerous!), modify the definition of **CAP_INIT_EFF_SET** in *include/linux/capability.h* and rebuild the kernel.

The system-wide capability bounding set feature was added to Linux 2.2.11.

Effect of user ID changes on capabilities

To preserve the traditional semantics for transitions between 0 and nonzero user IDs, the kernel makes the following changes to a thread's capability sets on changes to the thread's real, effective, saved set, and filesystem user IDs (using *setuid*(2), *setresuid*(2), or similar):

- If one or more of the real, effective, or saved set user IDs was previously 0, and as a result of the UID changes all of these IDs have a nonzero value, then all capabilities are cleared from the permitted, effective, and ambient capability sets.
- If the effective user ID is changed from 0 to nonzero, then all capabilities are cleared from the effective set.
- If the effective user ID is changed from nonzero to 0, then the permitted set is copied to the effective set.
- If the filesystem user ID is changed from 0 to nonzero (see *setfsuid*(2)), then the following capabilities are cleared from the effective set: **CAP_CHOWN**, **CAP_DAC_OVERRIDE**, **CAP_DAC_READ_SEARCH**, **CAP_FOWNER**, **CAP_FSETID**, **CAP_LINUX_IMMUTABLE** (since Linux 2.6.30), **CAP_MAC_OVERRIDE**, and **CAP_MKNOD** (since Linux 2.6.30). If the filesystem UID is changed from nonzero to 0, then any of these capabilities that are enabled in the permitted set are enabled in the effective set.

If a thread that has a 0 value for one or more of its user IDs wants to prevent its permitted capability set being cleared when it resets all of its user IDs to nonzero values, it can do so using the **SECBIT_KEEP_CAPS** securebits flag described below.

Programmatically adjusting capability sets

A thread can retrieve and change its permitted, effective, and inheritable capability sets using the *capget*(2) and *capset*(2) system calls. However, the use of *cap_get_proc*(3) and *cap_set_proc*(3), both provided in the *libcap* package, is preferred for this purpose. The following rules govern changes to the thread capability sets:

- If the caller does not have the **CAP_SETPCAP** capability, the new inheritable set must be a subset of the combination of the existing inheritable and permitted sets.
- (Since Linux 2.6.25) The new inheritable set must be a subset of the combination of the existing inheritable set and the capability bounding set.
- The new permitted set must be a subset of the existing permitted set (i.e., it is not possible to acquire permitted capabilities that the thread does not currently have).
- The new effective set must be a subset of the new permitted set.

The securebits flags: establishing a capabilities-only environment

Starting with Linux 2.6.26, and with a kernel in which file capabilities are enabled, Linux implements a set of per-thread *securebits* flags that can be used to disable special handling of capabilities for UID 0 (*root*). These flags are as follows:

SECBIT_KEEP_CAPS

Setting this flag allows a thread that has one or more 0 UIDs to retain capabilities in its permitted set when it switches all of its UIDs to nonzero values. If this flag is not set, then such a UID switch causes the thread to lose all permitted capabilities. This flag is always cleared on an *execve*(2).

Note that even with the **SECBIT_KEEP_CAPS** flag set, the effective capabilities of a thread are cleared when it switches its effective UID to a nonzero value. However, if the thread has set this flag and its effective UID is already nonzero, and the thread subsequently switches all other UIDs to nonzero values, then the effective capabilities will not be cleared.

The setting of the **SECBIT_KEEP_CAPS** flag is ignored if the **SECBIT_NO_SETUID_FIXUP** flag is set. (The latter flag provides a superset of the effect of the former flag.)

This flag provides the same functionality as the older *prctl*(2) **PR_SET_KEEPCAPS** operation.

SECBIT_NO_SETUID_FIXUP
Setting this flag stops the kernel from adjusting the process's permitted, effective, and ambient capability sets when the thread's effective and filesystem UIDs are switched between zero and nonzero values. See *Effect of user ID changes on capabilities* above.

SECBIT_NOROOT
If this bit is set, then the kernel does not grant capabilities when a set-user-ID-root program is executed, or when a process with an effective or real UID of 0 calls *execve*(2). (See *Capabilities and execution of programs by root* above.)

SECBIT_NO_CAP_AMBIENT_RAISE
Setting this flag disallows raising ambient capabilities via the *prctl*(2) **PR_CAP_AMBIENT_RAISE** operation.

Each of the above "base" flags has a companion "locked" flag. Setting any of the "locked" flags is irreversible, and has the effect of preventing further changes to the corresponding "base" flag. The locked flags are: **SECBIT_KEEP_CAPS_LOCKED**, **SECBIT_NO_SETUID_FIXUP_LOCKED**, **SECBIT_NOROOT_LOCKED**, and **SECBIT_NO_CAP_AMBIENT_RAISE_LOCKED**.

The *securebits* flags can be modified and retrieved using the *prctl*(2) **PR_SET_SECUREBITS** and **PR_GET_SECUREBITS** operations. The **CAP_SETPCAP** capability is required to modify the flags. Note that the **SECBIT_*** constants are available only after including the <*linux/securebits.h*> header file.

The *securebits* flags are inherited by child processes. During an *execve*(2), all of the flags are preserved, except **SECBIT_KEEP_CAPS** which is always cleared.

An application can use the following call to lock itself, and all of its descendants, into an environment where the only way of gaining capabilities is by executing a program with associated file capabilities:

```
prctl(PR_SET_SECUREBITS,
        /* SECBIT_KEEP_CAPS off */
        SECBIT_KEEP_CAPS_LOCKED |
        SECBIT_NO_SETUID_FIXUP |
        SECBIT_NO_SETUID_FIXUP_LOCKED |
        SECBIT_NOROOT |
        SECBIT_NOROOT_LOCKED);
        /* Setting/locking SECBIT_NO_CAP_AMBIENT_RAISE
           is not required */
```

Per-user-namespace "set-user-ID-root" programs
A set-user-ID program whose UID matches the UID that created a user namespace will confer capabilities in the process's permitted and effective sets when executed by any process inside that namespace or any descendant user namespace.

The rules about the transformation of the process's capabilities during the *execve*(2) are exactly as described in *Transformation of capabilities during execve()* and *Capabilities and execution of programs by root* above, with the difference that, in the latter subsection, "root" is the UID of the creator of the user namespace.

Namespaced file capabilities
Traditional (i.e., version 2) file capabilities associate only a set of capability masks with a binary executable file. When a process executes a binary with such capabilities, it gains the associated capabilities (within its user namespace) as per the rules described in *Transformation of capabilities during execve()* above.

Because version 2 file capabilities confer capabilities to the executing process regardless of which user namespace it resides in, only privileged processes are permitted to associate capabilities with a file. Here, "privileged" means a process that has the **CAP_SETFCAP** capability in the user namespace where the filesystem was mounted (normally the initial user namespace). This limitation renders file

capabilities useless for certain use cases. For example, in user-namespaced containers, it can be desirable to be able to create a binary that confers capabilities only to processes executed inside that container, but not to processes that are executed outside the container.

Linux 4.14 added so-called namespaced file capabilities to support such use cases. Namespaced file capabilities are recorded as version 3 (i.e., **VFS_CAP_REVISION_3**) *security.capability* extended attributes. Such an attribute is automatically created in the circumstances described in *File capability extended attribute versioning* above. When a version 3 *security.capability* extended attribute is created, the kernel records not just the capability masks in the extended attribute, but also the namespace root user ID.

As with a binary that has **VFS_CAP_REVISION_2** file capabilities, a binary with **VFS_CAP_REVISION_3** file capabilities confers capabilities to a process during **execve**(). However, capabilities are conferred only if the binary is executed by a process that resides in a user namespace whose UID 0 maps to the root user ID that is saved in the extended attribute, or when executed by a process that resides in a descendant of such a namespace.

Interaction with user namespaces

For further information on the interaction of capabilities and user namespaces, see *user_namespaces*(7).

STANDARDS

No standards govern capabilities, but the Linux capability implementation is based on the withdrawn POSIX.1e draft standard.

NOTES

When attempting to *strace*(1) binaries that have capabilities (or set-user-ID-root binaries), you may find the *−u <username>* option useful. Something like:

```
$ sudo strace -o trace.log -u ceci ./myprivprog
```

From Linux 2.5.27 to Linux 2.6.26, capabilities were an optional kernel component, and could be enabled/disabled via the **CONFIG_SECURITY_CAPABILITIES** kernel configuration option.

The */proc/*pid*/task/TID/status* file can be used to view the capability sets of a thread. The */proc/*pid*/status* file shows the capability sets of a process's main thread. Before Linux 3.8, nonexistent capabilities were shown as being enabled (1) in these sets. Since Linux 3.8, all nonexistent capabilities (above **CAP_LAST_CAP**) are shown as disabled (0).

The *libcap* package provides a suite of routines for setting and getting capabilities that is more comfortable and less likely to change than the interface provided by *capset*(2) and *capget*(2). This package also provides the *setcap*(8) and *getcap*(8) programs. It can be found at

.

Before Linux 2.6.24, and from Linux 2.6.24 to Linux 2.6.32 if file capabilities are not enabled, a thread with the **CAP_SETPCAP** capability can manipulate the capabilities of threads other than itself. However, this is only theoretically possible, since no thread ever has **CAP_SETPCAP** in either of these cases:

- In the pre-2.6.25 implementation the system-wide capability bounding set, */proc/sys/kernel/cap−bound*, always masks out the **CAP_SETPCAP** capability, and this can not be changed without modifying the kernel source and rebuilding the kernel.
- If file capabilities are disabled (i.e., the kernel **CONFIG_SECURITY_FILE_CAPABILITIES** option is disabled), then **init** starts out with the **CAP_SETPCAP** capability removed from its per-process bounding set, and that bounding set is inherited by all other processes created on the system.

include/linux/capability.h in the Linux kernel source tree

NAME

cgroup_namespaces − overview of Linux cgroup namespaces

DESCRIPTION

For an overview of namespaces, see *namespaces*(7).

Cgroup namespaces virtualize the view of a process's cgroups (see *cgroups*(7)) as seen via */proc/*pid*/cgroup* and */proc/*pid*/mountinfo*.

Each cgroup namespace has its own set of cgroup root directories. These root directories are the base points for the relative locations displayed in the corresponding records in the */proc/*pid*/cgroup* file. When a process creates a new cgroup namespace using *clone*(2) or *unshare*(2) with the **CLONE_NEWCGROUP** flag, its current cgroups directories become the cgroup root directories of the new namespace. (This applies both for the cgroups version 1 hierarchies and the cgroups version 2 unified hierarchy.)

When reading the cgroup memberships of a "target" process from */proc/*pid*/cgroup*, the pathname shown in the third field of each record will be relative to the reading process's root directory for the corresponding cgroup hierarchy. If the cgroup directory of the target process lies outside the root directory of the reading process's cgroup namespace, then the pathname will show ../ entries for each ancestor level in the cgroup hierarchy.

The following shell session demonstrates the effect of creating a new cgroup namespace.

First, (as superuser) in a shell in the initial cgroup namespace, we create a child cgroup in the *freezer* hierarchy, and place a process in that cgroup that we will use as part of the demonstration below:

```
# mkdir -p /sys/fs/cgroup/freezer/sub2
# sleep 10000 &     # Create a process that lives for a while
[1] 20124
# echo 20124 > /sys/fs/cgroup/freezer/sub2/cgroup.procs
```

We then create another child cgroup in the *freezer* hierarchy and put the shell into that cgroup:

```
# mkdir -p /sys/fs/cgroup/freezer/sub
# echo $$                     # Show PID of this shell
30655
# echo 30655 > /sys/fs/cgroup/freezer/sub/cgroup.procs
# cat /proc/self/cgroup | grep freezer
7:freezer:/sub
```

Next, we use *unshare*(1) to create a process running a new shell in new cgroup and mount namespaces:

```
# PS1="sh2# " unshare -Cm bash
```

From the new shell started by *unshare*(1), we then inspect the */proc/*pid*/cgroup* files of, respectively, the new shell, a process that is in the initial cgroup namespace (*init*, with PID 1), and the process in the sibling cgroup (*sub2*):

```
sh2# cat /proc/self/cgroup | grep freezer
7:freezer:/
sh2# cat /proc/1/cgroup | grep freezer
7:freezer:/..
sh2# cat /proc/20124/cgroup | grep freezer
7:freezer:/../sub2
```

From the output of the first command, we see that the freezer cgroup membership of the new shell (which is in the same cgroup as the initial shell) is shown defined relative to the freezer cgroup root directory that was established when the new cgroup namespace was created. (In absolute terms, the new shell is in the */sub* freezer cgroup, and the root directory of the freezer cgroup hierarchy in the new cgroup namespace is also */sub*. Thus, the new shell's cgroup membership is displayed as '/'.)

However, when we look in */proc/self/mountinfo* we see the following anomaly:

```
sh2# cat /proc/self/mountinfo | grep freezer
155 145 0:32 /.. /sys/fs/cgroup/freezer ...
```

The fourth field of this line (/..) should show the directory in the cgroup filesystem which forms the root of this mount. Since by the definition of cgroup namespaces, the process's current freezer cgroup

directory became its root freezer cgroup directory, we should see '/' in this field. The problem here is that we are seeing a mount entry for the cgroup filesystem corresponding to the initial cgroup namespace (whose cgroup filesystem is indeed rooted at the parent directory of *sub*). To fix this problem, we must remount the freezer cgroup filesystem from the new shell (i.e., perform the mount from a process that is in the new cgroup namespace), after which we see the expected results:

```
sh2# mount --make-rslave /     # Don't propagate mount events
                               # to other namespaces
sh2# umount /sys/fs/cgroup/freezer
sh2# mount -t cgroup -o freezer freezer /sys/fs/cgroup/freezer
sh2# cat /proc/self/mountinfo | grep freezer
155 145 0:32 / /sys/fs/cgroup/freezer rw,relatime ...
```

STANDARDS

Linux.

NOTES

Use of cgroup namespaces requires a kernel that is configured with the **CONFIG_CGROUPS** option.

The virtualization provided by cgroup namespaces serves a number of purposes:

- It prevents information leaks whereby cgroup directory paths outside of a container would otherwise be visible to processes in the container. Such leakages could, for example, reveal information about the container framework to containerized applications.
- It eases tasks such as container migration. The virtualization provided by cgroup namespaces allows containers to be isolated from knowledge of the pathnames of ancestor cgroups. Without such isolation, the full cgroup pathnames (displayed in */proc/self/cgroups*) would need to be replicated on the target system when migrating a container; those pathnames would also need to be unique, so that they don't conflict with other pathnames on the target system.
- It allows better confinement of containerized processes, because it is possible to mount the container's cgroup filesystems such that the container processes can't gain access to ancestor cgroup directories. Consider, for example, the following scenario:
  - We have a cgroup directory, */cg/1*, that is owned by user ID 9000.
  - We have a process, *X*, also owned by user ID 9000, that is namespaced under the cgroup */cg/1/2* (i.e., *X* was placed in a new cgroup namespace via *clone*(2) or *unshare*(2) with the **CLONE_NEWCGROUP** flag).

  In the absence of cgroup namespacing, because the cgroup directory */cg/1* is owned (and writable) by UID 9000 and process *X* is also owned by user ID 9000, process *X* would be able to modify the contents of cgroups files (i.e., change cgroup settings) not only in */cg/1/2* but also in the ancestor cgroup directory */cg/1*. Namespacing process *X* under the cgroup directory */cg/1/2*, in combination with suitable mount operations for the cgroup filesystem (as shown above), prevents it modifying files in */cg/1*, since it cannot even see the contents of that directory (or of further removed cgroup ancestor directories). Combined with correct enforcement of hierarchical limits, this prevents process *X* from escaping the limits imposed by ancestor cgroups.

NAME

cgroups − Linux control groups

DESCRIPTION

Control groups, usually referred to as cgroups, are a Linux kernel feature which allow processes to be organized into hierarchical groups whose usage of various types of resources can then be limited and monitored. The kernel's cgroup interface is provided through a pseudo-filesystem called cgroupfs. Grouping is implemented in the core cgroup kernel code, while resource tracking and limits are implemented in a set of per-resource-type subsystems (memory, CPU, and so on).

Terminology

A *cgroup* is a collection of processes that are bound to a set of limits or parameters defined via the cgroup filesystem.

A *subsystem* is a kernel component that modifies the behavior of the processes in a cgroup. Various subsystems have been implemented, making it possible to do things such as limiting the amount of CPU time and memory available to a cgroup, accounting for the CPU time used by a cgroup, and freezing and resuming execution of the processes in a cgroup. Subsystems are sometimes also known as *resource controllers* (or simply, controllers).

The cgroups for a controller are arranged in a *hierarchy*. This hierarchy is defined by creating, removing, and renaming subdirectories within the cgroup filesystem. At each level of the hierarchy, attributes (e.g., limits) can be defined. The limits, control, and accounting provided by cgroups generally have effect throughout the subhierarchy underneath the cgroup where the attributes are defined. Thus, for example, the limits placed on a cgroup at a higher level in the hierarchy cannot be exceeded by descendant cgroups.

Cgroups version 1 and version 2

The initial release of the cgroups implementation was in Linux 2.6.24. Over time, various cgroup controllers have been added to allow the management of various types of resources. However, the development of these controllers was largely uncoordinated, with the result that many inconsistencies arose between controllers and management of the cgroup hierarchies became rather complex. A longer description of these problems can be found in the kernel source file *Documentation/admin−guide/cgroup−v2.rst* (or *Documentation/cgroup−v2.txt* in Linux 4.17 and earlier).

Because of the problems with the initial cgroups implementation (cgroups version 1), starting in Linux 3.10, work began on a new, orthogonal implementation to remedy these problems. Initially marked experimental, and hidden behind the *−o __DEVEL__sane_behavior* mount option, the new version (cgroups version 2) was eventually made official with the release of Linux 4.5. Differences between the two versions are described in the text below. The file *cgroup.sane_behavior*, present in cgroups v1, is a relic of this mount option. The file always reports "0" and is only retained for backward compatibility.

Although cgroups v2 is intended as a replacement for cgroups v1, the older system continues to exist (and for compatibility reasons is unlikely to be removed). Currently, cgroups v2 implements only a subset of the controllers available in cgroups v1. The two systems are implemented so that both v1 controllers and v2 controllers can be mounted on the same system. Thus, for example, it is possible to use those controllers that are supported under version 2, while also using version 1 controllers where version 2 does not yet support those controllers. The only restriction here is that a controller can't be simultaneously employed in both a cgroups v1 hierarchy and in the cgroups v2 hierarchy.

CGROUPS VERSION 1

Under cgroups v1, each controller may be mounted against a separate cgroup filesystem that provides its own hierarchical organization of the processes on the system. It is also possible to comount multiple (or even all) cgroups v1 controllers against the same cgroup filesystem, meaning that the comounted controllers manage the same hierarchical organization of processes.

For each mounted hierarchy, the directory tree mirrors the control group hierarchy. Each control group is represented by a directory, with each of its child control cgroups represented as a child directory. For instance, */user/joe/1.session* represents control group *1.session*, which is a child of cgroup *joe*, which is a child of */user*. Under each cgroup directory is a set of files which can be read or written to, reflecting resource limits and a few general cgroup properties.

Tasks (threads) versus processes

In cgroups v1, a distinction is drawn between *processes* and *tasks*. In this view, a process can consist of multiple tasks (more commonly called threads, from a user-space perspective, and called such in the remainder of this man page). In cgroups v1, it is possible to independently manipulate the cgroup memberships of the threads in a process.

The cgroups v1 ability to split threads across different cgroups caused problems in some cases. For example, it made no sense for the *memory* controller, since all of the threads of a process share a single address space. Because of these problems, the ability to independently manipulate the cgroup memberships of the threads in a process was removed in the initial cgroups v2 implementation, and subsequently restored in a more limited form (see the discussion of "thread mode" below).

Mounting v1 controllers

The use of cgroups requires a kernel built with the **CONFIG_CGROUP** option. In addition, each of the v1 controllers has an associated configuration option that must be set in order to employ that controller.

In order to use a v1 controller, it must be mounted against a cgroup filesystem. The usual place for such mounts is under a *tmpfs*(5) filesystem mounted at */sys/fs/cgroup*. Thus, one might mount the *cpu* controller as follows:

```
mount -t cgroup -o cpu none /sys/fs/cgroup/cpu
```

It is possible to comount multiple controllers against the same hierarchy. For example, here the *cpu* and *cpuacct* controllers are comounted against a single hierarchy:

```
mount -t cgroup -o cpu,cpuacct none /sys/fs/cgroup/cpu,cpuacct
```

Comounting controllers has the effect that a process is in the same cgroup for all of the comounted controllers. Separately mounting controllers allows a process to be in cgroup */foo1* for one controller while being in */foo2/foo3* for another.

It is possible to comount all v1 controllers against the same hierarchy:

```
mount -t cgroup -o all cgroup /sys/fs/cgroup
```

(One can achieve the same result by omitting *-o all*, since it is the default if no controllers are explicitly specified.)

It is not possible to mount the same controller against multiple cgroup hierarchies. For example, it is not possible to mount both the *cpu* and *cpuacct* controllers against one hierarchy, and to mount the *cpu* controller alone against another hierarchy. It is possible to create multiple mount with exactly the same set of comounted controllers. However, in this case all that results is multiple mount points providing a view of the same hierarchy.

Note that on many systems, the v1 controllers are automatically mounted under */sys/fs/cgroup*; in particular, *systemd*(1) automatically creates such mounts.

Unmounting v1 controllers

A mounted cgroup filesystem can be unmounted using the *umount*(8) command, as in the following example:

```
umount /sys/fs/cgroup/pids
```

But note well: a cgroup filesystem is unmounted only if it is not busy, that is, it has no child cgroups. If this is not the case, then the only effect of the *umount*(8) is to make the mount invisible. Thus, to ensure that the mount is really removed, one must first remove all child cgroups, which in turn can be done only after all member processes have been moved from those cgroups to the root cgroup.

Cgroups version 1 controllers

Each of the cgroups version 1 controllers is governed by a kernel configuration option (listed below). Additionally, the availability of the cgroups feature is governed by the **CONFIG_CGROUPS** kernel configuration option.

cpu (since Linux 2.6.24; **CONFIG_CGROUP_SCHED**)

Cgroups can be guaranteed a minimum number of "CPU shares" when a system is busy. This does not limit a cgroup's CPU usage if the CPUs are not busy. For further information, see *Documentation/scheduler/sched-design-CFS.rst* (or *Documentation/scheduler/sched-design-CFS.txt* in Linux 5.2 and earlier).

In Linux 3.2, this controller was extended to provide CPU "bandwidth" control. If the kernel is configured with **CONFIG_CFS_BANDWIDTH**, then within each scheduling period (defined via a file in the cgroup directory), it is possible to define an upper limit on the CPU time allocated to the processes in a cgroup. This upper limit applies even if there is no other competition for the CPU. Further information can be found in the kernel source file *Documentation/scheduler/sched−bwc.rst* (or *Documentation/scheduler/sched−bwc.txt* in Linux 5.2 and earlier).

cpuacct (since Linux 2.6.24; **CONFIG_CGROUP_CPUACCT**)
This provides accounting for CPU usage by groups of processes.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/cpuacct.rst* (or *Documentation/cgroup−v1/cpuacct.txt* in Linux 5.2 and earlier).

cpuset (since Linux 2.6.24; **CONFIG_CPUSETS**)
This cgroup can be used to bind the processes in a cgroup to a specified set of CPUs and NUMA nodes.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/cpusets.rst* (or *Documentation/cgroup−v1/cpusets.txt* in Linux 5.2 and earlier).

memory (since Linux 2.6.25; **CONFIG_MEMCG**)
The memory controller supports reporting and limiting of process memory, kernel memory, and swap used by cgroups.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/memory.rst* (or *Documentation/cgroup−v1/memory.txt* in Linux 5.2 and earlier).

devices (since Linux 2.6.26; **CONFIG_CGROUP_DEVICE**)
This supports controlling which processes may create (mknod) devices as well as open them for reading or writing. The policies may be specified as allow-lists and deny-lists. Hierarchy is enforced, so new rules must not violate existing rules for the target or ancestor cgroups.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/devices.rst* (or *Documentation/cgroup−v1/devices.txt* in Linux 5.2 and earlier).

freezer (since Linux 2.6.28; **CONFIG_CGROUP_FREEZER**)
The *freezer* cgroup can suspend and restore (resume) all processes in a cgroup. Freezing a cgroup */A* also causes its children, for example, processes in */A/B*, to be frozen.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/freezer−subsystem.rst* (or *Documentation/cgroup−v1/freezer−subsystem.txt* in Linux 5.2 and earlier).

net_cls (since Linux 2.6.29; **CONFIG_CGROUP_NET_CLASSID**)
This places a classid, specified for the cgroup, on network packets created by a cgroup. These classids can then be used in firewall rules, as well as used to shape traffic using *tc*(8)This applies only to packets leaving the cgroup, not to traffic arriving at the cgroup.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/net_cls.rst* (or *Documentation/cgroup−v1/net_cls.txt* in Linux 5.2 and earlier).

blkio (since Linux 2.6.33; **CONFIG_BLK_CGROUP**)
The *blkio* cgroup controls and limits access to specified block devices by applying IO control in the form of throttling and upper limits against leaf nodes and intermediate nodes in the storage hierarchy.

Two policies are available. The first is a proportional-weight time-based division of disk implemented with CFQ. This is in effect for leaf nodes using CFQ. The second is a throttling policy which specifies upper I/O rate limits on a device.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/blkio−controller.rst* (or

Documentation/cgroup−v1/blkio−controller.txt in Linux 5.2 and earlier).

perf_event (since Linux 2.6.39; **CONFIG_CGROUP_PERF**)
This controller allows *perf* monitoring of the set of processes grouped in a cgroup.

Further information can be found in the kernel source files

net_prio (since Linux 3.3; **CONFIG_CGROUP_NET_PRIO**)
This allows priorities to be specified, per network interface, for cgroups.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/net_prio.rst* (or *Documentation/cgroup−v1/net_prio.txt* in Linux 5.2 and earlier).

hugetlb (since Linux 3.5; **CONFIG_CGROUP_HUGETLB**)
This supports limiting the use of huge pages by cgroups.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/hugetlb.rst* (or *Documentation/cgroup−v1/hugetlb.txt* in Linux 5.2 and earlier).

pids (since Linux 4.3; **CONFIG_CGROUP_PIDS**)
This controller permits limiting the number of process that may be created in a cgroup (and its descendants).

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/pids.rst* (or *Documentation/cgroup−v1/pids.txt* in Linux 5.2 and earlier).

rdma (since Linux 4.11; **CONFIG_CGROUP_RDMA**)
The RDMA controller permits limiting the use of RDMA/IB-specific resources per cgroup.

Further information can be found in the kernel source file *Documentation/admin−guide/cgroup−v1/rdma.rst* (or *Documentation/cgroup−v1/rdma.txt* in Linux 5.2 and earlier).

Creating cgroups and moving processes

A cgroup filesystem initially contains a single root cgroup, '/', which all processes belong to. A new cgroup is created by creating a directory in the cgroup filesystem:

```
mkdir /sys/fs/cgroup/cpu/cg1
```

This creates a new empty cgroup.

A process may be moved to this cgroup by writing its PID into the cgroup's *cgroup.procs* file:

```
echo $$ > /sys/fs/cgroup/cpu/cg1/cgroup.procs
```

Only one PID at a time should be written to this file.

Writing the value 0 to a *cgroup.procs* file causes the writing process to be moved to the corresponding cgroup.

When writing a PID into the *cgroup.procs*, all threads in the process are moved into the new cgroup at once.

Within a hierarchy, a process can be a member of exactly one cgroup. Writing a process's PID to a *cgroup.procs* file automatically removes it from the cgroup of which it was previously a member.

The *cgroup.procs* file can be read to obtain a list of the processes that are members of a cgroup. The returned list of PIDs is not guaranteed to be in order. Nor is it guaranteed to be free of duplicates. (For example, a PID may be recycled while reading from the list.)

In cgroups v1, an individual thread can be moved to another cgroup by writing its thread ID (i.e., the kernel thread ID returned by *clone*(2) and *gettid*(2)) to the *tasks* file in a cgroup directory. This file can be read to discover the set of threads that are members of the cgroup.

Removing cgroups

To remove a cgroup, it must first have no child cgroups and contain no (nonzombie) processes. So long as that is the case, one can simply remove the corresponding directory pathname. Note that files in a cgroup directory cannot and need not be removed.

Cgroups v1 release notification

Two files can be used to determine whether the kernel provides notifications when a cgroup becomes empty. A cgroup is considered to be empty when it contains no child cgroups and no member processes.

A special file in the root directory of each cgroup hierarchy, *release_agent*, can be used to register the pathname of a program that may be invoked when a cgroup in the hierarchy becomes empty. The pathname of the newly empty cgroup (relative to the cgroup mount point) is provided as the sole command-line argument when the *release_agent* program is invoked. The *release_agent* program might remove the cgroup directory, or perhaps repopulate it with a process.

The default value of the *release_agent* file is empty, meaning that no release agent is invoked.

The content of the *release_agent* file can also be specified via a mount option when the cgroup filesystem is mounted:

```
mount -o release_agent=pathname ...
```

Whether or not the *release_agent* program is invoked when a particular cgroup becomes empty is determined by the value in the *notify_on_release* file in the corresponding cgroup directory. If this file contains the value 0, then the *release_agent* program is not invoked. If it contains the value 1, the *release_agent* program is invoked. The default value for this file in the root cgroup is 0. At the time when a new cgroup is created, the value in this file is inherited from the corresponding file in the parent cgroup.

Cgroup v1 named hierarchies

In cgroups v1, it is possible to mount a cgroup hierarchy that has no attached controllers:

```
mount -t cgroup -o none,name=somename none /some/mount/point
```

Multiple instances of such hierarchies can be mounted; each hierarchy must have a unique name. The only purpose of such hierarchies is to track processes. (See the discussion of release notification below.) An example of this is the *name=systemd* cgroup hierarchy that is used by *systemd*(1) to track services and user sessions.

Since Linux 5.0, the *cgroup_no_v1* kernel boot option (described below) can be used to disable cgroup v1 named hierarchies, by specifying *cgroup_no_v1=named*.

CGROUPS VERSION 2

In cgroups v2, all mounted controllers reside in a single unified hierarchy. While (different) controllers may be simultaneously mounted under the v1 and v2 hierarchies, it is not possible to mount the same controller simultaneously under both the v1 and the v2 hierarchies.

The new behaviors in cgroups v2 are summarized here, and in some cases elaborated in the following subsections.

- Cgroups v2 provides a unified hierarchy against which all controllers are mounted.
- "Internal" processes are not permitted. With the exception of the root cgroup, processes may reside only in leaf nodes (cgroups that do not themselves contain child cgroups). The details are somewhat more subtle than this, and are described below.
- Active cgroups must be specified via the files *cgroup.controllers* and *cgroup.subtree_control*.
- The *tasks* file has been removed. In addition, the *cgroup.clone_children* file that is employed by the *cpuset* controller has been removed.
- An improved mechanism for notification of empty cgroups is provided by the *cgroup.events* file.

For more changes, see the *Documentation/admin-guide/cgroup-v2.rst* file in the kernel source (or *Documentation/cgroup-v2.txt* in Linux 4.17 and earlier).

Some of the new behaviors listed above saw subsequent modification with the addition in Linux 4.14 of "thread mode" (described below).

Cgroups v2 unified hierarchy

In cgroups v1, the ability to mount different controllers against different hierarchies was intended to allow great flexibility for application design. In practice, though, the flexibility turned out to be less useful than expected, and in many cases added complexity. Therefore, in cgroups v2, all available controllers are mounted against a single hierarchy. The available controllers are automatically mounted,

meaning that it is not necessary (or possible) to specify the controllers when mounting the cgroup v2 filesystem using a command such as the following:

```
mount -t cgroup2 none /mnt/cgroup2
```

A cgroup v2 controller is available only if it is not currently in use via a mount against a cgroup v1 hierarchy. Or, to put things another way, it is not possible to employ the same controller against both a v1 hierarchy and the unified v2 hierarchy. This means that it may be necessary first to unmount a v1 controller (as described above) before that controller is available in v2. Since *systemd*(1) makes heavy use of some v1 controllers by default, it can in some cases be simpler to boot the system with selected v1 controllers disabled. To do this, specify the *cgroup_no_v1=list* option on the kernel boot command line; *list* is a comma-separated list of the names of the controllers to disable, or the word *all* to disable all v1 controllers. (This situation is correctly handled by *systemd*(1), which falls back to operating without the specified controllers.)

Note that on many modern systems, *systemd*(1) automatically mounts the *cgroup2* filesystem at */sys/fs/cgroup/unified* during the boot process.

Cgroups v2 mount options

The following options (*mount -o*) can be specified when mounting the group v2 filesystem:

nsdelegate (since Linux 4.15)
: Treat cgroup namespaces as delegation boundaries. For details, see below.

memory_localevents (since Linux 5.2)
: The *memory.events* should show statistics only for the cgroup itself, and not for any descendant cgroups. This was the behavior before Linux 5.2. Starting in Linux 5.2, the default behavior is to include statistics for descendant cgroups in *memory.events*, and this mount option can be used to revert to the legacy behavior. This option is system wide and can be set on mount or modified through remount only from the initial mount namespace; it is silently ignored in noninitial namespaces.

Cgroups v2 controllers

The following controllers, documented in the kernel source file *Documentation/admin-guide/cgroup-v2.rst* (or *Documentation/cgroup-v2.txt* in Linux 4.17 and earlier), are supported in cgroups version 2:

cpu (since Linux 4.15)
: This is the successor to the version 1 *cpu* and *cpuacct* controllers.

cpuset (since Linux 5.0)
: This is the successor of the version 1 *cpuset* controller.

freezer (since Linux 5.2)
: This is the successor of the version 1 *freezer* controller.

hugetlb (since Linux 5.6)
: This is the successor of the version 1 *hugetlb* controller.

io (since Linux 4.5)
: This is the successor of the version 1 *blkio* controller.

memory (since Linux 4.5)
: This is the successor of the version 1 *memory* controller.

perf_event (since Linux 4.11)
: This is the same as the version 1 *perf_event* controller.

pids (since Linux 4.5)
: This is the same as the version 1 *pids* controller.

rdma (since Linux 4.11)
: This is the same as the version 1 *rdma* controller.

There is no direct equivalent of the *net_cls* and *net_prio* controllers from cgroups version 1. Instead, support has been added to *iptables*(8) to allow eBPF filters that hook on cgroup v2 pathnames to make decisions about network traffic on a per-cgroup basis.

The v2 *devices* controller provides no interface files; instead, device control is gated by attaching an

eBPF (**BPF_CGROUP_DEVICE**) program to a v2 cgroup.

Cgroups v2 subtree control

Each cgroup in the v2 hierarchy contains the following two files:

cgroup.controllers

This read-only file exposes a list of the controllers that are *available* in this cgroup. The contents of this file match the contents of the *cgroup.subtree_control* file in the parent cgroup.

cgroup.subtree_control

This is a list of controllers that are *active* (*enabled*) in the cgroup. The set of controllers in this file is a subset of the set in the *cgroup.controllers* of this cgroup. The set of active controllers is modified by writing strings to this file containing space-delimited controller names, each preceded by '+' (to enable a controller) or '−' (to disable a controller), as in the following example:

```
echo '+pids -memory' > x/y/cgroup.subtree_control
```

An attempt to enable a controller that is not present in *cgroup.controllers* leads to an **ENOENT** error when writing to the *cgroup.subtree_control* file.

Because the list of controllers in *cgroup.subtree_control* is a subset of those *cgroup.controllers*, a controller that has been disabled in one cgroup in the hierarchy can never be re-enabled in the subtree below that cgroup.

A cgroup's *cgroup.subtree_control* file determines the set of controllers that are exercised in the *child* cgroups. When a controller (e.g., *pids*) is present in the *cgroup.subtree_control* file of a parent cgroup, then the corresponding controller-interface files (e.g., *pids.max*) are automatically created in the children of that cgroup and can be used to exert resource control in the child cgroups.

Cgroups v2 "no internal processes" rule

Cgroups v2 enforces a so-called "no internal processes" rule. Roughly speaking, this rule means that, with the exception of the root cgroup, processes may reside only in leaf nodes (cgroups that do not themselves contain child cgroups). This avoids the need to decide how to partition resources between processes which are members of cgroup A and processes in child cgroups of A.

For instance, if cgroup */cg1/cg2* exists, then a process may reside in */cg1/cg2*, but not in */cg1*. This is to avoid an ambiguity in cgroups v1 with respect to the delegation of resources between processes in */cg1* and its child cgroups. The recommended approach in cgroups v2 is to create a subdirectory called *leaf* for any nonleaf cgroup which should contain processes, but no child cgroups. Thus, processes which previously would have gone into */cg1* would now go into */cg1/leaf*. This has the advantage of making explicit the relationship between processes in */cg1/leaf* and */cg1*'s other children.

The "no internal processes" rule is in fact more subtle than stated above. More precisely, the rule is that a (nonroot) cgroup can't both (1) have member processes, and (2) distribute resources into child cgroups—that is, have a nonempty *cgroup.subtree_control* file. Thus, it *is* possible for a cgroup to have both member processes and child cgroups, but before controllers can be enabled for that cgroup, the member processes must be moved out of the cgroup (e.g., perhaps into the child cgroups).

With the Linux 4.14 addition of "thread mode" (described below), the "no internal processes" rule has been relaxed in some cases.

Cgroups v2 cgroup.events file

Each nonroot cgroup in the v2 hierarchy contains a read-only file, *cgroup.events*, whose contents are key-value pairs (delimited by newline characters, with the key and value separated by spaces) providing state information about the cgroup:

```
$ cat mygrp/cgroup.events
populated 1
frozen 0
```

The following keys may appear in this file:

populated

The value of this key is either 1, if this cgroup or any of its descendants has member processes, or otherwise 0.

frozen (since Linux 5.2)
The value of this key is 1 if this cgroup is currently frozen, or 0 if it is not.

The *cgroup.events* file can be monitored, in order to receive notification when the value of one of its keys changes. Such monitoring can be done using *inotify*(7), which notifies changes as **IN_MODIFY** events, or *poll*(2), which notifies changes by returning the **POLLPRI** and **POLLERR** bits in the *revents* field.

Cgroup v2 release notification

Cgroups v2 provides a new mechanism for obtaining notification when a cgroup becomes empty. The cgroups v1 *release_agent* and *notify_on_release* files are removed, and replaced by the *populated* key in the *cgroup.events* file. This key either has the value 0, meaning that the cgroup (and its descendants) contain no (nonzombie) member processes, or 1, meaning that the cgroup (or one of its descendants) contains member processes.

The cgroups v2 release-notification mechanism offers the following advantages over the cgroups v1 *release_agent* mechanism:

- It allows for cheaper notification, since a single process can monitor multiple *cgroup.events* files (using the techniques described earlier). By contrast, the cgroups v1 mechanism requires the expense of creating a process for each notification.
- Notification for different cgroup subhierarchies can be delegated to different processes. By contrast, the cgroups v1 mechanism allows only one release agent for an entire hierarchy.

Cgroups v2 cgroup.stat file

Each cgroup in the v2 hierarchy contains a read-only *cgroup.stat* file (first introduced in Linux 4.14) that consists of lines containing key-value pairs. The following keys currently appear in this file:

nr_descendants
This is the total number of visible (i.e., living) descendant cgroups underneath this cgroup.

nr_dying_descendants
This is the total number of dying descendant cgroups underneath this cgroup. A cgroup enters the dying state after being deleted. It remains in that state for an undefined period (which will depend on system load) while resources are freed before the cgroup is destroyed. Note that the presence of some cgroups in the dying state is normal, and is not indicative of any problem.

A process can't be made a member of a dying cgroup, and a dying cgroup can't be brought back to life.

Limiting the number of descendant cgroups

Each cgroup in the v2 hierarchy contains the following files, which can be used to view and set limits on the number of descendant cgroups under that cgroup:

cgroup.max.depth (since Linux 4.14)
This file defines a limit on the depth of nesting of descendant cgroups. A value of 0 in this file means that no descendant cgroups can be created. An attempt to create a descendant whose nesting level exceeds the limit fails (*mkdir*(2) fails with the error **EAGAIN**).

Writing the string *"max"* to this file means that no limit is imposed. The default value in this file is *"max"*.

cgroup.max.descendants (since Linux 4.14)
This file defines a limit on the number of live descendant cgroups that this cgroup may have. An attempt to create more descendants than allowed by the limit fails (*mkdir*(2) fails with the error **EAGAIN**).

Writing the string *"max"* to this file means that no limit is imposed. The default value in this file is *"max"*.

CGROUPS DELEGATION: DELEGATING A HIERARCHY TO A LESS PRIVILEGED USER

In the context of cgroups, delegation means passing management of some subtree of the cgroup hierarchy to a nonprivileged user. Cgroups v1 provides support for delegation based on file permissions in the cgroup hierarchy but with less strict containment rules than v2 (as noted below). Cgroups v2 supports delegation with containment by explicit design. The focus of the discussion in this section is on

delegation in cgroups v2, with some differences for cgroups v1 noted along the way.

Some terminology is required in order to describe delegation. A *delegater* is a privileged user (i.e., root) who owns a parent cgroup. A *delegatee* is a nonprivileged user who will be granted the permissions needed to manage some subhierarchy under that parent cgroup, known as the *delegated subtree*.

To perform delegation, the delegater makes certain directories and files writable by the delegatee, typically by changing the ownership of the objects to be the user ID of the delegatee. Assuming that we want to delegate the hierarchy rooted at (say) */dlgt_grp* and that there are not yet any child cgroups under that cgroup, the ownership of the following is changed to the user ID of the delegatee:

/dlgt_grp
: Changing the ownership of the root of the subtree means that any new cgroups created under the subtree (and the files they contain) will also be owned by the delegatee.

/dlgt_grp/cgroup.procs
: Changing the ownership of this file means that the delegatee can move processes into the root of the delegated subtree.

/dlgt_grp/cgroup.subtree_control (cgroups v2 only)
: Changing the ownership of this file means that the delegatee can enable controllers (that are present in */dlgt_grp/cgroup.controllers*) in order to further redistribute resources at lower levels in the subtree. (As an alternative to changing the ownership of this file, the delegater might instead add selected controllers to this file.)

/dlgt_grp/cgroup.threads (cgroups v2 only)
: Changing the ownership of this file is necessary if a threaded subtree is being delegated (see the description of "thread mode", below). This permits the delegatee to write thread IDs to the file. (The ownership of this file can also be changed when delegating a domain subtree, but currently this serves no purpose, since, as described below, it is not possible to move a thread between domain cgroups by writing its thread ID to the *cgroup.threads* file.)

  In cgroups v1, the corresponding file that should instead be delegated is the *tasks* file.

The delegater should *not* change the ownership of any of the controller interfaces files (e.g., *pids.max*, *memory.high*) in *dlgt_grp*. Those files are used from the next level above the delegated subtree in order to distribute resources into the subtree, and the delegatee should not have permission to change the resources that are distributed into the delegated subtree.

See also the discussion of the */sys/kernel/cgroup/delegate* file in NOTES for information about further delegatable files in cgroups v2.

After the aforementioned steps have been performed, the delegatee can create child cgroups within the delegated subtree (the cgroup subdirectories and the files they contain will be owned by the delegatee) and move processes between cgroups in the subtree. If some controllers are present in *dlgt_grp/cgroup.subtree_control*, or the ownership of that file was passed to the delegatee, the delegatee can also control the further redistribution of the corresponding resources into the delegated subtree.

Cgroups v2 delegation: nsdelegate and cgroup namespaces

Starting with Linux 4.13, there is a second way to perform cgroup delegation in the cgroups v2 hierarchy. This is done by mounting or remounting the cgroup v2 filesystem with the *nsdelegate* mount option. For example, if the cgroup v2 filesystem has already been mounted, we can remount it with the *nsdelegate* option as follows:

```
mount -t cgroup2 -o remount,nsdelegate \
                 none /sys/fs/cgroup/unified
```

The effect of this mount option is to cause cgroup namespaces to automatically become delegation boundaries. More specifically, the following restrictions apply for processes inside the cgroup namespace:

- Writes to controller interface files in the root directory of the namespace will fail with the error **EPERM**. Processes inside the cgroup namespace can still write to delegatable files in the root directory of the cgroup namespace such as *cgroup.procs* and *cgroup.subtree_control*, and can create subhierarchy underneath the root directory.

- Attempts to migrate processes across the namespace boundary are denied (with the error **ENOENT**). Processes inside the cgroup namespace can still (subject to the containment rules described below) move processes between cgroups *within* the subhierarchy under the namespace root.

The ability to define cgroup namespaces as delegation boundaries makes cgroup namespaces more useful. To understand why, suppose that we already have one cgroup hierarchy that has been delegated to a nonprivileged user, *cecilia*, using the older delegation technique described above. Suppose further that *cecilia* wanted to further delegate a subhierarchy under the existing delegated hierarchy. (For example, the delegated hierarchy might be associated with an unprivileged container run by *cecilia*.) Even if a cgroup namespace was employed, because both hierarchies are owned by the unprivileged user *cecilia*, the following illegitimate actions could be performed:

- A process in the inferior hierarchy could change the resource controller settings in the root directory of that hierarchy. (These resource controller settings are intended to allow control to be exercised from the *parent* cgroup; a process inside the child cgroup should not be allowed to modify them.)
- A process inside the inferior hierarchy could move processes into and out of the inferior hierarchy if the cgroups in the superior hierarchy were somehow visible.

Employing the *nsdelegate* mount option prevents both of these possibilities.

The *nsdelegate* mount option only has an effect when performed in the initial mount namespace; in other mount namespaces, the option is silently ignored.

Note: On some systems, *systemd*(1) automatically mounts the cgroup v2 filesystem. In order to experiment with the *nsdelegate* operation, it may be useful to boot the kernel with the following command-line options:

```
cgroup_no_v1=all systemd.legacy_systemd_cgroup_controller
```

These options cause the kernel to boot with the cgroups v1 controllers disabled (meaning that the controllers are available in the v2 hierarchy), and tells *systemd*(1) not to mount and use the cgroup v2 hierarchy, so that the v2 hierarchy can be manually mounted with the desired options after boot-up.

Cgroup delegation containment rules

Some delegation *containment rules* ensure that the delegatee can move processes between cgroups within the delegated subtree, but can't move processes from outside the delegated subtree into the subtree or vice versa. A nonprivileged process (i.e., the delegatee) can write the PID of a "target" process into a *cgroup.procs* file only if all of the following are true:

- The writer has write permission on the *cgroup.procs* file in the destination cgroup.
- The writer has write permission on the *cgroup.procs* file in the nearest common ancestor of the source and destination cgroups. Note that in some cases, the nearest common ancestor may be the source or destination cgroup itself. This requirement is not enforced for cgroups v1 hierarchies, with the consequence that containment in v1 is less strict than in v2. (For example, in cgroups v1 the user that owns two distinct delegated subhierarchies can move a process between the hierarchies.)
- If the cgroup v2 filesystem was mounted with the *nsdelegate* option, the writer must be able to see the source and destination cgroups from its cgroup namespace.
- In cgroups v1: the effective UID of the writer (i.e., the delegatee) matches the real user ID or the saved set-user-ID of the target process. Before Linux 4.11, this requirement also applied in cgroups v2 (This was a historical requirement inherited from cgroups v1 that was later deemed unnecessary, since the other rules suffice for containment in cgroups v2.)

Note: one consequence of these delegation containment rules is that the unprivileged delegatee can't place the first process into the delegated subtree; instead, the delegater must place the first process (a process owned by the delegatee) into the delegated subtree.

CGROUPS VERSION 2 THREAD MODE

Among the restrictions imposed by cgroups v2 that were not present in cgroups v1 are the following:

- *No thread-granularity control*: all of the threads of a process must be in the same cgroup.

- *No internal processes*: a cgroup can't both have member processes and exercise controllers on child cgroups.

Both of these restrictions were added because the lack of these restrictions had caused problems in cgroups v1. In particular, the cgroups v1 ability to allow thread-level granularity for cgroup membership made no sense for some controllers. (A notable example was the *memory* controller: since threads share an address space, it made no sense to split threads across different *memory* cgroups.)

Notwithstanding the initial design decision in cgroups v2, there were use cases for certain controllers, notably the *cpu* controller, for which thread-level granularity of control was meaningful and useful. To accommodate such use cases, Linux 4.14 added *thread mode* for cgroups v2.

Thread mode allows the following:

- The creation of *threaded subtrees* in which the threads of a process may be spread across cgroups inside the tree. (A threaded subtree may contain multiple multithreaded processes.)
- The concept of *threaded controllers*, which can distribute resources across the cgroups in a threaded subtree.
- A relaxation of the "no internal processes rule", so that, within a threaded subtree, a cgroup can both contain member threads and exercise resource control over child cgroups.

With the addition of thread mode, each nonroot cgroup now contains a new file, *cgroup.type*, that exposes, and in some circumstances can be used to change, the "type" of a cgroup. This file contains one of the following type values:

domain This is a normal v2 cgroup that provides process-granularity control. If a process is a member of this cgroup, then all threads of the process are (by definition) in the same cgroup. This is the default cgroup type, and provides the same behavior that was provided for cgroups in the initial cgroups v2 implementation.

threaded
This cgroup is a member of a threaded subtree. Threads can be added to this cgroup, and controllers can be enabled for the cgroup.

domain threaded
This is a domain cgroup that serves as the root of a threaded subtree. This cgroup type is also known as "threaded root".

domain invalid
This is a cgroup inside a threaded subtree that is in an "invalid" state. Processes can't be added to the cgroup, and controllers can't be enabled for the cgroup. The only thing that can be done with this cgroup (other than deleting it) is to convert it to a *threaded* cgroup by writing the string *"threaded"* to the *cgroup.type* file.

The rationale for the existence of this "interim" type during the creation of a threaded subtree (rather than the kernel simply immediately converting all cgroups under the threaded root to the type *threaded*) is to allow for possible future extensions to the thread mode model

Threaded versus domain controllers

With the addition of threads mode, cgroups v2 now distinguishes two types of resource controllers:

- *Threaded* controllers: these controllers support thread-granularity for resource control and can be enabled inside threaded subtrees, with the result that the corresponding controller-interface files appear inside the cgroups in the threaded subtree. As at Linux 4.19, the following controllers are threaded: *cpu*, *perf_event*, and *pids*.
- *Domain* controllers: these controllers support only process granularity for resource control. From the perspective of a domain controller, all threads of a process are always in the same cgroup. Domain controllers can't be enabled inside a threaded subtree.

Creating a threaded subtree

There are two pathways that lead to the creation of a threaded subtree. The first pathway proceeds as follows:

(1) We write the string *"threaded"* to the *cgroup.type* file of a cgroup *y/z* that currently has the type *domain*. This has the following effects:

- The type of the cgroup *y/z* becomes *threaded*.
- The type of the parent cgroup, *y*, becomes *domain threaded*. The parent cgroup is the root of a threaded subtree (also known as the "threaded root").
- All other cgroups under *y* that were not already of type *threaded* (because they were inside already existing threaded subtrees under the new threaded root) are converted to type *domain invalid*. Any subsequently created cgroups under *y* will also have the type *domain invalid*.

(2) We write the string *"threaded"* to each of the *domain invalid* cgroups under *y*, in order to convert them to the type *threaded*. As a consequence of this step, all threads under the threaded root now have the type *threaded* and the threaded subtree is now fully usable. The requirement to write *"threaded"* to each of these cgroups is somewhat cumbersome, but allows for possible future extensions to the thread-mode model.

The second way of creating a threaded subtree is as follows:

(1) In an existing cgroup, *z*, that currently has the type *domain*, we (1.1) enable one or more threaded controllers and (1.2) make a process a member of *z*. (These two steps can be done in either order.) This has the following consequences:

- The type of *z* becomes *domain threaded*.
- All of the descendant cgroups of *z* that were not already of type *threaded* are converted to type *domain invalid*.

(2) As before, we make the threaded subtree usable by writing the string *"threaded"* to each of the *domain invalid* cgroups under *z*, in order to convert them to the type *threaded*.

One of the consequences of the above pathways to creating a threaded subtree is that the threaded root cgroup can be a parent only to *threaded* (and *domain invalid*) cgroups. The threaded root cgroup can't be a parent of a *domain* cgroups, and a *threaded* cgroup can't have a sibling that is a *domain* cgroup.

Using a threaded subtree

Within a threaded subtree, threaded controllers can be enabled in each subgroup whose type has been changed to *threaded*; upon doing so, the corresponding controller interface files appear in the children of that cgroup.

A process can be moved into a threaded subtree by writing its PID to the *cgroup.procs* file in one of the cgroups inside the tree. This has the effect of making all of the threads in the process members of the corresponding cgroup and makes the process a member of the threaded subtree. The threads of the process can then be spread across the threaded subtree by writing their thread IDs (see *gettid*(2)) to the *cgroup.threads* files in different cgroups inside the subtree. The threads of a process must all reside in the same threaded subtree.

As with writing to *cgroup.procs*, some containment rules apply when writing to the *cgroup.threads* file:

- The writer must have write permission on the cgroup.threads file in the destination cgroup.
- The writer must have write permission on the *cgroup.procs* file in the common ancestor of the source and destination cgroups. (In some cases, the common ancestor may be the source or destination cgroup itself.)
- The source and destination cgroups must be in the same threaded subtree. (Outside a threaded subtree, an attempt to move a thread by writing its thread ID to the *cgroup.threads* file in a different *domain* cgroup fails with the error **EOPNOTSUPP**.)

The *cgroup.threads* file is present in each cgroup (including *domain* cgroups) and can be read in order to discover the set of threads that is present in the cgroup. The set of thread IDs obtained when reading this file is not guaranteed to be ordered or free of duplicates.

The *cgroup.procs* file in the threaded root shows the PIDs of all processes that are members of the threaded subtree. The *cgroup.procs* files in the other cgroups in the subtree are not readable.

Domain controllers can't be enabled in a threaded subtree; no controller-interface files appear inside the cgroups underneath the threaded root. From the point of view of a domain controller, threaded subtrees are invisible: a multithreaded process inside a threaded subtree appears to a domain controller as a process that resides in the threaded root cgroup.

Within a threaded subtree, the "no internal processes" rule does not apply: a cgroup can both contain

member processes (or thread) and exercise controllers on child cgroups.

Rules for writing to cgroup.type and creating threaded subtrees

A number of rules apply when writing to the *cgroup.type* file:

- Only the string *"threaded"* may be written. In other words, the only explicit transition that is possible is to convert a *domain* cgroup to type *threaded*.
- The effect of writing *"threaded"* depends on the current value in *cgroup.type*, as follows:
  - *domain* or *domain threaded*: start the creation of a threaded subtree (whose root is the parent of this cgroup) via the first of the pathways described above;
  - *domain invalid*: convert this cgroup (which is inside a threaded subtree) to a usable (i.e., *threaded*) state;
  - *threaded*: no effect (a "no-op").
- We can't write to a *cgroup.type* file if the parent's type is *domain invalid*. In other words, the cgroups of a threaded subtree must be converted to the *threaded* state in a top-down manner.

There are also some constraints that must be satisfied in order to create a threaded subtree rooted at the cgroup *x*:

- There can be no member processes in the descendant cgroups of *x*. (The cgroup *x* can itself have member processes.)
- No domain controllers may be enabled in *x*'s *cgroup.subtree_control* file.

If any of the above constraints is violated, then an attempt to write *"threaded"* to a *cgroup.type* file fails with the error **ENOTSUP**.

The "domain threaded" cgroup type

According to the pathways described above, the type of a cgroup can change to *domain threaded* in either of the following cases:

- The string *"threaded"* is written to a child cgroup.
- A threaded controller is enabled inside the cgroup and a process is made a member of the cgroup.

A *domain threaded* cgroup, *x*, can revert to the type *domain* if the above conditions no longer hold true—that is, if all *threaded* child cgroups of *x* are removed and either *x* no longer has threaded controllers enabled or no longer has member processes.

When a *domain threaded* cgroup *x* reverts to the type *domain*:

- All *domain invalid* descendants of *x* that are not in lower-level threaded subtrees revert to the type *domain*.
- The root cgroups in any lower-level threaded subtrees revert to the type *domain threaded*.

Exceptions for the root cgroup

The root cgroup of the v2 hierarchy is treated exceptionally: it can be the parent of both *domain* and *threaded* cgroups. If the string *"threaded"* is written to the *cgroup.type* file of one of the children of the root cgroup, then

- The type of that cgroup becomes *threaded*.
- The type of any descendants of that cgroup that are not part of lower-level threaded subtrees changes to *domain invalid*.

Note that in this case, there is no cgroup whose type becomes *domain threaded*. (Notionally, the root cgroup can be considered as the threaded root for the cgroup whose type was changed to *threaded*.)

The aim of this exceptional treatment for the root cgroup is to allow a threaded cgroup that employs the *cpu* controller to be placed as high as possible in the hierarchy, so as to minimize the (small) cost of traversing the cgroup hierarchy.

The cgroups v2 "cpu" controller and realtime threads

As at Linux 4.19, the cgroups v2 *cpu* controller does not support control of realtime threads (specifically threads scheduled under any of the policies **SCHED_FIFO**, **SCHED_RR**, described **SCHED_DEADLINE**; see *sched*(7)). Therefore, the *cpu* controller can be enabled in the root cgroup only if all realtime threads are in the root cgroup. (If there are realtime threads in nonroot cgroups,

then a *write*(2) of the string *"+cpu"* to the *cgroup.subtree_control* file fails with the error **EINVAL**.)

On some systems, *systemd*(1) places certain realtime threads in nonroot cgroups in the v2 hierarchy. On such systems, these threads must first be moved to the root cgroup before the *cpu* controller can be enabled.

ERRORS

The following errors can occur for *mount*(2):

EBUSY
An attempt to mount a cgroup version 1 filesystem specified neither the *name*= option (to mount a named hierarchy) nor a controller name (or *all*).

NOTES

A child process created via *fork*(2) inherits its parent's cgroup memberships. A process's cgroup memberships are preserved across *execve*(2).

The *clone3*(2) **CLONE_INTO_CGROUP** flag can be used to create a child process that begins its life in a different version 2 cgroup from the parent process.

/proc files

/proc/cgroups (since Linux 2.6.24)
This file contains information about the controllers that are compiled into the kernel. An example of the contents of this file (reformatted for readability) is the following:

```
#subsys_name    hierarchy       num_cgroups     enabled
cpuset          4               1               1
cpu             8               1               1
cpuacct         8               1               1
blkio           6               1               1
memory          3               1               1
devices         10              84              1
freezer         7               1               1
net_cls         9               1               1
perf_event      5               1               1
net_prio        9               1               1
hugetlb         0               1               0
pids            2               1               1
```

The fields in this file are, from left to right:

[1] The name of the controller.

[2] The unique ID of the cgroup hierarchy on which this controller is mounted. If multiple cgroups v1 controllers are bound to the same hierarchy, then each will show the same hierarchy ID in this field. The value in this field will be 0 if:

- the controller is not mounted on a cgroups v1 hierarchy;
- the controller is bound to the cgroups v2 single unified hierarchy; or
- the controller is disabled (see below).

[3] The number of control groups in this hierarchy using this controller.

[4] This field contains the value 1 if this controller is enabled, or 0 if it has been disabled (via the *cgroup_disable* kernel command-line boot parameter).

*/proc/*pid*/cgroup* (since Linux 2.6.24)
This file describes control groups to which the process with the corresponding PID belongs. The displayed information differs for cgroups version 1 and version 2 hierarchies.

For each cgroup hierarchy of which the process is a member, there is one entry containing three colon-separated fields:

```
hierarchy-ID:controller-list:cgroup-path
```

For example:

```
5:cpuacct,cpu,cpuset:/daemons
```

The colon-separated fields are, from left to right:

[1] For cgroups version 1 hierarchies, this field contains a unique hierarchy ID number that can be matched to a hierarchy ID in */proc/cgroups*. For the cgroups version 2 hierarchy, this field contains the value 0.

[2] For cgroups version 1 hierarchies, this field contains a comma-separated list of the controllers bound to the hierarchy. For the cgroups version 2 hierarchy, this field is empty.

[3] This field contains the pathname of the control group in the hierarchy to which the process belongs. This pathname is relative to the mount point of the hierarchy.

/sys/kernel/cgroup files

/sys/kernel/cgroup/delegate (since Linux 4.15)

This file exports a list of the cgroups v2 files (one per line) that are delegatable (i.e., whose ownership should be changed to the user ID of the delegatee). In the future, the set of delegatable files may change or grow, and this file provides a way for the kernel to inform user-space applications of which files must be delegated. As at Linux 4.15, one sees the following when inspecting this file:

```
$ cat /sys/kernel/cgroup/delegate
cgroup.procs
cgroup.subtree_control
cgroup.threads
```

/sys/kernel/cgroup/features (since Linux 4.15)

Over time, the set of cgroups v2 features that are provided by the kernel may change or grow, or some features may not be enabled by default. This file provides a way for user-space applications to discover what features the running kernel supports and has enabled. Features are listed one per line:

```
$ cat /sys/kernel/cgroup/features
nsdelegate
memory_localevents
```

The entries that can appear in this file are:

memory_localevents (since Linux 5.2)
The kernel supports the *memory_localevents* mount option.

nsdelegate (since Linux 4.15)
The kernel supports the *nsdelegate* mount option.

memory_recursiveprot (since Linux 5.7)
The kernel supports the *memory_recursiveprot* mount option.

NAME

charsets − character set standards and internationalization

DESCRIPTION

This manual page gives an overview on different character set standards and how they were used on Linux before Unicode became ubiquitous. Some of this information is still helpful for people working with legacy systems and documents.

Standards discussed include such as ASCII, GB 2312, ISO/IEC 8859, JIS, KOI8-R, KS, and Unicode.

The primary emphasis is on character sets that were actually used by locale character sets, not the myriad others that could be found in data from other systems.

ASCII

ASCII (American Standard Code For Information Interchange) is the original 7-bit character set, originally designed for American English. Also known as US-ASCII. It is currently described by the ISO/IEC 646:1991 IRV (International Reference Version) standard.

Various ASCII variants replacing the dollar sign with other currency symbols and replacing punctuation with non-English alphabetic characters to cover German, French, Spanish, and others in 7 bits emerged. All are deprecated; glibc does not support locales whose character sets are not true supersets of ASCII.

As Unicode, when using UTF-8, is ASCII-compatible, plain ASCII text still renders properly on modern UTF-8 using systems.

ISO/IEC 8859

ISO/IEC 8859 is a series of 15 8-bit character sets, all of which have ASCII in their low (7-bit) half, invisible control characters in positions 128 to 159, and 96 fixed-width graphics in positions 160–255.

Of these, the most important is ISO/IEC 8859-1 ("Latin Alphabet No. 1" / Latin-1). It was widely adopted and supported by different systems, and is gradually being replaced with Unicode. The ISO/IEC 8859-1 characters are also the first 256 characters of Unicode.

Console support for the other ISO/IEC 8859 character sets is available under Linux through user-mode utilities (such as *setfont*(8)) that modify keyboard bindings and the EGA graphics table and employ the "user mapping" font table in the console driver.

Here are brief descriptions of each character set:

ISO/IEC 8859-1 (Latin-1)
: Latin-1 covers many European languages such as Albanian, Basque, Danish, English, Faroese, Galician, Icelandic, Irish, Italian, Norwegian, Portuguese, Spanish, and Swedish. The lack of the ligatures Dutch IJ/ij, French œ, and „German“ quotation marks was considered tolerable.

ISO/IEC 8859-2 (Latin-2)
: Latin-2 supports many Latin-written Central and East European languages such as Bosnian, Croatian, Czech, German, Hungarian, Polish, Slovak, and Slovene. Replacing Romanian / with ş/ţ was considered tolerable.

ISO/IEC 8859-3 (Latin-3)
: Latin-3 was designed to cover of Esperanto, Maltese, and Turkish, but ISO/IEC 8859-9 later superseded it for Turkish.

ISO/IEC 8859-4 (Latin-4)
: Latin-4 introduced letters for North European languages such as Estonian, Latvian, and Lithuanian, but was superseded by ISO/IEC 8859-10 and ISO/IEC 8859-13.

ISO/IEC 8859-5
: Cyrillic letters supporting Bulgarian, Byelorussian, Macedonian, Russian, Serbian, and (almost completely) Ukrainian. It was never widely used, see the discussion of KOI8-R/KOI8-U below.

ISO/IEC 8859-6
: Was created for Arabic. The ISO/IEC 8859-6 glyph table is a fixed font of separate letter forms, but a proper display engine should combine these using the proper initial, medial, and final forms.

ISO/IEC 8859-7
: Was created for Modern Greek in 1987, updated in 2003.

ISO/IEC 8859-8
: Supports Modern Hebrew without niqud (punctuation signs). Niqud and full-fledged Biblical Hebrew were outside the scope of this character set.

ISO/IEC 8859-9 (Latin-5)
: This is a variant of Latin-1 that replaces Icelandic letters with Turkish ones.

ISO/IEC 8859-10 (Latin-6)
: Latin-6 added the Inuit (Greenlandic) and Sami (Lappish) letters that were missing in Latin-4 to cover the entire Nordic area.

ISO/IEC 8859-11
: Supports the Thai alphabet and is nearly identical to the TIS-620 standard.

ISO/IEC 8859-12
: This character set does not exist.

ISO/IEC 8859-13 (Latin-7)
: Supports the Baltic Rim languages; in particular, it includes Latvian characters not found in Latin-4.

ISO/IEC 8859-14 (Latin-8)
: This is the Celtic character set, covering Old Irish, Manx, Gaelic, Welsh, Cornish, and Breton.

ISO/IEC 8859-15 (Latin-9)
: Latin-9 is similar to the widely used Latin-1 but replaces some less common symbols with the Euro sign and French and Finnish letters that were missing in Latin-1.

ISO/IEC 8859-16 (Latin-10)
: This character set covers many Southeast European languages, and most importantly supports Romanian more completely than Latin-2.

KOI8-R / KOI8-U
: KOI8-R is a non-ISO character set popular in Russia before Unicode. The lower half is ASCII; the upper is a Cyrillic character set somewhat better designed than ISO/IEC 8859-5. KOI8-U, based on KOI8-R, has better support for Ukrainian. Neither of these sets are ISO/IEC 2022 compatible, unlike the ISO/IEC 8859 series.

  Console support for KOI8-R is available under Linux through user-mode utilities that modify keyboard bindings and the EGA graphics table, and employ the "user mapping" font table in the console driver.

GB 2312
: GB 2312 is a mainland Chinese national standard character set used to express simplified Chinese. Just like JIS X 0208, characters are mapped into a 94x94 two-byte matrix used to construct EUC-CN. EUC-CN is the most important encoding for Linux and includes ASCII and GB 2312. Note that EUC-CN is often called as GB, GB 2312, or CN-GB.

Big5
: Big5 was a popular character set in Taiwan to express traditional Chinese. (Big5 is both a character set and an encoding.) It is a superset of ASCII. Non-ASCII characters are expressed in two bytes. Bytes 0xa1–0xfe are used as leading bytes for two-byte characters. Big5 and its extension were widely used in Taiwan and Hong Kong. It is not ISO/IEC 2022 compliant.

JIS X 0208
: JIS X 0208 is a Japanese national standard character set. Though there are some more Japanese national standard character sets (like JIS X 0201, JIS X 0212, and JIS X 0213), this is the most important one. Characters are mapped into a 94x94 two-byte matrix, whose each byte is in the range 0x21–0x7e. Note that JIS X 0208 is a character set, not an encoding. This means that JIS X 0208 itself is not used for expressing text data. JIS X 0208 is used as a component to construct encodings such as EUC-JP, Shift_JIS, and ISO/IEC 2022-JP. EUC-JP is the most important encoding for Linux and includes ASCII and JIS X 0208. In EUC-JP, JIS X 0208 characters are expressed in two bytes, each of which is the JIS X 0208 code plus 0x80.

KS X 1001

KS X 1001 is a Korean national standard character set. Just as JIS X 0208, characters are mapped into a 94x94 two-byte matrix. KS X 1001 is used like JIS X 0208, as a component to construct encodings such as EUC-KR, Johab, and ISO/IEC 2022-KR. EUC-KR is the most important encoding for Linux and includes ASCII and KS X 1001. KS C 5601 is an older name for KS X 1001.

ISO/IEC 2022 and ISO/IEC 4873

The ISO/IEC 2022 and ISO/IEC 4873 standards describe a font-control model based on VT100 practice. This model is (partially) supported by the Linux kernel and by *xterm*(1)Several ISO/IEC 2022-based character encodings have been defined, especially for Japanese.

There are 4 graphic character sets, called G0, G1, G2, and G3, and one of them is the current character set for codes with high bit zero (initially G0), and one of them is the current character set for codes with high bit one (initially G1). Each graphic character set has 94 or 96 characters, and is essentially a 7-bit character set. It uses codes either 040–0177 (041–0176) or 0240–0377 (0241–0376). G0 always has size 94 and uses codes 041–0176.

Switching between character sets is done using the shift functions **^N** (SO or LS1), **^O** (SI or LS0), ESC n (LS2), ESC o (LS3), ESC N (SS2), ESC O (SS3), ESC ~ (LS1R), ESC } (LS2R), ESC | (LS3R). The function LS*n* makes character set G*n* the current one for codes with high bit zero. The function LS*n*R makes character set G*n* the current one for codes with high bit one. The function SS*n* makes character set G*n* (*n*=2 or 3) the current one for the next character only (regardless of the value of its high order bit).

A 94-character set is designated as G*n* character set by an escape sequence ESC (xx (for G0), ESC) xx (for G1), ESC * xx (for G2), ESC + xx (for G3), where xx is a symbol or a pair of symbols found in the ISO/IEC 2375 International Register of Coded Character Sets. For example, ESC (@ selects the ISO/IEC 646 character set as G0, ESC (A selects the UK standard character set (with pound instead of number sign), ESC (B selects ASCII (with dollar instead of currency sign), ESC (M selects a character set for African languages, ESC (! A selects the Cuban character set, and so on.

A 96-character set is designated as G*n* character set by an escape sequence ESC − xx (for G1), ESC . xx (for G2) or ESC / xx (for G3). For example, ESC − G selects the Hebrew alphabet as G1.

A multibyte character set is designated as G*n* character set by an escape sequence ESC $ xx or ESC $ (xx (for G0), ESC $) xx (for G1), ESC $ * xx (for G2), ESC $ + xx (for G3). For example, ESC $ (C selects the Korean character set for G0. The Japanese character set selected by ESC $ B has a more recent version selected by ESC & @ ESC $ B.

ISO/IEC 4873 stipulates a narrower use of character sets, where G0 is fixed (always ASCII), so that G1, G2, and G3 can be invoked only for codes with the high order bit set. In particular, **^N** and **^O** are not used anymore, ESC (xx can be used only with xx=B, and ESC) xx, ESC * xx, ESC + xx are equivalent to ESC − xx, ESC . xx, ESC / xx, respectively.

TIS-620

TIS-620 is a Thai national standard character set and a superset of ASCII. In the same fashion as the ISO/IEC 8859 series, Thai characters are mapped into 0xa1–0xfe.

Unicode

Unicode (ISO/IEC 10646) is a standard which aims to unambiguously represent every character in every human language. Unicode's structure permits 20.1 bits to encode every character. Since most computers don't include 20.1-bit integers, Unicode is usually encoded as 32-bit integers internally and either a series of 16-bit integers (UTF-16) (needing two 16-bit integers only when encoding certain rare characters) or a series of 8-bit bytes (UTF-8).

Linux represents Unicode using the 8-bit Unicode Transformation Format (UTF-8). UTF-8 is a variable length encoding of Unicode. It uses 1 byte to code 7 bits, 2 bytes for 11 bits, 3 bytes for 16 bits, 4 bytes for 21 bits, 5 bytes for 26 bits, 6 bytes for 31 bits.

Let 0,1,x stand for a zero, one, or arbitrary bit. A byte 0xxxxxxx stands for the Unicode 00000000 0xxxxxxx which codes the same symbol as the ASCII 0xxxxxxx. Thus, ASCII goes unchanged into UTF-8, and people using only ASCII do not notice any change: not in code, and not in file size.

A byte 110xxxxx is the start of a 2-byte code, and 110xxxxx 10yyyyyy is assembled into 00000xxx xxyyyyyy. A byte 1110xxxx is the start of a 3-byte code, and 1110xxxx 10yyyyyy 10zzzzzz is assembled into xxxxyyyy yyzzzzzz. (When UTF-8 is used to code the 31-bit ISO/IEC 10646 then this

progression continues up to 6-byte codes.)

For most texts in ISO/IEC 8859 character sets, this means that the characters outside of ASCII are now coded with two bytes. This tends to expand ordinary text files by only one or two percent. For Russian or Greek texts, this expands ordinary text files by 100%, since text in those languages is mostly outside of ASCII. For Japanese users this means that the 16-bit codes now in common use will take three bytes. While there are algorithmic conversions from some character sets (especially ISO/IEC 8859-1) to Unicode, general conversion requires carrying around conversion tables, which can be quite large for 16-bit codes.

Note that UTF-8 is self-synchronizing: 10xxxxxx is a tail, any other byte is the head of a code. Note that the only way ASCII bytes occur in a UTF-8 stream, is as themselves. In particular, there are no embedded NULs ('\0') or '/'s that form part of some larger code.

Since ASCII, and, in particular, NUL and '/', are unchanged, the kernel does not notice that UTF-8 is being used. It does not care at all what the bytes it is handling stand for.

Rendering of Unicode data streams is typically handled through "subfont" tables which map a subset of Unicode to glyphs. Internally the kernel uses Unicode to describe the subfont loaded in video RAM. This means that in the Linux console in UTF-8 mode, one can use a character set with 512 different symbols. This is not enough for Japanese, Chinese, and Korean, but it is enough for most other purposes.

NAME

complex − basics of complex mathematics

LIBRARY

Math library (*libm*, *−lm*)

SYNOPSIS

#include <complex.h>

DESCRIPTION

Complex numbers are numbers of the form z = a+b*i, where a and b are real numbers and i = sqrt(−1), so that i*i = −1.

There are other ways to represent that number. The pair (a,b) of real numbers may be viewed as a point in the plane, given by X- and Y-coordinates. This same point may also be described by giving the pair of real numbers (r,phi), where r is the distance to the origin O, and phi the angle between the X-axis and the line Oz. Now z = r*exp(i*phi) = r*(cos(phi)+i*sin(phi)).

The basic operations are defined on z = a+b*i and w = c+d*i as:

addition: z+w = (a+c) + (b+d)*i

multiplication: z*w = (a*c − b*d) + (a*d + b*c)*i

division: z/w = ((a*c + b*d)/(c*c + d*d)) + ((b*c − a*d)/(c*c + d*d))*i

Nearly all math function have a complex counterpart but there are some complex-only functions.

EXAMPLES

Your C-compiler can work with complex numbers if it supports the C99 standard. The imaginary unit is represented by I.

```
/* check that exp(i * pi) == −1 */
#include <math.h>        /* for atan */
#include <stdio.h>
#include <complex.h>

int
main(void)
{
    double pi = 4 * atan(1.0);
    double complex z = cexp(I * pi);
    printf("%f + %f * i\n", creal(z), cimag(z));
}
```

NAME

cp1251 − CP 1251 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The Windows Code Pages include several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). CP 1251 encodes the characters used in Cyrillic scripts.

CP 1251 characters

The following table displays the characters in CP 1251 that are printable and unlisted in the *ascii*(7) manual page.

NAME

cpuset − confine processes to processor and memory node subsets

DESCRIPTION

The cpuset filesystem is a pseudo-filesystem interface to the kernel cpuset mechanism, which is used to control the processor placement and memory placement of processes. It is commonly mounted at */dev/cpuset*.

On systems with kernels compiled with built in support for cpusets, all processes are attached to a cpuset, and cpusets are always present. If a system supports cpusets, then it will have the entry **nodev cpuset** in the file */proc/filesystems*. By mounting the cpuset filesystem (see the **EXAMPLES** section below), the administrator can configure the cpusets on a system to control the processor and memory placement of processes on that system. By default, if the cpuset configuration on a system is not modified or if the cpuset filesystem is not even mounted, then the cpuset mechanism, though present, has no effect on the system's behavior.

A cpuset defines a list of CPUs and memory nodes.

The CPUs of a system include all the logical processing units on which a process can execute, including, if present, multiple processor cores within a package and Hyper-Threads within a processor core. Memory nodes include all distinct banks of main memory; small and SMP systems typically have just one memory node that contains all the system's main memory, while NUMA (non-uniform memory access) systems have multiple memory nodes.

Cpusets are represented as directories in a hierarchical pseudo-filesystem, where the top directory in the hierarchy (*/dev/cpuset*) represents the entire system (all online CPUs and memory nodes) and any cpuset that is the child (descendant) of another parent cpuset contains a subset of that parent's CPUs and memory nodes. The directories and files representing cpusets have normal filesystem permissions.

Every process in the system belongs to exactly one cpuset. A process is confined to run only on the CPUs in the cpuset it belongs to, and to allocate memory only on the memory nodes in that cpuset. When a process *fork*(2)s, the child process is placed in the same cpuset as its parent. With sufficient privilege, a process may be moved from one cpuset to another and the allowed CPUs and memory nodes of an existing cpuset may be changed.

When the system begins booting, a single cpuset is defined that includes all CPUs and memory nodes on the system, and all processes are in that cpuset. During the boot process, or later during normal system operation, other cpusets may be created, as subdirectories of this top cpuset, under the control of the system administrator, and processes may be placed in these other cpusets.

Cpusets are integrated with the *sched_setaffinity*(2) scheduling affinity mechanism and the *mbind*(2) and *set_mempolicy*(2) memory-placement mechanisms in the kernel. Neither of these mechanisms let a process make use of a CPU or memory node that is not allowed by that process's cpuset. If changes to a process's cpuset placement conflict with these other mechanisms, then cpuset placement is enforced even if it means overriding these other mechanisms. The kernel accomplishes this overriding by silently restricting the CPUs and memory nodes requested by these other mechanisms to those allowed by the invoking process's cpuset. This can result in these other calls returning an error, if for example, such a call ends up requesting an empty set of CPUs or memory nodes, after that request is restricted to the invoking process's cpuset.

Typically, a cpuset is used to manage the CPU and memory-node confinement for a set of cooperating processes such as a batch scheduler job, and these other mechanisms are used to manage the placement of individual processes or memory regions within that set or job.

FILES

Each directory below */dev/cpuset* represents a cpuset and contains a fixed set of pseudo-files describing the state of that cpuset.

New cpusets are created using the *mkdir*(2) system call or the *mkdir*(1) command. The properties of a cpuset, such as its flags, allowed CPUs and memory nodes, and attached processes, are queried and modified by reading or writing to the appropriate file in that cpuset's directory, as listed below.

The pseudo-files in each cpuset directory are automatically created when the cpuset is created, as a result of the *mkdir*(2) invocation. It is not possible to directly add or remove these pseudo-files.

A cpuset directory that contains no child cpuset directories, and has no attached processes, can be

removed using *rmdir*(2) or *rmdir*(1)It is not necessary, or possible, to remove the pseudo-files inside the directory before removing it.

The pseudo-files in each cpuset directory are small text files that may be read and written using traditional shell utilities such as *cat*(1), and *echo*(1), or from a program by using file I/O library functions or system calls, such as *open*(2), *read*(2), *write*(2), and *close*(2).

The pseudo-files in a cpuset directory represent internal kernel state and do not have any persistent image on disk. Each of these per-cpuset files is listed and described below.

tasks List of the process IDs (PIDs) of the processes in that cpuset. The list is formatted as a series of ASCII decimal numbers, each followed by a newline. A process may be added to a cpuset (automatically removing it from the cpuset that previously contained it) by writing its PID to that cpuset's *tasks* file (with or without a trailing newline).

Warning: only one PID may be written to the *tasks* file at a time. If a string is written that contains more than one PID, only the first one will be used.

notify_on_release
Flag (0 or 1). If set (1), that cpuset will receive special handling after it is released, that is, after all processes cease using it (i.e., terminate or are moved to a different cpuset) and all child cpuset directories have been removed. See the **Notify On Release** section, below.

cpuset.cpus
List of the physical numbers of the CPUs on which processes in that cpuset are allowed to execute. See **List Format** below for a description of the format of *cpus*.

The CPUs allowed to a cpuset may be changed by writing a new list to its *cpus* file.

cpuset.cpu_exclusive
Flag (0 or 1). If set (1), the cpuset has exclusive use of its CPUs (no sibling or cousin cpuset may overlap CPUs). By default, this is off (0). Newly created cpusets also initially default this to off (0).

Two cpusets are *sibling* cpusets if they share the same parent cpuset in the */dev/cpuset* hierarchy. Two cpusets are *cousin* cpusets if neither is the ancestor of the other. Regardless of the *cpu_exclusive* setting, if one cpuset is the ancestor of another, and if both of these cpusets have nonempty *cpus*, then their *cpus* must overlap, because the *cpus* of any cpuset are always a subset of the *cpus* of its parent cpuset.

cpuset.mems
List of memory nodes on which processes in this cpuset are allowed to allocate memory. See **List Format** below for a description of the format of *mems*.

cpuset.mem_exclusive
Flag (0 or 1). If set (1), the cpuset has exclusive use of its memory nodes (no sibling or cousin may overlap). Also if set (1), the cpuset is a **Hardwall** cpuset (see below). By default, this is off (0). Newly created cpusets also initially default this to off (0).

Regardless of the *mem_exclusive* setting, if one cpuset is the ancestor of another, then their memory nodes must overlap, because the memory nodes of any cpuset are always a subset of the memory nodes of that cpuset's parent cpuset.

cpuset.mem_hardwall (since Linux 2.6.26)
Flag (0 or 1). If set (1), the cpuset is a **Hardwall** cpuset (see below). Unlike **mem_exclusive**, there is no constraint on whether cpusets marked **mem_hardwall** may have overlapping memory nodes with sibling or cousin cpusets. By default, this is off (0). Newly created cpusets also initially default this to off (0).

cpuset.memory_migrate (since Linux 2.6.16)
Flag (0 or 1). If set (1), then memory migration is enabled. By default, this is off (0). See the **Memory Migration** section, below.

cpuset.memory_pressure (since Linux 2.6.16)
A measure of how much memory pressure the processes in this cpuset are causing. See the **Memory Pressure** section, below. Unless *memory_pressure_enabled* is enabled, always has value zero (0). This file is read-only. See the **WARNINGS** section, below.

cpuset.memory_pressure_enabled (since Linux 2.6.16)
Flag (0 or 1). This file is present only in the root cpuset, normally */dev/cpuset*. If set (1), the *memory_pressure* calculations are enabled for all cpusets in the system. By default, this is off (0). See the **Memory Pressure** section, below.

cpuset.memory_spread_page (since Linux 2.6.17)
Flag (0 or 1). If set (1), pages in the kernel page cache (filesystem buffers) are uniformly spread across the cpuset. By default, this is off (0) in the top cpuset, and inherited from the parent cpuset in newly created cpusets. See the **Memory Spread** section, below.

cpuset.memory_spread_slab (since Linux 2.6.17)
Flag (0 or 1). If set (1), the kernel slab caches for file I/O (directory and inode structures) are uniformly spread across the cpuset. By default, is off (0) in the top cpuset, and inherited from the parent cpuset in newly created cpusets. See the **Memory Spread** section, below.

cpuset.sched_load_balance (since Linux 2.6.24)
Flag (0 or 1). If set (1, the default) the kernel will automatically load balance processes in that cpuset over the allowed CPUs in that cpuset. If cleared (0) the kernel will avoid load balancing processes in this cpuset, *unless* some other cpuset with overlapping CPUs has its *sched_load_balance* flag set. See **Scheduler Load Balancing**, below, for further details.

cpuset.sched_relax_domain_level (since Linux 2.6.26)
Integer, between −1 and a small positive value. The *sched_relax_domain_level* controls the width of the range of CPUs over which the kernel scheduler performs immediate rebalancing of runnable tasks across CPUs. If *sched_load_balance* is disabled, then the setting of *sched_relax_domain_level* does not matter, as no such load balancing is done. If *sched_load_balance* is enabled, then the higher the value of the *sched_relax_domain_level*, the wider the range of CPUs over which immediate load balancing is attempted. See **Scheduler Relax Domain Level**, below, for further details.

In addition to the above pseudo-files in each directory below */dev/cpuset*, each process has a pseudo-file, */proc/*pid*/cpuset*, that displays the path of the process's cpuset directory relative to the root of the cpuset filesystem.

Also the */proc/*pid*/status* file for each process has four added lines, displaying the process's *Cpus_allowed* (on which CPUs it may be scheduled) and *Mems_allowed* (on which memory nodes it may obtain memory), in the two formats **Mask Format** and **List Format** (see below) as shown in the following example:

```
Cpus_allowed:   ffffffff,ffffffff,ffffffff,ffffffff
Cpus_allowed_list:     0-127
Mems_allowed:   ffffffff,ffffffff
Mems_allowed_list:     0-63
```

The "allowed" fields were added in Linux 2.6.24; the "allowed_list" fields were added in Linux 2.6.26.

EXTENDED CAPABILITIES

In addition to controlling which *cpus* and *mems* a process is allowed to use, cpusets provide the following extended capabilities.

Exclusive cpusets

If a cpuset is marked *cpu_exclusive* or *mem_exclusive*, no other cpuset, other than a direct ancestor or descendant, may share any of the same CPUs or memory nodes.

A cpuset that is *mem_exclusive* restricts kernel allocations for buffer cache pages and other internal kernel data pages commonly shared by the kernel across multiple users. All cpusets, whether *mem_exclusive* or not, restrict allocations of memory for user space. This enables configuring a system so that several independent jobs can share common kernel data, while isolating each job's user allocation in its own cpuset. To do this, construct a large *mem_exclusive* cpuset to hold all the jobs, and construct child, non-*mem_exclusive* cpusets for each individual job. Only a small amount of kernel memory, such as requests from interrupt handlers, is allowed to be placed on memory nodes outside even a *mem_exclusive* cpuset.

Hardwall

A cpuset that has *mem_exclusive* or *mem_hardwall* set is a *hardwall* cpuset. A *hardwall* cpuset restricts kernel allocations for page, buffer, and other data commonly shared by the kernel across multiple

users. All cpusets, whether *hardwall* or not, restrict allocations of memory for user space.

This enables configuring a system so that several independent jobs can share common kernel data, such as filesystem pages, while isolating each job's user allocation in its own cpuset. To do this, construct a large *hardwall* cpuset to hold all the jobs, and construct child cpusets for each individual job which are not *hardwall* cpusets.

Only a small amount of kernel memory, such as requests from interrupt handlers, is allowed to be taken outside even a *hardwall* cpuset.

Notify on release

If the *notify_on_release* flag is enabled (1) in a cpuset, then whenever the last process in the cpuset leaves (exits or attaches to some other cpuset) and the last child cpuset of that cpuset is removed, the kernel will run the command */sbin/cpuset_release_agent*, supplying the pathname (relative to the mount point of the cpuset filesystem) of the abandoned cpuset. This enables automatic removal of abandoned cpusets.

The default value of *notify_on_release* in the root cpuset at system boot is disabled (0). The default value of other cpusets at creation is the current value of their parent's *notify_on_release* setting.

The command */sbin/cpuset_release_agent* is invoked, with the name (*/dev/cpuset* relative path) of the to-be-released cpuset in *argv[1]*.

The usual contents of the command */sbin/cpuset_release_agent* is simply the shell script:

```
#!/bin/sh
rmdir /dev/cpuset/$1
```

As with other flag values below, this flag can be changed by writing an ASCII number 0 or 1 (with optional trailing newline) into the file, to clear or set the flag, respectively.

Memory pressure

The *memory_pressure* of a cpuset provides a simple per-cpuset running average of the rate that the processes in a cpuset are attempting to free up in-use memory on the nodes of the cpuset to satisfy additional memory requests.

This enables batch managers that are monitoring jobs running in dedicated cpusets to efficiently detect what level of memory pressure that job is causing.

This is useful both on tightly managed systems running a wide mix of submitted jobs, which may choose to terminate or reprioritize jobs that are trying to use more memory than allowed on the nodes assigned them, and with tightly coupled, long-running, massively parallel scientific computing jobs that will dramatically fail to meet required performance goals if they start to use more memory than allowed to them.

This mechanism provides a very economical way for the batch manager to monitor a cpuset for signs of memory pressure. It's up to the batch manager or other user code to decide what action to take if it detects signs of memory pressure.

Unless memory pressure calculation is enabled by setting the pseudo-file */dev/cpuset/cpuset.memory_pressure_enabled*, it is not computed for any cpuset, and reads from any *memory_pressure* always return zero, as represented by the ASCII string "0\n". See the **WARNINGS** section, below.

A per-cpuset, running average is employed for the following reasons:

- Because this meter is per-cpuset rather than per-process or per virtual memory region, the system load imposed by a batch scheduler monitoring this metric is sharply reduced on large systems, because a scan of the tasklist can be avoided on each set of queries.
- Because this meter is a running average rather than an accumulating counter, a batch scheduler can detect memory pressure with a single read, instead of having to read and accumulate results for a period of time.
- Because this meter is per-cpuset rather than per-process, the batch scheduler can obtain the key information—memory pressure in a cpuset—with a single read, rather than having to query and accumulate results over all the (dynamically changing) set of processes in the cpuset.

The *memory_pressure* of a cpuset is calculated using a per-cpuset simple digital filter that is kept within the kernel. For each cpuset, this filter tracks the recent rate at which processes attached to that

cpuset enter the kernel direct reclaim code.

The kernel direct reclaim code is entered whenever a process has to satisfy a memory page request by first finding some other page to repurpose, due to lack of any readily available already free pages. Dirty filesystem pages are repurposed by first writing them to disk. Unmodified filesystem buffer pages are repurposed by simply dropping them, though if that page is needed again, it will have to be reread from disk.

The *cpuset.memory_pressure* file provides an integer number representing the recent (half-life of 10 seconds) rate of entries to the direct reclaim code caused by any process in the cpuset, in units of reclaims attempted per second, times 1000.

Memory spread

There are two Boolean flag files per cpuset that control where the kernel allocates pages for the filesystem buffers and related in-kernel data structures. They are called *cpuset.memory_spread_page* and *cpuset.memory_spread_slab*.

If the per-cpuset Boolean flag file *cpuset.memory_spread_page* is set, then the kernel will spread the filesystem buffers (page cache) evenly over all the nodes that the faulting process is allowed to use, instead of preferring to put those pages on the node where the process is running.

If the per-cpuset Boolean flag file *cpuset.memory_spread_slab* is set, then the kernel will spread some filesystem-related slab caches, such as those for inodes and directory entries, evenly over all the nodes that the faulting process is allowed to use, instead of preferring to put those pages on the node where the process is running.

The setting of these flags does not affect the data segment (see *brk*(2)) or stack segment pages of a process.

By default, both kinds of memory spreading are off and the kernel prefers to allocate memory pages on the node local to where the requesting process is running. If that node is not allowed by the process's NUMA memory policy or cpuset configuration or if there are insufficient free memory pages on that node, then the kernel looks for the nearest node that is allowed and has sufficient free memory.

When new cpusets are created, they inherit the memory spread settings of their parent.

Setting memory spreading causes allocations for the affected page or slab caches to ignore the process's NUMA memory policy and be spread instead. However, the effect of these changes in memory placement caused by cpuset-specified memory spreading is hidden from the *mbind*(2) or *set_mempolicy*(2) calls. These two NUMA memory policy calls always appear to behave as if no cpuset-specified memory spreading is in effect, even if it is. If cpuset memory spreading is subsequently turned off, the NUMA memory policy most recently specified by these calls is automatically reapplied.

Both *cpuset.memory_spread_page* and *cpuset.memory_spread_slab* are Boolean flag files. By default, they contain "0", meaning that the feature is off for that cpuset. If a "1" is written to that file, that turns the named feature on.

Cpuset-specified memory spreading behaves similarly to what is known (in other contexts) as round-robin or interleave memory placement.

Cpuset-specified memory spreading can provide substantial performance improvements for jobs that:

- need to place thread-local data on memory nodes close to the CPUs which are running the threads that most frequently access that data; but also
- need to access large filesystem data sets that must to be spread across the several nodes in the job's cpuset in order to fit.

Without this policy, the memory allocation across the nodes in the job's cpuset can become very uneven, especially for jobs that might have just a single thread initializing or reading in the data set.

Memory migration

Normally, under the default setting (disabled) of *cpuset.memory_migrate*, once a page is allocated (given a physical page of main memory), then that page stays on whatever node it was allocated, so long as it remains allocated, even if the cpuset's memory-placement policy *mems* subsequently changes.

When memory migration is enabled in a cpuset, if the *mems* setting of the cpuset is changed, then any memory page in use by any process in the cpuset that is on a memory node that is no longer allowed

will be migrated to a memory node that is allowed.

Furthermore, if a process is moved into a cpuset with *memory_migrate* enabled, any memory pages it uses that were on memory nodes allowed in its previous cpuset, but which are not allowed in its new cpuset, will be migrated to a memory node allowed in the new cpuset.

The relative placement of a migrated page within the cpuset is preserved during these migration operations if possible. For example, if the page was on the second valid node of the prior cpuset, then the page will be placed on the second valid node of the new cpuset, if possible.

Scheduler load balancing

The kernel scheduler automatically load balances processes. If one CPU is underutilized, the kernel will look for processes on other more overloaded CPUs and move those processes to the underutilized CPU, within the constraints of such placement mechanisms as cpusets and *sched_setaffinity*(2).

The algorithmic cost of load balancing and its impact on key shared kernel data structures such as the process list increases more than linearly with the number of CPUs being balanced. For example, it costs more to load balance across one large set of CPUs than it does to balance across two smaller sets of CPUs, each of half the size of the larger set. (The precise relationship between the number of CPUs being balanced and the cost of load balancing depends on implementation details of the kernel process scheduler, which is subject to change over time, as improved kernel scheduler algorithms are implemented.)

The per-cpuset flag *sched_load_balance* provides a mechanism to suppress this automatic scheduler load balancing in cases where it is not needed and suppressing it would have worthwhile performance benefits.

By default, load balancing is done across all CPUs, except those marked isolated using the kernel boot time "isolcpus=" argument. (See **Scheduler Relax Domain Level**, below, to change this default.)

This default load balancing across all CPUs is not well suited to the following two situations:

- On large systems, load balancing across many CPUs is expensive. If the system is managed using cpusets to place independent jobs on separate sets of CPUs, full load balancing is unnecessary.
- Systems supporting real-time on some CPUs need to minimize system overhead on those CPUs, including avoiding process load balancing if that is not needed.

When the per-cpuset flag *sched_load_balance* is enabled (the default setting), it requests load balancing across all the CPUs in that cpuset's allowed CPUs, ensuring that load balancing can move a process (not otherwise pinned, as by *sched_setaffinity*(2)) from any CPU in that cpuset to any other.

When the per-cpuset flag *sched_load_balance* is disabled, then the scheduler will avoid load balancing across the CPUs in that cpuset, *except* in so far as is necessary because some overlapping cpuset has *sched_load_balance* enabled.

So, for example, if the top cpuset has the flag *sched_load_balance* enabled, then the scheduler will load balance across all CPUs, and the setting of the *sched_load_balance* flag in other cpusets has no effect, as we're already fully load balancing.

Therefore in the above two situations, the flag *sched_load_balance* should be disabled in the top cpuset, and only some of the smaller, child cpusets would have this flag enabled.

When doing this, you don't usually want to leave any unpinned processes in the top cpuset that might use nontrivial amounts of CPU, as such processes may be artificially constrained to some subset of CPUs, depending on the particulars of this flag setting in descendant cpusets. Even if such a process could use spare CPU cycles in some other CPUs, the kernel scheduler might not consider the possibility of load balancing that process to the underused CPU.

Of course, processes pinned to a particular CPU can be left in a cpuset that disables *sched_load_balance* as those processes aren't going anywhere else anyway.

Scheduler relax domain level

The kernel scheduler performs immediate load balancing whenever a CPU becomes free or another task becomes runnable. This load balancing works to ensure that as many CPUs as possible are usefully employed running tasks. The kernel also performs periodic load balancing off the software clock described in *time*(7). The setting of *sched_relax_domain_level* applies only to immediate load balancing. Regardless of the *sched_relax_domain_level* setting, periodic load balancing is attempted over all

CPUs (unless disabled by turning off *sched_load_balance*.) In any case, of course, tasks will be scheduled to run only on CPUs allowed by their cpuset, as modified by *sched_setaffinity*(2) system calls.

On small systems, such as those with just a few CPUs, immediate load balancing is useful to improve system interactivity and to minimize wasteful idle CPU cycles. But on large systems, attempting immediate load balancing across a large number of CPUs can be more costly than it is worth, depending on the particular performance characteristics of the job mix and the hardware.

The exact meaning of the small integer values of *sched_relax_domain_level* will depend on internal implementation details of the kernel scheduler code and on the non-uniform architecture of the hardware. Both of these will evolve over time and vary by system architecture and kernel version.

As of this writing, when this capability was introduced in Linux 2.6.26, on certain popular architectures, the positive values of *sched_relax_domain_level* have the following meanings.

1 Perform immediate load balancing across Hyper-Thread siblings on the same core.
2 Perform immediate load balancing across other cores in the same package.
3 Perform immediate load balancing across other CPUs on the same node or blade.
4 Perform immediate load balancing across over several (implementation detail) nodes [On NUMA systems].
5 Perform immediate load balancing across over all CPUs in system [On NUMA systems].

The *sched_relax_domain_level* value of zero (0) always means don't perform immediate load balancing, hence that load balancing is done only periodically, not immediately when a CPU becomes available or another task becomes runnable.

The *sched_relax_domain_level* value of minus one (−1) always means use the system default value. The system default value can vary by architecture and kernel version. This system default value can be changed by kernel boot-time "relax_domain_level=" argument.

In the case of multiple overlapping cpusets which have conflicting *sched_relax_domain_level* values, then the highest such value applies to all CPUs in any of the overlapping cpusets. In such cases, **−1** is the lowest value, overridden by any other value, and **0** is the next lowest value.

FORMATS

The following formats are used to represent sets of CPUs and memory nodes.

Mask format

The **Mask Format** is used to represent CPU and memory-node bit masks in the */proc/*pid*/status* file.

This format displays each 32-bit word in hexadecimal (using ASCII characters "0" - "9" and "a" - "f"); words are filled with leading zeros, if required. For masks longer than one word, a comma separator is used between words. Words are displayed in big-endian order, which has the most significant bit first. The hex digits within a word are also in big-endian order.

The number of 32-bit words displayed is the minimum number needed to display all bits of the bit mask, based on the size of the bit mask.

Examples of the **Mask Format**:

```
00000001                        # just bit 0 set
40000000,00000000,00000000      # just bit 94 set
00000001,00000000,00000000      # just bit 64 set
000000ff,00000000               # bits 32-39 set
00000000,000e3862               # 1,5,6,11-13,17-19 set
```

A mask with bits 0, 1, 2, 4, 8, 16, 32, and 64 set displays as:

```
00000001,00000001,00010117
```

The first "1" is for bit 64, the second for bit 32, the third for bit 16, the fourth for bit 8, the fifth for bit 4, and the "7" is for bits 2, 1, and 0.

List format

The **List Format** for *cpus* and *mems* is a comma-separated list of CPU or memory-node numbers and ranges of numbers, in ASCII decimal.

Examples of the **List Format**:

```
0-4,9           # bits 0, 1, 2, 3, 4, and 9 set
```

```
0-2,7,12-14     # bits 0, 1, 2, 7, 12, 13, and 14 set
```

RULES

The following rules apply to each cpuset:

- Its CPUs and memory nodes must be a (possibly equal) subset of its parent's.
- It can be marked *cpu_exclusive* only if its parent is.
- It can be marked *mem_exclusive* only if its parent is.
- If it is *cpu_exclusive*, its CPUs may not overlap any sibling.
- If it is *mem_exclusive*, its memory nodes may not overlap any sibling.

PERMISSIONS

The permissions of a cpuset are determined by the permissions of the directories and pseudo-files in the cpuset filesystem, normally mounted at */dev/cpuset*.

For instance, a process can put itself in some other cpuset (than its current one) if it can write the *tasks* file for that cpuset. This requires execute permission on the encompassing directories and write permission on the *tasks* file.

An additional constraint is applied to requests to place some other process in a cpuset. One process may not attach another to a cpuset unless it would have permission to send that process a signal (see *kill*(2)).

A process may create a child cpuset if it can access and write the parent cpuset directory. It can modify the CPUs or memory nodes in a cpuset if it can access that cpuset's directory (execute permissions on the each of the parent directories) and write the corresponding *cpus* or *mems* file.

There is one minor difference between the manner in which these permissions are evaluated and the manner in which normal filesystem operation permissions are evaluated. The kernel interprets relative pathnames starting at a process's current working directory. Even if one is operating on a cpuset file, relative pathnames are interpreted relative to the process's current working directory, not relative to the process's current cpuset. The only ways that cpuset paths relative to a process's current cpuset can be used are if either the process's current working directory is its cpuset (it first did a **cd** or *chdir*(2) to its cpuset directory beneath */dev/cpuset*, which is a bit unusual) or if some user code converts the relative cpuset path to a full filesystem path.

In theory, this means that user code should specify cpusets using absolute pathnames, which requires knowing the mount point of the cpuset filesystem (usually, but not necessarily, */dev/cpuset*). In practice, all user level code that this author is aware of simply assumes that if the cpuset filesystem is mounted, then it is mounted at */dev/cpuset*. Furthermore, it is common practice for carefully written user code to verify the presence of the pseudo-file */dev/cpuset/tasks* in order to verify that the cpuset pseudo-filesystem is currently mounted.

WARNINGS

Enabling memory_pressure

By default, the per-cpuset file *cpuset.memory_pressure* always contains zero (0). Unless this feature is enabled by writing "1" to the pseudo-file */dev/cpuset/cpuset.memory_pressure_enabled*, the kernel does not compute per-cpuset *memory_pressure*.

Using the echo command

When using the **echo** command at the shell prompt to change the values of cpuset files, beware that the built-in **echo** command in some shells does not display an error message if the *write*(2) system call fails. For example, if the command:

```
echo 19 > cpuset.mems
```

failed because memory node 19 was not allowed (perhaps the current system does not have a memory node 19), then the **echo** command might not display any error. It is better to use the **/bin/echo** external command to change cpuset file settings, as this command will display *write*(2) errors, as in the example:

```
/bin/echo 19 > cpuset.mems
/bin/echo: write error: Invalid argument
```

EXCEPTIONS

Memory placement

Not all allocations of system memory are constrained by cpusets, for the following reasons.

If hot-plug functionality is used to remove all the CPUs that are currently assigned to a cpuset, then the kernel will automatically update the *cpus_allowed* of all processes attached to CPUs in that cpuset to allow all CPUs. When memory hot-plug functionality for removing memory nodes is available, a similar exception is expected to apply there as well. In general, the kernel prefers to violate cpuset placement, rather than starving a process that has had all its allowed CPUs or memory nodes taken offline. User code should reconfigure cpusets to refer only to online CPUs and memory nodes when using hot-plug to add or remove such resources.

A few kernel-critical, internal memory-allocation requests, marked GFP_ATOMIC, must be satisfied immediately. The kernel may drop some request or malfunction if one of these allocations fail. If such a request cannot be satisfied within the current process's cpuset, then we relax the cpuset, and look for memory anywhere we can find it. It's better to violate the cpuset than stress the kernel.

Allocations of memory requested by kernel drivers while processing an interrupt lack any relevant process context, and are not confined by cpusets.

Renaming cpusets

You can use the *rename*(2) system call to rename cpusets. Only simple renaming is supported; that is, changing the name of a cpuset directory is permitted, but moving a directory into a different directory is not permitted.

ERRORS

The Linux kernel implementation of cpusets sets *errno* to specify the reason for a failed system call affecting cpusets.

The possible *errno* settings and their meaning when set on a failed cpuset call are as listed below.

E2BIG Attempted a *write*(2) on a special cpuset file with a length larger than some kernel-determined upper limit on the length of such writes.

EACCES
Attempted to *write*(2) the process ID (PID) of a process to a cpuset *tasks* file when one lacks permission to move that process.

EACCES
Attempted to add, using *write*(2), a CPU or memory node to a cpuset, when that CPU or memory node was not already in its parent.

EACCES
Attempted to set, using *write*(2), *cpuset.cpu_exclusive* or *cpuset.mem_exclusive* on a cpuset whose parent lacks the same setting.

EACCES
Attempted to *write*(2) a *cpuset.memory_pressure* file.

EACCES
Attempted to create a file in a cpuset directory.

EBUSY
Attempted to remove, using *rmdir*(2), a cpuset with attached processes.

EBUSY
Attempted to remove, using *rmdir*(2), a cpuset with child cpusets.

EBUSY
Attempted to remove a CPU or memory node from a cpuset that is also in a child of that cpuset.

EEXIST
Attempted to create, using *mkdir*(2), a cpuset that already exists.

EEXIST
Attempted to *rename*(2) a cpuset to a name that already exists.

EFAULT
Attempted to *read*(2) or *write*(2) a cpuset file using a buffer that is outside the writing processes accessible address space.

EINVAL
Attempted to change a cpuset, using *write*(2), in a way that would violate a *cpu_exclusive* or *mem_exclusive* attribute of that cpuset or any of its siblings.

EINVAL
Attempted to *write*(2) an empty *cpuset.cpus* or *cpuset.mems* list to a cpuset which has attached processes or child cpusets.

EINVAL
Attempted to *write*(2) a *cpuset.cpus* or *cpuset.mems* list which included a range with the second number smaller than the first number.

EINVAL
Attempted to *write*(2) a *cpuset.cpus* or *cpuset.mems* list which included an invalid character in the string.

EINVAL
Attempted to *write*(2) a list to a *cpuset.cpus* file that did not include any online CPUs.

EINVAL
Attempted to *write*(2) a list to a *cpuset.mems* file that did not include any online memory nodes.

EINVAL
Attempted to *write*(2) a list to a *cpuset.mems* file that included a node that held no memory.

EIO Attempted to *write*(2) a string to a cpuset *tasks* file that does not begin with an ASCII decimal integer.

EIO Attempted to *rename*(2) a cpuset into a different directory.

ENAMETOOLONG
Attempted to *read*(2) a */proc/*pid*/cpuset* file for a cpuset path that is longer than the kernel page size.

ENAMETOOLONG
Attempted to create, using *mkdir*(2), a cpuset whose base directory name is longer than 255 characters.

ENAMETOOLONG
Attempted to create, using *mkdir*(2), a cpuset whose full pathname, including the mount point (typically "/dev/cpuset/") prefix, is longer than 4095 characters.

ENODEV
The cpuset was removed by another process at the same time as a *write*(2) was attempted on one of the pseudo-files in the cpuset directory.

ENOENT
Attempted to create, using *mkdir*(2), a cpuset in a parent cpuset that doesn't exist.

ENOENT
Attempted to *access*(2) or *open*(2) a nonexistent file in a cpuset directory.

ENOMEM
Insufficient memory is available within the kernel; can occur on a variety of system calls affecting cpusets, but only if the system is extremely short of memory.

ENOSPC
Attempted to *write*(2) the process ID (PID) of a process to a cpuset *tasks* file when the cpuset had an empty *cpuset.cpus* or empty *cpuset.mems* setting.

ENOSPC
Attempted to *write*(2) an empty *cpuset.cpus* or *cpuset.mems* setting to a cpuset that has tasks attached.

ENOTDIR
Attempted to *rename*(2) a nonexistent cpuset.

EPERM
Attempted to remove a file from a cpuset directory.

ERANGE
Specified a *cpuset.cpus* or *cpuset.mems* list to the kernel which included a number too large for the kernel to set in its bit masks.

ESRCH
Attempted to *write*(2) the process ID (PID) of a nonexistent process to a cpuset *tasks* file.

VERSIONS

Cpusets appeared in Linux 2.6.12.

NOTES

Despite its name, the *pid* parameter is actually a thread ID, and each thread in a threaded group can be attached to a different cpuset. The value returned from a call to *gettid*(2) can be passed in the argument *pid*.

BUGS

cpuset.memory_pressure cpuset files can be opened for writing, creation, or truncation, but then the *write*(2) fails with *errno* set to **EACCES**, and the creation and truncation options on *open*(2) have no effect.

EXAMPLES

The following examples demonstrate querying and setting cpuset options using shell commands.

Creating and attaching to a cpuset.

To create a new cpuset and attach the current command shell to it, the steps are:

(1) mkdir /dev/cpuset (if not already done)
(2) mount −t cpuset none /dev/cpuset (if not already done)
(3) Create the new cpuset using *mkdir*(1)
(4) Assign CPUs and memory nodes to the new cpuset.
(5) Attach the shell to the new cpuset.

For example, the following sequence of commands will set up a cpuset named "Charlie", containing just CPUs 2 and 3, and memory node 1, and then attach the current shell to that cpuset.

```
$ mkdir /dev/cpuset
$ mount -t cpuset cpuset /dev/cpuset
$ cd /dev/cpuset
$ mkdir Charlie
$ cd Charlie
$ /bin/echo 2-3 > cpuset.cpus
$ /bin/echo 1 > cpuset.mems
$ /bin/echo $$ > tasks
# The current shell is now running in cpuset Charlie
# The next line should display '/Charlie'
$ cat /proc/self/cpuset
```

Migrating a job to different memory nodes.

To migrate a job (the set of processes attached to a cpuset) to different CPUs and memory nodes in the system, including moving the memory pages currently allocated to that job, perform the following steps.

(1) Let's say we want to move the job in cpuset *alpha* (CPUs 4–7 and memory nodes 2–3) to a new cpuset *beta* (CPUs 16–19 and memory nodes 8–9).
(2) First create the new cpuset *beta*.
(3) Then allow CPUs 16–19 and memory nodes 8–9 in *beta*.
(4) Then enable *memory_migration* in *beta*.
(5) Then move each process from *alpha* to *beta*.

The following sequence of commands accomplishes this.

```
$ cd /dev/cpuset
```

```
$ mkdir beta
$ cd beta
$ /bin/echo 16-19 > cpuset.cpus
$ /bin/echo 8-9 > cpuset.mems
$ /bin/echo 1 > cpuset.memory_migrate
$ while read i; do /bin/echo $i; done < ../alpha/tasks > tasks
```

The above should move any processes in *alpha* to *beta*, and any memory held by these processes on memory nodes 2–3 to memory nodes 8–9, respectively.

Notice that the last step of the above sequence did not do:

```
$ cp ../alpha/tasks tasks
```

The *while* loop, rather than the seemingly easier use of the *cp*(1) command, was necessary because only one process PID at a time may be written to the *tasks* file.

The same effect (writing one PID at a time) as the *while* loop can be accomplished more efficiently, in fewer keystrokes and in syntax that works on any shell, but alas more obscurely, by using the **-u** (unbuffered) option of *sed*(1):

```
$ sed -un p < ../alpha/tasks > tasks
```

NAME

credentials − process identifiers

DESCRIPTION

Process ID (PID)

Each process has a unique nonnegative integer identifier that is assigned when the process is created using *fork*(2). A process can obtain its PID using *getpid*(2). A PID is represented using the type *pid_t* (defined in <*sys/types.h*>).

PIDs are used in a range of system calls to identify the process affected by the call, for example: *kill*(2), *ptrace*(2), *setpriority*(2), *setpgid*(2), *setsid*(2), *sigqueue*(3), and *waitpid*(2).

A process's PID is preserved across an *execve*(2).

Parent process ID (PPID)

A process's parent process ID identifies the process that created this process using *fork*(2). A process can obtain its PPID using *getppid*(2). A PPID is represented using the type *pid_t*.

A process's PPID is preserved across an *execve*(2).

Process group ID and session ID

Each process has a session ID and a process group ID, both represented using the type *pid_t*. A process can obtain its session ID using *getsid*(2), and its process group ID using *getpgrp*(2).

A child created by *fork*(2) inherits its parent's session ID and process group ID. A process's session ID and process group ID are preserved across an *execve*(2).

Sessions and process groups are abstractions devised to support shell job control. A process group (sometimes called a "job") is a collection of processes that share the same process group ID; the shell creates a new process group for the process(es) used to execute single command or pipeline (e.g., the two processes created to execute the command "ls | wc" are placed in the same process group). A process's group membership can be set using *setpgid*(2). The process whose process ID is the same as its process group ID is the *process group leader* for that group.

A session is a collection of processes that share the same session ID. All of the members of a process group also have the same session ID (i.e., all of the members of a process group always belong to the same session, so that sessions and process groups form a strict two-level hierarchy of processes.) A new session is created when a process calls *setsid*(2), which creates a new session whose session ID is the same as the PID of the process that called *setsid*(2). The creator of the session is called the *session leader*.

All of the processes in a session share a *controlling terminal*. The controlling terminal is established when the session leader first opens a terminal (unless the **O_NOCTTY** flag is specified when calling *open*(2)). A terminal may be the controlling terminal of at most one session.

At most one of the jobs in a session may be the *foreground job*; other jobs in the session are *background jobs*. Only the foreground job may read from the terminal; when a process in the background attempts to read from the terminal, its process group is sent a **SIGTTIN** signal, which suspends the job. If the **TOSTOP** flag has been set for the terminal (see *termios*(3)), then only the foreground job may write to the terminal; writes from background jobs cause a **SIGTTOU** signal to be generated, which suspends the job. When terminal keys that generate a signal (such as the *interrupt* key, normally control-C) are pressed, the signal is sent to the processes in the foreground job.

Various system calls and library functions may operate on all members of a process group, including *kill*(2), *killpg*(3), *getpriority*(2), *setpriority*(2), *ioprio_get*(2), *ioprio_set*(2), *waitid*(2), and *waitpid*(2). See also the discussion of the **F_GETOWN**, **F_GETOWN_EX**, **F_SETOWN**, and **F_SETOWN_EX** operations in *fcntl*(2).

User and group identifiers

Each process has various associated user and group IDs. These IDs are integers, respectively represented using the types *uid_t* and *gid_t* (defined in <*sys/types.h*>).

On Linux, each process has the following user and group identifiers:

- Real user ID and real group ID. These IDs determine who owns the process. A process can obtain its real user (group) ID using *getuid*(2) (**getgid**(2)).

- Effective user ID and effective group ID. These IDs are used by the kernel to determine the permissions that the process will have when accessing shared resources such as message queues, shared memory, and semaphores. On most UNIX systems, these IDs also determine the permissions when accessing files. However, Linux uses the filesystem IDs described below for this task. A process can obtain its effective user (group) ID using *geteuid*(2) (**getegid**(2)).
- Saved set-user-ID and saved set-group-ID. These IDs are used in set-user-ID and set-group-ID programs to save a copy of the corresponding effective IDs that were set when the program was executed (see *execve*(2)). A set-user-ID program can assume and drop privileges by switching its effective user ID back and forth between the values in its real user ID and saved set-user-ID. This switching is done via calls to *seteuid*(2), *setreuid*(2), or *setresuid*(2). A set-group-ID program performs the analogous tasks using *setegid*(2), *setregid*(2), or *setresgid*(2). A process can obtain its saved set-user-ID (set-group-ID) using *getresuid*(2) (**getresgid**(2)).
- Filesystem user ID and filesystem group ID (Linux-specific). These IDs, in conjunction with the supplementary group IDs described below, are used to determine permissions for accessing files; see *path_resolution*(7) for details. Whenever a process's effective user (group) ID is changed, the kernel also automatically changes the filesystem user (group) ID to the same value. Consequently, the filesystem IDs normally have the same values as the corresponding effective ID, and the semantics for file-permission checks are thus the same on Linux as on other UNIX systems. The filesystem IDs can be made to differ from the effective IDs by calling *setfsuid*(2) and *setfsgid*(2).
- Supplementary group IDs. This is a set of additional group IDs that are used for permission checks when accessing files and other shared resources. Before Linux 2.6.4, a process can be a member of up to 32 supplementary groups; since Linux 2.6.4, a process can be a member of up to 65536 supplementary groups. The call *sysconf(_SC_NGROUPS_MAX)* can be used to determine the number of supplementary groups of which a process may be a member. A process can obtain its set of supplementary group IDs using *getgroups*(2).

A child process created by *fork*(2) inherits copies of its parent's user and groups IDs. During an *execve*(2), a process's real user and group ID and supplementary group IDs are preserved; the effective and saved set IDs may be changed, as described in *execve*(2).

Aside from the purposes noted above, a process's user IDs are also employed in a number of other contexts:

- when determining the permissions for sending signals (see *kill*(2));
- when determining the permissions for setting process-scheduling parameters (nice value, real time scheduling policy and priority, CPU affinity, I/O priority) using *setpriority*(2), *sched_setaffinity*(2), *sched_setscheduler*(2), *sched_setparam*(2), *sched_setattr*(2), and *ioprio_set*(2);
- when checking resource limits (see *getrlimit*(2));
- when checking the limit on the number of inotify instances that the process may create (see *inotify*(7)).

Modifying process user and group IDs

Subject to rules described in the relevant manual pages, a process can use the following APIs to modify its user and group IDs:

setuid(2) (*setgid*(2))
: Modify the process's real (and possibly effective and saved-set) user (group) IDs.

seteuid(2) (*setegid*(2))
: Modify the process's effective user (group) ID.

setfsuid(2) (*setfsgid*(2))
: Modify the process's filesystem user (group) ID.

setreuid(2) (*setregid*(2))
: Modify the process's real and effective (and possibly saved-set) user (group) IDs.

setresuid(2) (*setresgid*(2))
: Modify the process's real, effective, and saved-set user (group) IDs.

setgroups(2)
: Modify the process's supplementary group list.

Any changes to a process's effective user (group) ID are automatically carried over to the process's filesystem user (group) ID. Changes to a process's effective user or group ID can also affect the process "dumpable" attribute, as described in *prctl*(2).

Changes to process user and group IDs can affect the capabilities of the process, as described in *capabilities*(7).

STANDARDS

Process IDs, parent process IDs, process group IDs, and session IDs are specified in POSIX.1. The real, effective, and saved set user and groups IDs, and the supplementary group IDs, are specified in POSIX.1.

The filesystem user and group IDs are a Linux extension.

NOTES

Various fields in the */proc/*pid*/status* file show the process credentials described above. See *proc*(5) for further information.

The POSIX threads specification requires that credentials are shared by all of the threads in a process. However, at the kernel level, Linux maintains separate user and group credentials for each thread. The NPTL threading implementation does some work to ensure that any change to user or group credentials (e.g., calls to *setuid*(2), *setresuid*(2)) is carried through to all of the POSIX threads in a process. See *nptl*(7) for further details.

NAME

ddp − Linux AppleTalk protocol implementation

SYNOPSIS

#include <sys/socket.h>
#include <netatalk/at.h>

ddp_socket = **socket(AF_APPLETALK, SOCK_DGRAM, 0);**
raw_socket = **socket(AF_APPLETALK, SOCK_RAW,** *protocol***);**

DESCRIPTION

Linux implements the AppleTalk protocols described in *Inside AppleTalk*. Only the DDP layer and AARP are present in the kernel. They are designed to be used via the **netatalk** protocol libraries. This page documents the interface for those who wish or need to use the DDP layer directly.

The communication between AppleTalk and the user program works using a BSD-compatible socket interface. For more information on sockets, see *socket*(7).

An AppleTalk socket is created by calling the *socket*(2) function with a **AF_APPLETALK** socket family argument. Valid socket types are **SOCK_DGRAM** to open a **ddp** socket or **SOCK_RAW** to open a **raw** socket. *protocol* is the AppleTalk protocol to be received or sent. For **SOCK_RAW** you must specify **ATPROTO_DDP**.

Raw sockets may be opened only by a process with effective user ID 0 or when the process has the **CAP_NET_RAW** capability.

Address format

An AppleTalk socket address is defined as a combination of a network number, a node number, and a port number.

```
struct at_addr {
    unsigned short s_net;
    unsigned char  s_node;
};

struct sockaddr_atalk {
    sa_family_t    sat_family;    /* address family */
    unsigned char  sat_port;      /* port */
    struct at_addr sat_addr;      /* net/node */
};
```

sat_family is always set to **AF_APPLETALK**. *sat_port* contains the port. The port numbers below 129 are known as *reserved ports*. Only processes with the effective user ID 0 or the **CAP_NET_BIND_SERVICE** capability may *bind*(2) to these sockets. *sat_addr* is the host address. The *net* member of *struct at_addr* contains the host network in network byte order. The value of **AT_ANYNET** is a wildcard and also implies "this network." The *node* member of *struct at_addr* contains the host node number. The value of **AT_ANYNODE** is a wildcard and also implies "this node." The value of **ATADDR_BCAST** is a link local broadcast address.

Socket options

No protocol-specific socket options are supported.

/proc interfaces

IP supports a set of */proc* interfaces to configure some global AppleTalk parameters. The parameters can be accessed by reading or writing files in the directory */proc/sys/net/atalk/* .

aarp−expiry−time
The time interval (in seconds) before an AARP cache entry expires.

aarp−resolve−time
The time interval (in seconds) before an AARP cache entry is resolved.

aarp−retransmit−limit
The number of retransmissions of an AARP query before the node is declared dead.

aarp−tick−time
The timer rate (in seconds) for the timer driving AARP.

The default values match the specification and should never need to be changed.

Ioctls

All ioctls described in *socket*(7) apply to DDP.

ERRORS

EACCES
The user tried to execute an operation without the necessary permissions. These include sending to a broadcast address without having the broadcast flag set, and trying to bind to a reserved port without effective user ID 0 or **CAP_NET_BIND_SERVICE**.

EADDRINUSE
Tried to bind to an address already in use.

EADDRNOTAVAIL
A nonexistent interface was requested or the requested source address was not local.

EAGAIN
Operation on a nonblocking socket would block.

EALREADY
A connection operation on a nonblocking socket is already in progress.

ECONNABORTED
A connection was closed during an *accept*(2).

EHOSTUNREACH
No routing table entry matches the destination address.

EINVAL
Invalid argument passed.

EISCONN
connect(2) was called on an already connected socket.

EMSGSIZE
Datagram is bigger than the DDP MTU.

ENODEV
Network device not available or not capable of sending IP.

ENOENT
SIOCGSTAMP was called on a socket where no packet arrived.

ENOMEM and **ENOBUFS**
Not enough memory available.

ENOPKG
A kernel subsystem was not configured.

ENOPROTOOPT and **EOPNOTSUPP**
Invalid socket option passed.

ENOTCONN
The operation is defined only on a connected socket, but the socket wasn't connected.

EPERM
User doesn't have permission to set high priority, make a configuration change, or send signals to the requested process or group.

EPIPE The connection was unexpectedly closed or shut down by the other end.

ESOCKTNOSUPPORT
The socket was unconfigured, or an unknown socket type was requested.

VERSIONS

AppleTalk is supported by Linux 2.0 or higher. The */proc* interfaces exist since Linux 2.2.

NOTES

Be very careful with the **SO_BROADCAST** option; it is not privileged in Linux. It is easy to overload the network with careless sending to broadcast addresses.

Compatibility

The basic AppleTalk socket interface is compatible with **netatalk** on BSD-derived systems. Many BSD systems fail to check **SO_BROADCAST** when sending broadcast frames; this can lead to compatibility problems.

The raw socket mode is unique to Linux and exists to support the alternative CAP package and AppleTalk monitoring tools more easily.

BUGS

There are too many inconsistent error values.

The ioctls used to configure routing tables, devices, AARP tables, and other devices are not yet described.

SEE ALSO

recvmsg(2), *sendmsg*(2), *capabilities*(7), *socket*(7)

NAME

environ − user environment

SYNOPSIS

extern char *****environ*;**

DESCRIPTION

The variable *environ* points to an array of pointers to strings called the "environment". The last pointer in this array has the value NULL. This array of strings is made available to the process by the *execve*(2) call when a new program is started. When a child process is created via *fork*(2), it inherits a *copy* of its parent's environment.

By convention, the strings in *environ* have the form "*name*=*value*". The name is case-sensitive and may not contain the character "=". The value can be anything that can be represented as a string. The name and the value may not contain an embedded null byte ('\0'), since this is assumed to terminate the string.

Environment variables may be placed in the shell's environment by the *export* command in *sh*(1), or by the *setenv* command if you use *csh*(1)

The initial environment of the shell is populated in various ways, such as definitions from */etc/environment* that are processed by *pam_env*(8) for all users at login time (on systems that employ *pam*(8)). In addition, various shell initialization scripts, such as the system-wide */etc/profile* script and per-user initializations script may include commands that add variables to the shell's environment; see the manual page of your preferred shell for details.

Bourne-style shells support the syntax

```
NAME=value command
```

to create an environment variable definition only in the scope of the process that executes *command*. Multiple variable definitions, separated by white space, may precede *command*.

Arguments may also be placed in the environment at the point of an *exec*(3). A C program can manipulate its environment using the functions *getenv*(3), *putenv*(3), *setenv*(3), and *unsetenv*(3).

What follows is a list of environment variables typically seen on a system. This list is incomplete and includes only common variables seen by average users in their day-to-day routine. Environment variables specific to a particular program or library function are documented in the ENVIRONMENT section of the appropriate manual page.

USER The name of the logged-in user (used by some BSD-derived programs). Set at login time, see section NOTES below.

LOGNAME
The name of the logged-in user (used by some System-V derived programs). Set at login time, see section NOTES below.

HOME
A user's login directory. Set at login time, see section NOTES below.

LANG The name of a locale to use for locale categories when not overridden by **LC_ALL** or more specific environment variables such as **LC_COLLATE**, **LC_CTYPE**, **LC_MESSAGES**, **LC_MONETARY**, **LC_NUMERIC**, and **LC_TIME** (see *locale*(7) for further details of the **LC_*** environment variables).

PATH The sequence of directory prefixes that *sh*(1) and many other programs employ when searching for an executable file that is specified as a simple filename (i.a., a pathname that contains no slashes). The prefixes are separated by colons (**:**). The list of prefixes is searched from beginning to end, by checking the pathname formed by concatenating a prefix, a slash, and the filename, until a file with execute permission is found.

As a legacy feature, a zero-length prefix (specified as two adjacent colons, or an initial or terminating colon) is interpreted to mean the current working directory. However, use of this feature is deprecated, and POSIX notes that a conforming application shall use an explicit pathname (e.g., .) to specify the current working directory.

Analogously to **PATH**, one has **CDPATH** used by some shells to find the target of a change directory command, **MANPATH** used by *man*(1) to find manual pages, and so on.

PWD Absolute path to the current working directory; required to be partially canonical (no . or .. components).

SHELL
The absolute pathname of the user's login shell. Set at login time, see section NOTES below.

TERM The terminal type for which output is to be prepared.

PAGER
The user's preferred utility to display text files. Any string acceptable as a command-string operand to the *sh* −*c* command shall be valid. If **PAGER** is null or is not set, then applications that launch a pager will default to a program such as *less*(1) or *more*(1)

EDITOR/VISUAL
The user's preferred utility to edit text files. Any string acceptable as a command_string operand to the *sh* −*c* command shall be valid.

Note that the behavior of many programs and library routines is influenced by the presence or value of certain environment variables. Examples include the following:

- The variables **LANG**, **LANGUAGE**, **NLSPATH**, **LOCPATH**, **LC_ALL**, **LC_MESSAGES**, and so on influence locale handling; see *catopen*(3), *gettext*(3), and *locale*(7).
- **TMPDIR** influences the path prefix of names created by *tempnam*(3) and other routines, and the temporary directory used by *sort*(1) and other programs.
- **LD_LIBRARY_PATH**, **LD_PRELOAD**, and other **LD_*** variables influence the behavior of the dynamic loader/linker. See also *ld.so*(8).
- **POSIXLY_CORRECT** makes certain programs and library routines follow the prescriptions of POSIX.
- The behavior of *malloc*(3) is influenced by **MALLOC_*** variables.
- The variable **HOSTALIASES** gives the name of a file containing aliases to be used with *gethostbyname*(3).
- **TZ** and **TZDIR** give timezone information used by *tzset*(3) and through that by functions like *ctime*(3), *localtime*(3), *mktime*(3), *strftime*(3). See also *tzselect*(8).
- **TERMCAP** gives information on how to address a given terminal (or gives the name of a file containing such information).
- **COLUMNS** and **LINES** tell applications about the window size, possibly overriding the actual size.
- **PRINTER** or **LPDEST** may specify the desired printer to use. See *lpr*(1)

NOTES

Historically and by standard, *environ* must be declared in the user program. However, as a (nonstandard) programmer convenience, *environ* is declared in the header file <*unistd.h*> if the **_GNU_SOURCE** feature test macro is defined (see *feature_test_macros*(7)).

The *prctl*(2) **PR_SET_MM_ENV_START** and **PR_SET_MM_ENV_END** operations can be used to control the location of the process's environment.

The **HOME**, **LOGNAME**, **SHELL**, and **USER** variables are set when the user is changed via a session management interface, typically by a program such as *login*(1) from a user database (such as *passwd*(5)). (Switching to the root user using *su*(1) may result in a mixed environment where **LOGNAME** and **USER** are retained from old user; see the *su*(1) manual page.)

BUGS

Clearly there is a security risk here. Many a system command has been tricked into mischief by a user who specified unusual values for **IFS** or **LD_LIBRARY_PATH**.

There is also the risk of name space pollution. Programs like *make* and *autoconf* allow overriding of default utility names from the environment with similarly named variables in all caps. Thus one uses **CC** to select the desired C compiler (and similarly **MAKE**, **AR**, **AS**, **FC**, **LD**, **LEX**, **RM**, **YACC**, etc.). However, in some traditional uses such an environment variable gives options for the program instead of a pathname. Thus, one has **MORE** and **LESS**. Such usage is considered mistaken, and to be avoided in new programs.

NAME

epoll − I/O event notification facility

SYNOPSIS

#include <sys/epoll.h>

DESCRIPTION

The **epoll** API performs a similar task to *poll*(2): monitoring multiple file descriptors to see if I/O is possible on any of them. The **epoll** API can be used either as an edge-triggered or a level-triggered interface and scales well to large numbers of watched file descriptors.

The central concept of the **epoll** API is the **epoll** *instance*, an in-kernel data structure which, from a user-space perspective, can be considered as a container for two lists:

- The *interest* list (sometimes also called the **epoll** set): the set of file descriptors that the process has registered an interest in monitoring.
- The *ready* list: the set of file descriptors that are "ready" for I/O. The ready list is a subset of (or, more precisely, a set of references to) the file descriptors in the interest list. The ready list is dynamically populated by the kernel as a result of I/O activity on those file descriptors.

The following system calls are provided to create and manage an **epoll** instance:

- *epoll_create*(2) creates a new **epoll** instance and returns a file descriptor referring to that instance. (The more recent *epoll_create1*(2) extends the functionality of *epoll_create*(2).)
- Interest in particular file descriptors is then registered via *epoll_ctl*(2), which adds items to the interest list of the **epoll** instance.
- *epoll_wait*(2) waits for I/O events, blocking the calling thread if no events are currently available. (This system call can be thought of as fetching items from the ready list of the **epoll** instance.)

Level-triggered and edge-triggered

The **epoll** event distribution interface is able to behave both as edge-triggered (ET) and as level-triggered (LT). The difference between the two mechanisms can be described as follows. Suppose that this scenario happens:

(1) The file descriptor that represents the read side of a pipe (*rfd*) is registered on the **epoll** instance.

(2) A pipe writer writes 2 kB of data on the write side of the pipe.

(3) A call to *epoll_wait*(2) is done that will return *rfd* as a ready file descriptor.

(4) The pipe reader reads 1 kB of data from *rfd*.

(5) A call to *epoll_wait*(2) is done.

If the *rfd* file descriptor has been added to the **epoll** interface using the **EPOLLET** (edge-triggered) flag, the call to *epoll_wait*(2) done in step **5** will probably hang despite the available data still present in the file input buffer; meanwhile the remote peer might be expecting a response based on the data it already sent. The reason for this is that edge-triggered mode delivers events only when changes occur on the monitored file descriptor. So, in step **5** the caller might end up waiting for some data that is already present inside the input buffer. In the above example, an event on *rfd* will be generated because of the write done in **2** and the event is consumed in **3**. Since the read operation done in **4** does not consume the whole buffer data, the call to *epoll_wait*(2) done in step **5** might block indefinitely.

An application that employs the **EPOLLET** flag should use nonblocking file descriptors to avoid having a blocking read or write starve a task that is handling multiple file descriptors. The suggested way to use **epoll** as an edge-triggered (**EPOLLET**) interface is as follows:

(1) with nonblocking file descriptors; and

(2) by waiting for an event only after *read*(2) or *write*(2) return **EAGAIN**.

By contrast, when used as a level-triggered interface (the default, when **EPOLLET** is not specified), **epoll** is simply a faster *poll*(2), and can be used wherever the latter is used since it shares the same semantics.

Since even with edge-triggered **epoll**, multiple events can be generated upon receipt of multiple chunks of data, the caller has the option to specify the **EPOLLONESHOT** flag, to tell **epoll** to disable the associated file descriptor after the receipt of an event with *epoll_wait*(2). When the **EPOLLONESHOT**

flag is specified, it is the caller's responsibility to rearm the file descriptor using *epoll_ctl*(2) with **EPOLL_CTL_MOD**.

If multiple threads (or processes, if child processes have inherited the **epoll** file descriptor across *fork*(2)) are blocked in *epoll_wait*(2) waiting on the same epoll file descriptor and a file descriptor in the interest list that is marked for edge-triggered (**EPOLLET**) notification becomes ready, just one of the threads (or processes) is awoken from *epoll_wait*(2). This provides a useful optimization for avoiding "thundering herd" wake-ups in some scenarios.

Interaction with autosleep

If the system is in **autosleep** mode via */sys/power/autosleep* and an event happens which wakes the device from sleep, the device driver will keep the device awake only until that event is queued. To keep the device awake until the event has been processed, it is necessary to use the *epoll_ctl*(2) **EPOLLWAKEUP** flag.

When the **EPOLLWAKEUP** flag is set in the **events** field for a *struct epoll_event*, the system will be kept awake from the moment the event is queued, through the *epoll_wait*(2) call which returns the event until the subsequent *epoll_wait*(2) call. If the event should keep the system awake beyond that time, then a separate *wake_lock* should be taken before the second *epoll_wait*(2) call.

/proc interfaces

The following interfaces can be used to limit the amount of kernel memory consumed by epoll:

/proc/sys/fs/epoll/max_user_watches (since Linux 2.6.28)

This specifies a limit on the total number of file descriptors that a user can register across all epoll instances on the system. The limit is per real user ID. Each registered file descriptor costs roughly 90 bytes on a 32-bit kernel, and roughly 160 bytes on a 64-bit kernel. Currently, the default value for *max_user_watches* is 1/25 (4%) of the available low memory, divided by the registration cost in bytes.

Example for suggested usage

While the usage of **epoll** when employed as a level-triggered interface does have the same semantics as *poll*(2), the edge-triggered usage requires more clarification to avoid stalls in the application event loop. In this example, listener is a nonblocking socket on which *listen*(2) has been called. The function *do_use_fd()* uses the new ready file descriptor until **EAGAIN** is returned by either *read*(2) or *write*(2). An event-driven state machine application should, after having received **EAGAIN**, record its current state so that at the next call to *do_use_fd()* it will continue to *read*(2) or *write*(2) from where it stopped before.

```
#define MAX_EVENTS 10
struct epoll_event ev, events[MAX_EVENTS];
int listen_sock, conn_sock, nfds, epollfd;

/* Code to set up listening socket, 'listen_sock',
   (socket(), bind(), listen()) omitted. */

epollfd = epoll_create1(0);
if (epollfd == -1) {
    perror("epoll_create1");
    exit(EXIT_FAILURE);
}

ev.events = EPOLLIN;
ev.data.fd = listen_sock;
if (epoll_ctl(epollfd, EPOLL_CTL_ADD, listen_sock, &ev) == -1) {
    perror("epoll_ctl: listen_sock");
    exit(EXIT_FAILURE);
}

for (;;) {
    nfds = epoll_wait(epollfd, events, MAX_EVENTS, -1);
    if (nfds == -1) {
        perror("epoll_wait");
```

```
            exit(EXIT_FAILURE);
        }

        for (n = 0; n < nfds; ++n) {
            if (events[n].data.fd == listen_sock) {
                conn_sock = accept(listen_sock,
                                   (struct sockaddr *) &addr, &addrlen);
                if (conn_sock == -1) {
                    perror("accept");
                    exit(EXIT_FAILURE);
                }
                setnonblocking(conn_sock);
                ev.events = EPOLLIN | EPOLLET;
                ev.data.fd = conn_sock;
                if (epoll_ctl(epollfd, EPOLL_CTL_ADD, conn_sock,
                              &ev) == -1) {
                    perror("epoll_ctl: conn_sock");
                    exit(EXIT_FAILURE);
                }
            } else {
                do_use_fd(events[n].data.fd);
            }
        }
    }
```

When used as an edge-triggered interface, for performance reasons, it is possible to add the file descriptor inside the **epoll** interface (**EPOLL_CTL_ADD**) once by specifying (**EPOLLIN**|**EPOLLOUT**). This allows you to avoid continuously switching between **EPOLLIN** and **EPOLLOUT** calling *epoll_ctl*(2) with **EPOLL_CTL_MOD**.

Questions and answers

- What is the key used to distinguish the file descriptors registered in an interest list?

  The key is the combination of the file descriptor number and the open file description (also known as an "open file handle", the kernel's internal representation of an open file).

- What happens if you register the same file descriptor on an **epoll** instance twice?

  You will probably get **EEXIST**. However, it is possible to add a duplicate (**dup**(2), *dup2*(2), *fcntl*(2) **F_DUPFD**) file descriptor to the same **epoll** instance. This can be a useful technique for filtering events, if the duplicate file descriptors are registered with different *events* masks.

- Can two **epoll** instances wait for the same file descriptor? If so, are events reported to both **epoll** file descriptors?

  Yes, and events would be reported to both. However, careful programming may be needed to do this correctly.

- Is the **epoll** file descriptor itself poll/epoll/selectable?

  Yes. If an **epoll** file descriptor has events waiting, then it will indicate as being readable.

- What happens if one attempts to put an **epoll** file descriptor into its own file descriptor set?

  The *epoll_ctl*(2) call fails (**EINVAL**). However, you can add an **epoll** file descriptor inside another **epoll** file descriptor set.

- Can I send an **epoll** file descriptor over a UNIX domain socket to another process?

  Yes, but it does not make sense to do this, since the receiving process would not have copies of the file descriptors in the interest list.

- Will closing a file descriptor cause it to be removed from all **epoll** interest lists?

  Yes, but be aware of the following point. A file descriptor is a reference to an open file description (see *open*(2)). Whenever a file descriptor is duplicated via *dup*(2), *dup2*(2), *fcntl*(2) **F_DUPFD**, or *fork*(2), a new file descriptor referring to the same open file description is created. An open file description continues to exist until all file descriptors referring to it have been closed.

A file descriptor is removed from an interest list only after all the file descriptors referring to the underlying open file description have been closed. This means that even after a file descriptor that is part of an interest list has been closed, events may be reported for that file descriptor if other file descriptors referring to the same underlying file description remain open. To prevent this happening, the file descriptor must be explicitly removed from the interest list (using *epoll_ctl*(2) **EPOLL_CTL_DEL**) before it is duplicated. Alternatively, the application must ensure that all file descriptors are closed (which may be difficult if file descriptors were duplicated behind the scenes by library functions that used *dup*(2) or *fork*(2)).

- If more than one event occurs between *epoll_wait*(2) calls, are they combined or reported separately?

  They will be combined.

- Does an operation on a file descriptor affect the already collected but not yet reported events?

  You can do two operations on an existing file descriptor. Remove would be meaningless for this case. Modify will reread available I/O.

- Do I need to continuously read/write a file descriptor until **EAGAIN** when using the **EPOLLET** flag (edge-triggered behavior)?

  Receiving an event from *epoll_wait*(2) should suggest to you that such file descriptor is ready for the requested I/O operation. You must consider it ready until the next (nonblocking) read/write yields **EAGAIN**. When and how you will use the file descriptor is entirely up to you.

  For packet/token-oriented files (e.g., datagram socket, terminal in canonical mode), the only way to detect the end of the read/write I/O space is to continue to read/write until **EAGAIN**.

  For stream-oriented files (e.g., pipe, FIFO, stream socket), the condition that the read/write I/O space is exhausted can also be detected by checking the amount of data read from / written to the target file descriptor. For example, if you call *read*(2) by asking to read a certain amount of data and *read*(2) returns a lower number of bytes, you can be sure of having exhausted the read I/O space for the file descriptor. The same is true when writing using *write*(2). (Avoid this latter technique if you cannot guarantee that the monitored file descriptor always refers to a stream-oriented file.)

Possible pitfalls and ways to avoid them

- **Starvation (edge-triggered)**

  If there is a large amount of I/O space, it is possible that by trying to drain it the other files will not get processed causing starvation. (This problem is not specific to **epoll**.)

  The solution is to maintain a ready list and mark the file descriptor as ready in its associated data structure, thereby allowing the application to remember which files need to be processed but still round robin amongst all the ready files. This also supports ignoring subsequent events you receive for file descriptors that are already ready.

- **If using an event cache...**

  If you use an event cache or store all the file descriptors returned from *epoll_wait*(2), then make sure to provide a way to mark its closure dynamically (i.e., caused by a previous event's processing). Suppose you receive 100 events from *epoll_wait*(2), and in event #47 a condition causes event #13 to be closed. If you remove the structure and *close*(2) the file descriptor for event #13, then your event cache might still say there are events waiting for that file descriptor causing confusion.

  One solution for this is to call, during the processing of event 47, *epoll_ctl*(*EPOLL_CTL_DEL*) to delete file descriptor 13 and *close*(2), then mark its associated data structure as removed and link it to a cleanup list. If you find another event for file descriptor 13 in your batch processing, you will discover the file descriptor had been previously removed and there will be no confusion.

VERSIONS

Some other systems provide similar mechanisms; for example, FreeBSD has *kqueue*, and Solaris has */dev/poll*.

STANDARDS

Linux.

HISTORY

Linux 2.5.44. glibc 2.3.2.

NOTES

The set of file descriptors that is being monitored via an epoll file descriptor can be viewed via the entry for the epoll file descriptor in the process's */proc/*pid*/fdinfo* directory. See *proc*(5) for further details.

The *kcmp*(2) **KCMP_EPOLL_TFD** operation can be used to test whether a file descriptor is present in an epoll instance.

NAME

fanotify − monitoring filesystem events

DESCRIPTION

The fanotify API provides notification and interception of filesystem events. Use cases include virus scanning and hierarchical storage management. In the original fanotify API, only a limited set of events was supported. In particular, there was no support for create, delete, and move events. The support for those events was added in Linux 5.1. (See *inotify*(7) for details of an API that did notify those events pre Linux 5.1.)

Additional capabilities compared to the *inotify*(7) API include the ability to monitor all of the objects in a mounted filesystem, the ability to make access permission decisions, and the possibility to read or modify files before access by other applications.

The following system calls are used with this API: *fanotify_init*(2), *fanotify_mark*(2), *read*(2), *write*(2), and *close*(2).

fanotify_init(), fanotify_mark(), and notification groups

The *fanotify_init*(2) system call creates and initializes an fanotify notification group and returns a file descriptor referring to it.

An fanotify notification group is a kernel-internal object that holds a list of files, directories, filesystems, and mounts for which events shall be created.

For each entry in an fanotify notification group, two bit masks exist: the *mark* mask and the *ignore* mask. The mark mask defines file activities for which an event shall be created. The ignore mask defines activities for which no event shall be generated. Having these two types of masks permits a filesystem, mount, or directory to be marked for receiving events, while at the same time ignoring events for specific objects under a mount or directory.

The *fanotify_mark*(2) system call adds a file, directory, filesystem, or mount to a notification group and specifies which events shall be reported (or ignored), or removes or modifies such an entry.

A possible usage of the ignore mask is for a file cache. Events of interest for a file cache are modification of a file and closing of the same. Hence, the cached directory or mount is to be marked to receive these events. After receiving the first event informing that a file has been modified, the corresponding cache entry will be invalidated. No further modification events for this file are of interest until the file is closed. Hence, the modify event can be added to the ignore mask. Upon receiving the close event, the modify event can be removed from the ignore mask and the file cache entry can be updated.

The entries in the fanotify notification groups refer to files and directories via their inode number and to mounts via their mount ID. If files or directories are renamed or moved within the same mount, the respective entries survive. If files or directories are deleted or moved to another mount or if filesystems or mounts are unmounted, the corresponding entries are deleted.

The event queue

As events occur on the filesystem objects monitored by a notification group, the fanotify system generates events that are collected in a queue. These events can then be read (using *read*(2) or similar) from the fanotify file descriptor returned by *fanotify_init*(2).

Two types of events are generated: *notification* events and *permission* events. Notification events are merely informative and require no action to be taken by the receiving application with one exception: if a valid file descriptor is provided within a generic event, the file descriptor must be closed. Permission events are requests to the receiving application to decide whether permission for a file access shall be granted. For these events, the recipient must write a response which decides whether access is granted or not.

An event is removed from the event queue of the fanotify group when it has been read. Permission events that have been read are kept in an internal list of the fanotify group until either a permission decision has been taken by writing to the fanotify file descriptor or the fanotify file descriptor is closed.

Reading fanotify events

Calling *read*(2) for the file descriptor returned by *fanotify_init*(2) blocks (if the flag **FAN_NONBLOCK** is not specified in the call to *fanotify_init*(2)) until either a file event occurs or the call is interrupted by a signal (see *signal*(7)).

After a successful *read*(2), the read buffer contains one or more of the following structures:

```
struct fanotify_event_metadata {
    __u32 event_len;
    __u8 vers;
    __u8 reserved;
    __u16 metadata_len;
    __aligned_u64 mask;
    __s32 fd;
    __s32 pid;
};
```

Information records are supplemental pieces of information that may be provided alongside the generic *fanotify_event_metadata* structure. The *flags* passed to *fanotify_init*(2) have influence over the type of information records that may be returned for an event. For example, if a notification group is initialized with **FAN_REPORT_FID** or **FAN_REPORT_DIR_FID**, then event listeners should also expect to receive a *fanotify_event_info_fid* structure alongside the *fanotify_event_metadata* structure, whereby file handles are used to identify filesystem objects rather than file descriptors. Information records may also be stacked, meaning that using the various **FAN_REPORT_*** flags in conjunction with one another is supported. In such cases, multiple information records can be returned for an event alongside the generic *fanotify_event_metadata* structure. For example, if a notification group is initialized with **FAN_REPORT_TARGET_FID** and **FAN_REPORT_PIDFD**, then an event listener should expect to receive up to two *fanotify_event_info_fid* information records and one *fanotify_event_info_pidfd* information record alongside the generic *fanotify_event_metadata* structure. Importantly, fanotify provides no guarantee around the ordering of information records when a notification group is initialized with a stacked based configuration. Each information record has a nested structure of type *fanotify_event_info_header*. It is imperative for event listeners to inspect the *info_type* field of this structure in order to determine the type of information record that had been received for a given event.

In cases where an fanotify group identifies filesystem objects by file handles, event listeners should also expect to receive one or more of the below information record objects alongside the generic *fanotify_event_metadata* structure within the read buffer:

```
struct fanotify_event_info_fid {
    struct fanotify_event_info_header hdr;
    __kernel_fsid_t fsid;
    unsigned char handle[];
};
```

In cases where an fanotify group is initialized with **FAN_REPORT_PIDFD**, event listeners should expect to receive the below information record object alongside the generic *fanotify_event_metadata* structure within the read buffer:

```
struct fanotify_event_info_pidfd {
        struct fanotify_event_info_header hdr;
        __s32 pidfd;
};
```

In case of a **FAN_FS_ERROR** event, an additional information record describing the error that occurred is returned alongside the generic *fanotify_event_metadata* structure within the read buffer. This structure is defined as follows:

```
struct fanotify_event_info_error {
    struct fanotify_event_info_header hdr;
    __s32 error;
    __u32 error_count;
};
```

All information records contain a nested structure of type *fanotify_event_info_header*. This structure holds meta-information about the information record that may have been returned alongside the generic *fanotify_event_metadata* structure. This structure is defined as follows:

```
struct fanotify_event_info_header {
      __u8 info_type;
      __u8 pad;
      __u16 len;
```

```
};
```

For performance reasons, it is recommended to use a large buffer size (for example, 4096 bytes), so that multiple events can be retrieved by a single *read*(2).

The return value of *read*(2) is the number of bytes placed in the buffer, or −1 in case of an error (but see BUGS).

The fields of the *fanotify_event_metadata* structure are as follows:

event_len
: This is the length of the data for the current event and the offset to the next event in the buffer. Unless the group identifies filesystem objects by file handles, the value of *event_len* is always **FAN_EVENT_METADATA_LEN**. For a group that identifies filesystem objects by file handles, *event_len* also includes the variable length file identifier records.

vers
: This field holds a version number for the structure. It must be compared to **FANOTIFY_METADATA_VERSION** to verify that the structures returned at run time match the structures defined at compile time. In case of a mismatch, the application should abandon trying to use the fanotify file descriptor.

reserved
: This field is not used.

metadata_len
: This is the length of the structure. The field was introduced to facilitate the implementation of optional headers per event type. No such optional headers exist in the current implementation.

mask
: This is a bit mask describing the event (see below).

fd
: This is an open file descriptor for the object being accessed, or **FAN_NOFD** if a queue overflow occurred. With an fanotify group that identifies filesystem objects by file handles, applications should expect this value to be set to **FAN_NOFD** for each event that is received. The file descriptor can be used to access the contents of the monitored file or directory. The reading application is responsible for closing this file descriptor.

  When calling *fanotify_init*(2), the caller may specify (via the *event_f_flags* argument) various file status flags that are to be set on the open file description that corresponds to this file descriptor. In addition, the (kernel-internal) **FMODE_NONOTIFY** file status flag is set on the open file description. This flag suppresses fanotify event generation. Hence, when the receiver of the fanotify event accesses the notified file or directory using this file descriptor, no additional events will be created.

pid
: If flag **FAN_REPORT_TID** was set in *fanotify_init*(2), this is the TID of the thread that caused the event. Otherwise, this the PID of the process that caused the event.

A program listening to fanotify events can compare this PID to the PID returned by *getpid*(2), to determine whether the event is caused by the listener itself, or is due to a file access by another process.

The bit mask in *mask* indicates which events have occurred for a single filesystem object. Multiple bits may be set in this mask, if more than one event occurred for the monitored filesystem object. In particular, consecutive events for the same filesystem object and originating from the same process may be merged into a single event, with the exception that two permission events are never merged into one queue entry.

The bits that may appear in *mask* are as follows:

FAN_ACCESS
: A file or a directory (but see BUGS) was accessed (read).

FAN_OPEN
: A file or a directory was opened.

FAN_OPEN_EXEC
: A file was opened with the intent to be executed. See NOTES in *fanotify_mark*(2) for additional details.

FAN_ATTRIB
A file or directory metadata was changed.

FAN_CREATE
A child file or directory was created in a watched parent.

FAN_DELETE
A child file or directory was deleted in a watched parent.

FAN_DELETE_SELF
A watched file or directory was deleted.

FAN_FS_ERROR
A filesystem error was detected.

FAN_RENAME
A file or directory has been moved to or from a watched parent directory.

FAN_MOVED_FROM
A file or directory has been moved from a watched parent directory.

FAN_MOVED_TO
A file or directory has been moved to a watched parent directory.

FAN_MOVE_SELF
A watched file or directory was moved.

FAN_MODIFY
A file was modified.

FAN_CLOSE_WRITE
A file that was opened for writing (**O_WRONLY** or **O_RDWR**) was closed.

FAN_CLOSE_NOWRITE
A file or directory that was opened read-only (**O_RDONLY**) was closed.

FAN_Q_OVERFLOW
The event queue exceeded the limit on number of events. This limit can be overridden by specifying the **FAN_UNLIMITED_QUEUE** flag when calling *fanotify_init*(2).

FAN_ACCESS_PERM
An application wants to read a file or directory, for example using *read*(2) or *readdir*(2). The reader must write a response (as described below) that determines whether the permission to access the filesystem object shall be granted.

FAN_OPEN_PERM
An application wants to open a file or directory. The reader must write a response that determines whether the permission to open the filesystem object shall be granted.

FAN_OPEN_EXEC_PERM
An application wants to open a file for execution. The reader must write a response that determines whether the permission to open the filesystem object for execution shall be granted. See NOTES in *fanotify_mark*(2) for additional details.

To check for any close event, the following bit mask may be used:

FAN_CLOSE
A file was closed. This is a synonym for:

```
FAN_CLOSE_WRITE | FAN_CLOSE_NOWRITE
```

To check for any move event, the following bit mask may be used:

FAN_MOVE
A file or directory was moved. This is a synonym for:

```
FAN_MOVED_FROM | FAN_MOVED_TO
```

The following bits may appear in *mask* only in conjunction with other event type bits:

FAN_ONDIR
The events described in the *mask* have occurred on a directory object. Reporting events on directories requires setting this flag in the mark mask. See *fanotify_mark*(2) for additional details. The **FAN_ONDIR** flag is reported in an event mask only if the fanotify group identifies filesystem objects by file handles.

Information records that are supplied alongside the generic *fanotify_event_metadata* structure will always contain a nested structure of type *fanotify_event_info_header*. The fields of the *fanotify_event_info_header* are as follows:

info_type
A unique integer value representing the type of information record object received for an event. The value of this field can be set to one of the following: **FAN_EVENT_INFO_TYPE_FID**, **FAN_EVENT_INFO_TYPE_DFID**, **FAN_EVENT_INFO_TYPE_DFID_NAME**, or **FAN_EVENT_INFO_TYPE_PIDFD**. The value set for this field is dependent on the flags that have been supplied to *fanotify_init*(2). Refer to the field details of each information record object type below to understand the different cases in which the *info_type* values can be set.

pad This field is currently not used by any information record object type and therefore is set to zero.

len The value of *len* is set to the size of the information record object, including the *fanotify_event_info_header*. The total size of all additional information records is not expected to be larger than (*event_len* − *metadata_len*).

The fields of the *fanotify_event_info_fid* structure are as follows:

hdr This is a structure of type *fanotify_event_info_header*. For example, when an fanotify file descriptor is created using **FAN_REPORT_FID**, a single information record is expected to be attached to the event with *info_type* field value of **FAN_EVENT_INFO_TYPE_FID**. When an fanotify file descriptor is created using the combination of **FAN_REPORT_FID** and **FAN_REPORT_DIR_FID**, there may be two information records attached to the event: one with *info_type* field value of **FAN_EVENT_INFO_TYPE_DFID**, identifying a parent directory object, and one with *info_type* field value of **FAN_EVENT_INFO_TYPE_FID**, identifying a child object. Note that for the directory entry modification events **FAN_CREATE**, **FAN_DELETE**, **FAN_MOVE**, and **FAN_RENAME**, an information record identifying the created/deleted/moved child object is reported only if an fanotify group was initialized with the flag **FAN_REPORT_TARGET_FID**.

fsid This is a unique identifier of the filesystem containing the object associated with the event. It is a structure of type *__kernel_fsid_t* and contains the same value as *f_fsid* when calling *statfs*(2).

handle This field contains a variable-length structure of type *struct file_handle*. It is an opaque handle that corresponds to a specified object on a filesystem as returned by *name_to_handle_at*(2). It can be used to uniquely identify a file on a filesystem and can be passed as an argument to *open_by_handle_at*(2). If the value of *info_type* field is **FAN_EVENT_INFO_TYPE_DFID_NAME**, the file handle is followed by a null terminated string that identifies the created/deleted/moved directory entry name. For other events such as **FAN_OPEN**, **FAN_ATTRIB**, **FAN_DELETE_SELF**, and **FAN_MOVE_SELF**, if the value of *info_type* field is **FAN_EVENT_INFO_TYPE_FID**, the *handle* identifies the object correlated to the event. If the value of *info_type* field is **FAN_EVENT_INFO_TYPE_DFID**, the *handle* identifies the directory object correlated to the event or the parent directory of a non-directory object correlated to the event. If the value of *info_type* field is **FAN_EVENT_INFO_TYPE_DFID_NAME**, the *handle* identifies the same directory object that would be reported with **FAN_EVENT_INFO_TYPE_DFID** and the file handle is followed by a null terminated string that identifies the name of a directory entry in that directory, or '.' to identify the directory object itself.

The fields of the *fanotify_event_info_pidfd* structure are as follows:

hdr This is a structure of type *fanotify_event_info_header*. When an fanotify group is initialized using **FAN_REPORT_PIDFD**, the *info_type* field value of the *fanotify_event_info_header* is set to **FAN_EVENT_INFO_TYPE_PIDFD**.

pidfd This is a process file descriptor that refers to the process responsible for generating the event. The returned process file descriptor is no different from one which could be obtained manually if *pidfd_open*(2) were to be called on *fanotify_event_metadata.pid*. In the instance that an error is encountered during pidfd creation, one of two possible error types represented by a negative integer value may be returned in this *pidfd* field. In cases where the process responsible for generating the event has terminated prior to the event listener being able to read events from the notification queue, **FAN_NOPIDFD** is returned. The pidfd creation for an event is only performed at the time the events are read from the notification queue. All other possible pidfd creation failures are represented by **FAN_EPIDFD**. Once the event listener has dealt with an event and the pidfd is no longer required, the pidfd should be closed via *close*(2).

The fields of the *fanotify_event_info_error* structure are as follows:

hdr This is a structure of type *fanotify_event_info_header*. The *info_type* field is set to **FAN_EVENT_INFO_TYPE_ERROR**.

error Identifies the type of error that occurred.

error_count
This is a counter of the number of errors suppressed since the last error was read.

The following macros are provided to iterate over a buffer containing fanotify event metadata returned by a *read*(2) from an fanotify file descriptor:

FAN_EVENT_OK(meta, len)
This macro checks the remaining length *len* of the buffer *meta* against the length of the metadata structure and the *event_len* field of the first metadata structure in the buffer.

FAN_EVENT_NEXT(meta, len)
This macro uses the length indicated in the *event_len* field of the metadata structure pointed to by *meta* to calculate the address of the next metadata structure that follows *meta*. *len* is the number of bytes of metadata that currently remain in the buffer. The macro returns a pointer to the next metadata structure that follows *meta*, and reduces *len* by the number of bytes in the metadata structure that has been skipped over (i.e., it subtracts *meta->event_len* from *len*).

In addition, there is:

FAN_EVENT_METADATA_LEN
This macro returns the size (in bytes) of the structure *fanotify_event_metadata*. This is the minimum size (and currently the only size) of any event metadata.

Monitoring an fanotify file descriptor for events

When an fanotify event occurs, the fanotify file descriptor indicates as readable when passed to *epoll*(7), *poll*(2), or *select*(2).

Dealing with permission events

For permission events, the application must *write*(2) a structure of the following form to the fanotify file descriptor:

```
struct fanotify_response {
    __s32 fd;
    __u32 response;
};
```

The fields of this structure are as follows:

fd This is the file descriptor from the structure *fanotify_event_metadata*.

response
This field indicates whether or not the permission is to be granted. Its value must be either **FAN_ALLOW** to allow the file operation or **FAN_DENY** to deny the file operation.

If access is denied, the requesting application call will receive an **EPERM** error. Additionally, if the notification group has been created with the **FAN_ENABLE_AUDIT** flag, then the **FAN_AUDIT** flag can be set in the *response* field. In that case, the audit subsystem will log information about the access decision to the audit logs.

Monitoring filesystems for errors

A single **FAN_FS_ERROR** event is stored per filesystem at once. Extra error messages are suppressed and accounted for in the *error_count* field of the existing **FAN_FS_ERROR** event record, but details about the errors are lost.

Errors reported by **FAN_FS_ERROR** are generic *errno* values, but not all kinds of error types are reported by all filesystems.

Errors not directly related to a file (i.e. super block corruption) are reported with an invalid *handle*. For these errors, the *handle* will have the field *handle_type* set to **FILEID_INVALID**, and the handle buffer size set to **0**.

Closing the fanotify file descriptor

When all file descriptors referring to the fanotify notification group are closed, the fanotify group is released and its resources are freed for reuse by the kernel. Upon *close*(2), outstanding permission events will be set to allowed.

/proc interfaces

The file */proc/*pid*/fdinfo/*fd contains information about fanotify marks for file descriptor *fd* of process *pid*. See *proc*(5) for details.

Since Linux 5.13, the following interfaces can be used to control the amount of kernel resources consumed by fanotify:

/proc/sys/fs/fanotify/max_queued_events

The value in this file is used when an application calls *fanotify_init*(2) to set an upper limit on the number of events that can be queued to the corresponding fanotify group. Events in excess of this limit are dropped, but an **FAN_Q_OVERFLOW** event is always generated. Prior to Linux kernel 5.13, the hardcoded limit was 16384 events.

/proc/sys/fs/fanotify/max_user_group

This specifies an upper limit on the number of fanotify groups that can be created per real user ID. Prior to Linux kernel 5.13, the hardcoded limit was 128 groups per user.

/proc/sys/fs/fanotify/max_user_marks

This specifies an upper limit on the number of fanotify marks that can be created per real user ID. Prior to Linux kernel 5.13, the hardcoded limit was 8192 marks per group (not per user).

ERRORS

In addition to the usual errors for *read*(2), the following errors can occur when reading from the fanotify file descriptor:

EINVAL

The buffer is too small to hold the event.

EMFILE

The per-process limit on the number of open files has been reached. See the description of **RLIMIT_NOFILE** in *getrlimit*(2).

ENFILE

The system-wide limit on the total number of open files has been reached. See */proc/sys/fs/file-max* in *proc*(5).

ETXTBSY

This error is returned by *read*(2) if **O_RDWR** or **O_WRONLY** was specified in the *event_f_flags* argument when calling *fanotify_init*(2) and an event occurred for a monitored file that is currently being executed.

In addition to the usual errors for *write*(2), the following errors can occur when writing to the fanotify file descriptor:

EINVAL

Fanotify access permissions are not enabled in the kernel configuration or the value of *response* in the response structure is not valid.

ENOENT

The file descriptor *fd* in the response structure is not valid. This may occur when a response for the permission event has already been written.

STANDARDS

Linux.

HISTORY

The fanotify API was introduced in Linux 2.6.36 and enabled in Linux 2.6.37. fdinfo support was added in Linux 3.8.

NOTES

The fanotify API is available only if the kernel was built with the **CONFIG_FANOTIFY** configuration option enabled. In addition, fanotify permission handling is available only if the **CONFIG_FANOTIFY_ACCESS_PERMISSIONS** configuration option is enabled.

Limitations and caveats

Fanotify reports only events that a user-space program triggers through the filesystem API. As a result, it does not catch remote events that occur on network filesystems.

The fanotify API does not report file accesses and modifications that may occur because of *mmap*(2), *msync*(2), and *munmap*(2).

Events for directories are created only if the directory itself is opened, read, and closed. Adding, removing, or changing children of a marked directory does not create events for the monitored directory itself.

Fanotify monitoring of directories is not recursive: to monitor subdirectories under a directory, additional marks must be created. The **FAN_CREATE** event can be used for detecting when a subdirectory has been created under a marked directory. An additional mark must then be set on the newly created subdirectory. This approach is racy, because it can lose events that occurred inside the newly created subdirectory, before a mark is added on that subdirectory. Monitoring mounts offers the capability to monitor a whole directory tree in a race-free manner. Monitoring filesystems offers the capability to monitor changes made from any mount of a filesystem instance in a race-free manner.

The event queue can overflow. In this case, events are lost.

BUGS

Before Linux 3.19, *fallocate*(2) did not generate fanotify events. Since Linux 3.19, calls to *fallocate*(2) generate **FAN_MODIFY** events.

As of Linux 3.17, the following bugs exist:

- On Linux, a filesystem object may be accessible through multiple paths, for example, a part of a filesystem may be remounted using the −−*bind* option of *mount*(8)A listener that marked a mount will be notified only of events that were triggered for a filesystem object using the same mount. Any other event will pass unnoticed.
- When an event is generated, no check is made to see whether the user ID of the receiving process has authorization to read or write the file before passing a file descriptor for that file. This poses a security risk, when the **CAP_SYS_ADMIN** capability is set for programs executed by unprivileged users.
- If a call to *read*(2) processes multiple events from the fanotify queue and an error occurs, the return value will be the total length of the events successfully copied to the user-space buffer before the error occurred. The return value will not be −1, and *errno* will not be set. Thus, the reading application has no way to detect the error.

EXAMPLES

The two example programs below demonstrate the usage of the fanotify API.

Example program: fanotify_example.c

The first program is an example of fanotify being used with its event object information passed in the form of a file descriptor. The program marks the mount passed as a command-line argument and waits for events of type **FAN_OPEN_PERM** and **FAN_CLOSE_WRITE**. When a permission event occurs, a **FAN_ALLOW** response is given.

The following shell session shows an example of running this program. This session involved editing the file */home/user/temp/notes*. Before the file was opened, a **FAN_OPEN_PERM** event occurred. After the file was closed, a **FAN_CLOSE_WRITE** event occurred. Execution of the program ends when the user presses the ENTER key.

```
# ./fanotify_example /home
Press enter key to terminate.
Listening for events.
FAN_OPEN_PERM: File /home/user/temp/notes
FAN_CLOSE_WRITE: File /home/user/temp/notes

Listening for events stopped.
```

        }

        printf("Listening for events stopped.\n");
        exit(EXIT_SUCCESS);
    }
```

Example program: fanotify_fid.c

The second program is an example of fanotify being used with a group that identifies objects by file handles. The program marks the filesystem object that is passed as a command-line argument and waits until an event of type **FAN_CREATE** has occurred. The event mask indicates which type of filesystem object—either a file or a directory—was created. Once all events have been read from the buffer and processed accordingly, the program simply terminates.

The following shell sessions show two different invocations of this program, with different actions performed on a watched object.

The first session shows a mark being placed on */home/user*. This is followed by the creation of a regular file, */home/user/testfile.txt*. This results in a **FAN_CREATE** event being generated and reported against the file's parent watched directory object and with the created file name. Program execution ends once all events captured within the buffer have been processed.

```
# ./fanotify_fid /home/user
Listening for events.
FAN_CREATE (file created):
        Directory /home/user has been modified.
        Entry 'testfile.txt' is not a subdirectory.
All events processed successfully. Program exiting.

$ touch /home/user/testfile.txt              # In another terminal
```

The second session shows a mark being placed on */home/user*. This is followed by the creation of a directory, */home/user/testdir*. This specific action results in a **FAN_CREATE** event being generated and is reported with the **FAN_ONDIR** flag set and with the created directory name.

```
# ./fanotify_fid /home/user
Listening for events.
FAN_CREATE | FAN_ONDIR (subdirectory created):
        Directory /home/user has been modified.
        Entry 'testdir' is a subdirectory.
All events processed successfully. Program exiting.

$ mkdir -p /home/user/testdir          # In another terminal
```

            } else {
                fprintf(stderr, "Received unexpected event info type.\n");
                exit(EXIT_FAILURE);
            }

            if (metadata->mask == FAN_CREATE)
                printf("FAN_CREATE (file created):\n");

            if (metadata->mask == (FAN_CREATE | FAN_ONDIR))
                printf("FAN_CREATE | FAN_ONDIR (subdirectory created):\n");

          /* metadata->fd is set to FAN_NOFD when the group identifies
             objects by file handles.  To obtain a file descriptor for
             the file object corresponding to an event you can use the
             struct file_handle that's provided within the
             fanotify_event_info_fid in conjunction with the
             open_by_handle_at(2) system call.  A check for ESTALE is
             done to accommodate for the situation where the file handle
             for the object was deleted prior to this system call. */

            event_fd = open_by_handle_at(mount_fd, file_handle, O_RDONLY);
            if (event_fd == -1) {
                if (errno == ESTALE) {
                    printf("File handle is no longer valid. "
                            "File has been deleted\n");
                    continue;
                } else {
                    perror("open_by_handle_at");
                    exit(EXIT_FAILURE);
                }
            }

            snprintf(procfd_path, sizeof(procfd_path), "/proc/self/fd/%d",
                    event_fd);
```

```
            /* Retrieve and print the path of the modified dentry. */

            path_len = readlink(procfd_path, path, sizeof(path) - 1);
            if (path_len == -1) {
                perror("readlink");
                exit(EXIT_FAILURE);
            }

            path[path_len] = '\0';
            printf("\tDirectory '%s' has been modified.\n", path);

            if (file_name) {
                ret = fstatat(event_fd, file_name, &sb, 0);
                if (ret == -1) {
                    if (errno != ENOENT) {
                        perror("fstatat");
                        exit(EXIT_FAILURE);
                    }
                    printf("\tEntry '%s' does not exist.\n", file_name);
                } else if ((sb.st_mode & S_IFMT) == S_IFDIR) {
                    printf("\tEntry '%s' is a subdirectory.\n", file_name);
                } else {
                    printf("\tEntry '%s' is not a subdirectory.\n",
                            file_name);
                }
            }

            /* Close associated file descriptor for this event. */

            close(event_fd);
        }

        printf("All events processed successfully. Program exiting.\n");
        exit(EXIT_SUCCESS);
    }
```

NAME

feature_test_macros − feature test macros

DESCRIPTION

Feature test macros allow the programmer to control the definitions that are exposed by system header files when a program is compiled.

NOTE: In order to be effective, a feature test macro *must be defined before including any header files*. This can be done either in the compilation command (*cc −DMACRO=value*) or by defining the macro within the source code before including any headers. The requirement that the macro must be defined before including any header file exists because header files may freely include one another. Thus, for example, in the following lines, defining the **_GNU_SOURCE** macro may have no effect because the header <*abc.h*> itself includes <*xyz.h*> (POSIX explicitly allows this):

```
#include <abc.h>
#define _GNU_SOURCE
#include <xyz.h>
```

Some feature test macros are useful for creating portable applications, by preventing nonstandard definitions from being exposed. Other macros can be used to expose nonstandard definitions that are not exposed by default.

The precise effects of each of the feature test macros described below can be ascertained by inspecting the <*features.h*> header file. **Note**: applications do *not* need to directly include <*features.h*>; indeed, doing so is actively discouraged. See NOTES.

Specification of feature test macro requirements in manual pages

When a function requires that a feature test macro is defined, the manual page SYNOPSIS typically includes a note of the following form (this example from the *acct*(2) manual page):

#include <unistd.h>

int acct(const char * *filename***);**

```
Feature Test Macro Requirements for glibc (see
feature_test_macros(7)):
```

acct(): _BSD_SOURCE || (_XOPEN_SOURCE && _XOPEN_SOURCE < 500)

The **||** means that in order to obtain the declaration of *acct*(2) from <*unistd.h*>, *either* of the following macro definitions must be made before including any header files:

```
#define _BSD_SOURCE
#define _XOPEN_SOURCE        /* or any value < 500 */
```

Alternatively, equivalent definitions can be included in the compilation command:

```
cc −D_BSD_SOURCE
cc −D_XOPEN_SOURCE           # Or any value < 500
```

Note that, as described below, **some feature test macros are defined by default**, so that it may not always be necessary to explicitly specify the feature test macro(s) shown in the SYNOPSIS.

In a few cases, manual pages use a shorthand for expressing the feature test macro requirements (this example from *readahead*(2)):

```
#define _GNU_SOURCE
#define _FILE_OFFSET_BITS 64
#include <fcntl.h>

ssize_t readahead(int fd, off_t *offset, size_t count);
```

This format is employed when the feature test macros ensure that the proper function declarations are visible, and the macros are not defined by default.

Feature test macros understood by glibc

The paragraphs below explain how feature test macros are handled in glibc 2.*x*, *x* > 0.

First, though, a summary of a few details for the impatient:

- The macros that you most likely need to use in modern source code are **_POSIX_C_SOURCE** (for definitions from various versions of POSIX.1), **_XOPEN_SOURCE** (for definitions from various versions of SUS), **_GNU_SOURCE** (for GNU and/or Linux specific stuff), and **_DEFAULT_SOURCE** (to get definitions that would normally be provided by default).
- Certain macros are defined with default values. Thus, although one or more macros may be indicated as being required in the SYNOPSIS of a man page, it may not be necessary to define them explicitly. Full details of the defaults are given later in this man page.
- Defining **_XOPEN_SOURCE** with a value of 600 or greater produces the same effects as defining **_POSIX_C_SOURCE** with a value of 200112L or greater. Where one sees

  ```
  _POSIX_C_SOURCE >= 200112L
  ```

  in the feature test macro requirements in the SYNOPSIS of a man page, it is implicit that the following has the same effect:

  ```
  _XOPEN_SOURCE >= 600
  ```
- Defining **_XOPEN_SOURCE** with a value of 700 or greater produces the same effects as defining **_POSIX_C_SOURCE** with a value of 200809L or greater. Where one sees

  ```
  _POSIX_C_SOURCE >= 200809L
  ```

  in the feature test macro requirements in the SYNOPSIS of a man page, it is implicit that the following has the same effect:

  ```
  _XOPEN_SOURCE >= 700
  ```

glibc understands the following feature test macros:

__STRICT_ANSI__
: ISO Standard C. This macro is implicitly defined by *gcc*(1) when invoked with, for example, the *−std=c99* or *−ansi* flag.

_POSIX_C_SOURCE
: Defining this macro causes header files to expose definitions as follows:
  - The value 1 exposes definitions conforming to POSIX.1-1990 and ISO C (1990).
  - The value 2 or greater additionally exposes definitions for POSIX.2-1992.
  - The value 199309L or greater additionally exposes definitions for POSIX.1b (real-time extensions).
  - The value 199506L or greater additionally exposes definitions for POSIX.1c (threads).
  - (Since glibc 2.3.3) The value 200112L or greater additionally exposes definitions corresponding to the POSIX.1-2001 base specification (excluding the XSI extension). This value also causes C95 (since glibc 2.12) and C99 (since glibc 2.10) features to be exposed (in other words, the equivalent of defining **_ISOC99_SOURCE**).
  - (Since glibc 2.10) The value 200809L or greater additionally exposes definitions corresponding to the POSIX.1-2008 base specification (excluding the XSI extension).

_POSIX_SOURCE
: Defining this obsolete macro with any value is equivalent to defining **_POSIX_C_SOURCE** with the value 1.

  Since this macro is obsolete, its usage is generally not documented when discussing feature test macro requirements in the man pages.

_XOPEN_SOURCE
: Defining this macro causes header files to expose definitions as follows:
  - Defining with any value exposes definitions conforming to POSIX.1, POSIX.2, and XPG4.
  - The value 500 or greater additionally exposes definitions for SUSv2 (UNIX 98).
  - (Since glibc 2.2) The value 600 or greater additionally exposes definitions for SUSv3 (UNIX 03; i.e., the POSIX.1-2001 base specification plus the XSI extension) and C99 definitions.

- (Since glibc 2.10) The value 700 or greater additionally exposes definitions for SUSv4 (i.e., the POSIX.1-2008 base specification plus the XSI extension).

If **__STRICT_ANSI__** is not defined, or **_XOPEN_SOURCE** is defined with a value greater than or equal to 500 *and* neither **_POSIX_SOURCE** nor **_POSIX_C_SOURCE** is explicitly defined, then the following macros are implicitly defined:

- **_POSIX_SOURCE** is defined with the value 1.
- **_POSIX_C_SOURCE** is defined, according to the value of **_XOPEN_SOURCE**:

  _XOPEN_SOURCE < 500
  : **_POSIX_C_SOURCE** is defined with the value 2.

  500 <= **_XOPEN_SOURCE** < 600
  : **_POSIX_C_SOURCE** is defined with the value 199506L.

  600 <= **_XOPEN_SOURCE** < 700
  : **_POSIX_C_SOURCE** is defined with the value 200112L.

  700 <= **_XOPEN_SOURCE** (since glibc 2.10)
  : **_POSIX_C_SOURCE** is defined with the value 200809L.

In addition, defining **_XOPEN_SOURCE** with a value of 500 or greater produces the same effects as defining **_XOPEN_SOURCE_EXTENDED**.

_XOPEN_SOURCE_EXTENDED
: If this macro is defined, *and* **_XOPEN_SOURCE** is defined, then expose definitions corresponding to the XPG4v2 (SUSv1) UNIX extensions (UNIX 95). Defining **_XOPEN_SOURCE** with a value of 500 or more also produces the same effect as defining **_XOPEN_SOURCE_EXTENDED**. Use of **_XOPEN_SOURCE_EXTENDED** in new source code should be avoided.

  Since defining **_XOPEN_SOURCE** with a value of 500 or more has the same effect as defining **_XOPEN_SOURCE_EXTENDED**, the latter (obsolete) feature test macro is generally not described in the SYNOPSIS in man pages.

_ISOC99_SOURCE (since glibc 2.1.3)
: Exposes declarations consistent with the ISO C99 standard.

  Earlier glibc 2.1.x versions recognized an equivalent macro named **_ISOC9X_SOURCE** (because the C99 standard had not then been finalized). Although the use of this macro is obsolete, glibc continues to recognize it for backward compatibility.

  Defining **_ISOC99_SOURCE** also exposes ISO C (1990) Amendment 1 ("C95") definitions. (The primary change in C95 was support for international character sets.)

  Invoking the C compiler with the option *−std=c99* produces the same effects as defining this macro.

_ISOC11_SOURCE (since glibc 2.16)
: Exposes declarations consistent with the ISO C11 standard. Defining this macro also enables C99 and C95 features (like **_ISOC99_SOURCE**).

  Invoking the C compiler with the option *−std=c11* produces the same effects as defining this macro.

_LARGEFILE64_SOURCE
: Expose definitions for the alternative API specified by the LFS (Large File Summit) as a "transitional extension" to the Single UNIX Specification. (See .) The alternative API consists of a set of new objects (i.e., functions and types) whose names are suffixed with "64" (e.g., *off64_t* versus *off_t*, **lseek64**() versus **lseek**(), etc.). New programs should not employ this macro; instead *_FILE_OFFSET_BITS=64* should be employed.

_LARGEFILE_SOURCE
: This macro was historically used to expose certain functions (specifically *fseeko*(3) and *ftello*(3)) that address limitations of earlier APIs (**fseek**(3) and *ftell*(3)) that use *long* for file offsets. This macro is implicitly defined if **_XOPEN_SOURCE** is defined with a value greater than or equal to 500. New programs should not employ this macro; defining

_XOPEN_SOURCE as just described or defining **_FILE_OFFSET_BITS** with the value 64 is the preferred mechanism to achieve the same result.

_FILE_OFFSET_BITS
Defining this macro with the value 64 automatically converts references to 32-bit functions and data types related to file I/O and filesystem operations into references to their 64-bit counterparts. This is useful for performing I/O on large files (> 2 Gigabytes) on 32-bit systems. It is also useful when calling functions like *copy_file_range*(2) that were added more recently and that come only in 64-bit flavors. (Defining this macro permits correctly written programs to use large files with only a recompilation being required.)

64-bit systems naturally permit file sizes greater than 2 Gigabytes, and on those systems this macro has no effect.

_TIME_BITS
Defining this macro with the value 64 changes the width of *time_t*(3type) to 64-bit which allows handling of timestamps beyond 2038. It is closely related to **_FILE_OFFSET_BITS** and depending on implementation, may require it set. This macro is available as of glibc 2.34.

_BSD_SOURCE (deprecated since glibc 2.20)
Defining this macro with any value causes header files to expose BSD-derived definitions.

In glibc versions up to and including 2.18, defining this macro also causes BSD definitions to be preferred in some situations where standards conflict, unless one or more of **_SVID_SOURCE**, **_POSIX_SOURCE**, **_POSIX_C_SOURCE**, **_XOPEN_SOURCE**, **_XOPEN_SOURCE_EXTENDED**, or **_GNU_SOURCE** is defined, in which case BSD definitions are disfavored. Since glibc 2.19, **_BSD_SOURCE** no longer causes BSD definitions to be preferred in case of conflicts.

Since glibc 2.20, this macro is deprecated. It now has the same effect as defining **_DEFAULT_SOURCE**, but generates a compile-time warning (unless **_DEFAULT_SOURCE** is also defined). Use **_DEFAULT_SOURCE** instead. To allow code that requires **_BSD_SOURCE** in glibc 2.19 and earlier and **_DEFAULT_SOURCE** in glibc 2.20 and later to compile without warnings, define *both* **_BSD_SOURCE** and **_DEFAULT_SOURCE**.

_SVID_SOURCE (deprecated since glibc 2.20)
Defining this macro with any value causes header files to expose System V-derived definitions. (SVID == System V Interface Definition; see *standards*(7).)

Since glibc 2.20, this macro is deprecated in the same fashion as **_BSD_SOURCE**.

_DEFAULT_SOURCE (since glibc 2.19)
This macro can be defined to ensure that the "default" definitions are provided even when the defaults would otherwise be disabled, as happens when individual macros are explicitly defined, or the compiler is invoked in one of its "standard" modes (e.g., *cc −std=c99*). Defining **_DEFAULT_SOURCE** without defining other individual macros or invoking the compiler in one of its "standard" modes has no effect.

The "default" definitions comprise those required by POSIX.1-2008 and ISO C99, as well as various definitions originally derived from BSD and System V. On glibc 2.19 and earlier, these defaults were approximately equivalent to explicitly defining the following:

```
cc −D_BSD_SOURCE −D_SVID_SOURCE −D_POSIX_C_SOURCE=200809
```

_ATFILE_SOURCE (since glibc 2.4)
Defining this macro with any value causes header files to expose declarations of a range of functions with the suffix "at"; see *openat*(2). Since glibc 2.10, this macro is also implicitly defined if **_POSIX_C_SOURCE** is defined with a value greater than or equal to 200809L.

_GNU_SOURCE
Defining this macro (with any value) implicitly defines **_ATFILE_SOURCE**, **_LARGEFILE64_SOURCE**, **_ISOC99_SOURCE**, **_XOPEN_SOURCE_EXTENDED**, **_POSIX_SOURCE**, **_POSIX_C_SOURCE** with the value 200809L (200112L before glibc 2.10; 199506L before glibc 2.5; 199309L before glibc 2.1) and **_XOPEN_SOURCE** with the value 700 (600 before glibc 2.10; 500 before glibc 2.2). In addition, various GNU-specific extensions are also exposed.

Since glibc 2.19, defining **_GNU_SOURCE** also has the effect of implicitly defining **_DEFAULT_SOURCE**. Before glibc 2.20, defining **_GNU_SOURCE** also had the effect of implicitly defining **_BSD_SOURCE** and **_SVID_SOURCE**.

_REENTRANT
Historically, on various C libraries it was necessary to define this macro in all multithreaded code. (Some C libraries may still require this.) In glibc, this macro also exposed definitions of certain reentrant functions.

However, glibc has been thread-safe by default for many years; since glibc 2.3, the only effect of defining **_REENTRANT** has been to enable one or two of the same declarations that are also enabled by defining **_POSIX_C_SOURCE** with a value of 199606L or greater.

_REENTRANT is now obsolete. In glibc 2.25 and later, defining **_REENTRANT** is equivalent to defining **_POSIX_C_SOURCE** with the value 199606L. If a higher POSIX conformance level is selected by any other means (such as **_POSIX_C_SOURCE** itself, **_XOPEN_SOURCE**, **_DEFAULT_SOURCE**, or **_GNU_SOURCE**), then defining **_REENTRANT** has no effect.

This macro is automatically defined if one compiles with *cc −pthread*.

_THREAD_SAFE
Synonym for the (deprecated) **_REENTRANT**, provided for compatibility with some other implementations.

_FORTIFY_SOURCE (since glibc 2.3.4)
Defining this macro causes some lightweight checks to be performed to detect some buffer overflow errors when employing various string and memory manipulation functions (for example, *memcpy*(3), *memset*(3), *stpcpy*(3), *strcpy*(3), *strncpy*(3), *strcat*(3), *strncat*(3), *sprintf*(3), *snprintf*(3), *vsprintf*(3), *vsnprintf*(3), *gets*(3), and wide character variants thereof). For some functions, argument consistency is checked; for example, a check is made that *open*(2) has been supplied with a *mode* argument when the specified flags include **O_CREAT**. Not all problems are detected, just some common cases.

If **_FORTIFY_SOURCE** is set to 1, with compiler optimization level 1 (*gcc −O1*) and above, checks that shouldn't change the behavior of conforming programs are performed. With **_FORTIFY_SOURCE** set to 2, some more checking is added, but some conforming programs might fail.

Some of the checks can be performed at compile time (via macros logic implemented in header files), and result in compiler warnings; other checks take place at run time, and result in a run-time error if the check fails.

With **_FORTIFY_SOURCE** set to 3, additional checking is added to intercept some function calls used with an argument of variable size where the compiler can deduce an upper bound for its value. For example, a program where *malloc*(3)'s size argument is variable can now be fortified.

Use of this macro requires compiler support, available since gcc 4.0 and clang 2.6. Use of **_FORTIFY_SOURCE** set to 3 requires gcc 12.0 or later, or clang 9.0 or later, in conjunction with glibc 2.33 or later.

Default definitions, implicit definitions, and combining definitions
If no feature test macros are explicitly defined, then the following feature test macros are defined by default: **_BSD_SOURCE** (in glibc 2.19 and earlier), **_SVID_SOURCE** (in glibc 2.19 and earlier), **_DEFAULT_SOURCE** (since glibc 2.19), **_POSIX_SOURCE**, and **_POSIX_C_SOURCE**=200809L (200112L before glibc 2.10; 199506L before glibc 2.4; 199309L before glibc 2.1).

If any of **__STRICT_ANSI__**, **_ISOC99_SOURCE**, **_ISOC11_SOURCE** (since glibc 2.18), **_POSIX_SOURCE**, **_POSIX_C_SOURCE**, **_XOPEN_SOURCE**, **_XOPEN_SOURCE_EXTENDED** (in glibc 2.11 and earlier), **_BSD_SOURCE** (in glibc 2.19 and earlier), or **_SVID_SOURCE** (in glibc 2.19 and earlier) is explicitly defined, then **_BSD_SOURCE**, **_SVID_SOURCE**, and **_DEFAULT_SOURCE** are not defined by default.

If **_POSIX_SOURCE** and **_POSIX_C_SOURCE** are not explicitly defined, and either **__STRICT_ANSI__** is not defined or **_XOPEN_SOURCE** is defined with a value of 500 or more,

then

- **_POSIX_SOURCE** is defined with the value 1; and
- **_POSIX_C_SOURCE** is defined with one of the following values:
  - 2, if **_XOPEN_SOURCE** is defined with a value less than 500;
  - 199506L, if **_XOPEN_SOURCE** is defined with a value greater than or equal to 500 and less than 600; or
  - (since glibc 2.4) 200112L, if **_XOPEN_SOURCE** is defined with a value greater than or equal to 600 and less than 700.
  - (Since glibc 2.10) 200809L, if **_XOPEN_SOURCE** is defined with a value greater than or equal to 700.
  - Older versions of glibc do not know about the values 200112L and 200809L for **_POSIX_C_SOURCE**, and the setting of this macro will depend on the glibc version.
  - If **_XOPEN_SOURCE** is undefined, then the setting of **_POSIX_C_SOURCE** depends on the glibc version: 199506L, before glibc 2.4; 200112L, since glibc 2.4 to glibc 2.9; and 200809L, since glibc 2.10.

Multiple macros can be defined; the results are additive.

STANDARDS

POSIX.1 specifies **_POSIX_C_SOURCE**, **_POSIX_SOURCE**, and **_XOPEN_SOURCE**.

_FILE_OFFSET_BITS is not specified by any standard, but is employed on some other implementations.

_BSD_SOURCE, **_SVID_SOURCE**, **_DEFAULT_SOURCE**, **_ATFILE_SOURCE**, **_GNU_SOURCE**, **_FORTIFY_SOURCE**, **_REENTRANT**, and **_THREAD_SAFE** are specific to glibc.

HISTORY

_XOPEN_SOURCE_EXTENDED was specified by XPG4v2 (aka SUSv1), but is not present in SUSv2 and later.

NOTES

<*features.h*> is a Linux/glibc-specific header file. Other systems have an analogous file, but typically with a different name. This header file is automatically included by other header files as required: it is not necessary to explicitly include it in order to employ feature test macros.

According to which of the above feature test macros are defined, <*features.h*> internally defines various other macros that are checked by other glibc header files. These macros have names prefixed by two underscores (e.g., **__USE_MISC**). Programs should *never* define these macros directly: instead, the appropriate feature test macro(s) from the list above should be employed.

EXAMPLES

The program below can be used to explore how the various feature test macros are set depending on the glibc version and what feature test macros are explicitly set. The following shell session, on a system with glibc 2.10, shows some examples of what we would see:

```
$ cc ftm.c
$ ./a.out
_POSIX_SOURCE defined
_POSIX_C_SOURCE defined: 200809L
_BSD_SOURCE defined
_SVID_SOURCE defined
_ATFILE_SOURCE defined
$ cc -D_XOPEN_SOURCE=500 ftm.c
$ ./a.out
_POSIX_SOURCE defined
_POSIX_C_SOURCE defined: 199506L
_XOPEN_SOURCE defined: 500
$ cc -D_GNU_SOURCE ftm.c
$ ./a.out
```

```
    _POSIX_SOURCE defined
    _POSIX_C_SOURCE defined: 200809L
    _ISOC99_SOURCE defined
    _XOPEN_SOURCE defined: 700
    _XOPEN_SOURCE_EXTENDED defined
    _LARGEFILE64_SOURCE defined
    _BSD_SOURCE defined
    _SVID_SOURCE defined
    _ATFILE_SOURCE defined
    _GNU_SOURCE defined
```

Program source

```
/* ftm.c */

#include <stdint.h>
#include <stdio.h>
#include <unistd.h>
#include <stdlib.h>

int
main(int argc, char *argv[])
{
#ifdef _POSIX_SOURCE
    printf("_POSIX_SOURCE defined\n");
#endif

#ifdef _POSIX_C_SOURCE
    printf("_POSIX_C_SOURCE defined: %jdL\n",
            (intmax_t) _POSIX_C_SOURCE);
#endif

#ifdef _ISOC99_SOURCE
    printf("_ISOC99_SOURCE defined\n");
#endif

#ifdef _ISOC11_SOURCE
    printf("_ISOC11_SOURCE defined\n");

NAME

fifo − first-in first-out special file, named pipe

DESCRIPTION

A FIFO special file (a named pipe) is similar to a pipe, except that it is accessed as part of the filesystem. It can be opened by multiple processes for reading or writing. When processes are exchanging data via the FIFO, the kernel passes all data internally without writing it to the filesystem. Thus, the FIFO special file has no contents on the filesystem; the filesystem entry merely serves as a reference point so that processes can access the pipe using a name in the filesystem.

The kernel maintains exactly one pipe object for each FIFO special file that is opened by at least one process. The FIFO must be opened on both ends (reading and writing) before data can be passed. Normally, opening the FIFO blocks until the other end is opened also.

A process can open a FIFO in nonblocking mode. In this case, opening for read-only succeeds even if no one has opened on the write side yet and opening for write-only fails with **ENXIO** (no such device or address) unless the other end has already been opened.

Under Linux, opening a FIFO for read and write will succeed both in blocking and nonblocking mode. POSIX leaves this behavior undefined. This can be used to open a FIFO for writing while there are no readers available. A process that uses both ends of the connection in order to communicate with itself should be very careful to avoid deadlocks.

NOTES

For details of the semantics of I/O on FIFOs, see *pipe*(7).

When a process tries to write to a FIFO that is not opened for read on the other side, the process is sent a **SIGPIPE** signal.

FIFO special files can be created by *mkfifo*(3), and are indicated by *ls −l* with the file type 'p'.

NAME

futex − fast user-space locking

SYNOPSIS

#include <linux/futex.h>

DESCRIPTION

The Linux kernel provides futexes ("Fast user-space mutexes") as a building block for fast user-space locking and semaphores. Futexes are very basic and lend themselves well for building higher-level locking abstractions such as mutexes, condition variables, read-write locks, barriers, and semaphores.

Most programmers will in fact not be using futexes directly but will instead rely on system libraries built on them, such as the Native POSIX Thread Library (NPTL) (see *pthreads*(7)).

A futex is identified by a piece of memory which can be shared between processes or threads. In these different processes, the futex need not have identical addresses. In its bare form, a futex has semaphore semantics; it is a counter that can be incremented and decremented atomically; processes can wait for the value to become positive.

Futex operation occurs entirely in user space for the noncontended case. The kernel is involved only to arbitrate the contended case. As any sane design will strive for noncontention, futexes are also optimized for this situation.

In its bare form, a futex is an aligned integer which is touched only by atomic assembler instructions. This integer is four bytes long on all platforms. Processes can share this integer using *mmap*(2), via shared memory segments, or because they share memory space, in which case the application is commonly called multithreaded.

Semantics

Any futex operation starts in user space, but it may be necessary to communicate with the kernel using the *futex*(2) system call.

To "up" a futex, execute the proper assembler instructions that will cause the host CPU to atomically increment the integer. Afterward, check if it has in fact changed from 0 to 1, in which case there were no waiters and the operation is done. This is the noncontended case which is fast and should be common.

In the contended case, the atomic increment changed the counter from −1 (or some other negative number). If this is detected, there are waiters. User space should now set the counter to 1 and instruct the kernel to wake up any waiters using the **FUTEX_WAKE** operation.

Waiting on a futex, to "down" it, is the reverse operation. Atomically decrement the counter and check if it changed to 0, in which case the operation is done and the futex was uncontended. In all other circumstances, the process should set the counter to −1 and request that the kernel wait for another process to up the futex. This is done using the **FUTEX_WAIT** operation.

The *futex*(2) system call can optionally be passed a timeout specifying how long the kernel should wait for the futex to be upped. In this case, semantics are more complex and the programmer is referred to *futex*(2) for more details. The same holds for asynchronous futex waiting.

VERSIONS

Initial futex support was merged in Linux 2.5.7 but with different semantics from those described above. Current semantics are available from Linux 2.5.40 onward.

NOTES

To reiterate, bare futexes are not intended as an easy-to-use abstraction for end users. Implementors are expected to be assembly literate and to have read the sources of the futex user-space library referenced below.

This man page illustrates the most common use of the *futex*(2) primitives; it is by no means the only one.

NAME

glob − globbing pathnames

DESCRIPTION

Long ago, in UNIX V6, there was a program */etc/glob* that would expand wildcard patterns. Soon afterward this became a shell built-in.

These days there is also a library routine *glob*(3) that will perform this function for a user program.

The rules are as follows (POSIX.2, 3.13).

Wildcard matching

A string is a wildcard pattern if it contains one of the characters '?', '*', or '['. Globbing is the operation that expands a wildcard pattern into the list of pathnames matching the pattern. Matching is defined by:

A '?' (not between brackets) matches any single character.

A '*' (not between brackets) matches any string, including the empty string.

Character classes

An expression "*[...]*" where the first character after the leading '[' is not an '!' matches a single character, namely any of the characters enclosed by the brackets. The string enclosed by the brackets cannot be empty; therefore ']' can be allowed between the brackets, provided that it is the first character. (Thus, "*[][!]*" matches the three characters '[', ']', and '!'.)

Ranges

There is one special convention: two characters separated by '−' denote a range. (Thus, "*[A−Fa−f0−9]*" is equivalent to "*[ABCDEFabcdef0123456789]*".) One may include '−' in its literal meaning by making it the first or last character between the brackets. (Thus, "*[]−]*" matches just the two characters ']' and '−', and "*[−−0]*" matches the three characters '−', '.', and '0', since '/' cannot be matched.)

Complementation

An expression "*[!...]*" matches a single character, namely any character that is not matched by the expression obtained by removing the first '!' from it. (Thus, "*[!]a−]*" matches any single character except ']', 'a', and '−'.)

One can remove the special meaning of '?', '*', and '[' by preceding them by a backslash, or, in case this is part of a shell command line, enclosing them in quotes. Between brackets these characters stand for themselves. Thus, "*[[?*\]*" matches the four characters '[', '?', '*', and '\'.

Pathnames

Globbing is applied on each of the components of a pathname separately. A '/' in a pathname cannot be matched by a '?' or '*' wildcard, or by a range like "*[.−0]*". A range containing an explicit '/' character is syntactically incorrect. (POSIX requires that syntactically incorrect patterns are left unchanged.)

If a filename starts with a '.', this character must be matched explicitly. (Thus, *rm* * will not remove .profile, and *tar c* * will not archive all your files; *tar c* . is better.)

Empty lists

The nice and simple rule given above: "expand a wildcard pattern into the list of matching pathnames" was the original UNIX definition. It allowed one to have patterns that expand into an empty list, as in

```
xv −wait 0 *.gif *.jpg
```

where perhaps no *.gif files are present (and this is not an error). However, POSIX requires that a wildcard pattern is left unchanged when it is syntactically incorrect, or the list of matching pathnames is empty. With *bash* one can force the classical behavior using this command:

```
shopt −s nullglob
```

(Similar problems occur elsewhere. For example, where old scripts have

```
rm `find . −name "*~"`
```

new scripts require

```
rm −f nosuchfile `find . −name "*~"`
```

to avoid error messages from *rm* called with an empty argument list.)

NOTES

Regular expressions

Note that wildcard patterns are not regular expressions, although they are a bit similar. First of all, they match filenames, rather than text, and secondly, the conventions are not the same: for example, in a regular expression '*' means zero or more copies of the preceding thing.

Now that regular expressions have bracket expressions where the negation is indicated by a '^', POSIX has declared the effect of a wildcard pattern "*[^...]*" to be undefined.

Character classes and internationalization

Of course ranges were originally meant to be ASCII ranges, so that "*[−%]*" stands for "*[!"#$%]*" and "*[a−z]*" stands for "any lowercase letter". Some UNIX implementations generalized this so that a range X−Y stands for the set of characters with code between the codes for X and for Y. However, this requires the user to know the character coding in use on the local system, and moreover, is not convenient if the collating sequence for the local alphabet differs from the ordering of the character codes. Therefore, POSIX extended the bracket notation greatly, both for wildcard patterns and for regular expressions. In the above we saw three types of items that can occur in a bracket expression: namely (i) the negation, (ii) explicit single characters, and (iii) ranges. POSIX specifies ranges in an internationally more useful way and adds three more types:

(iii) Ranges X−Y comprise all characters that fall between X and Y (inclusive) in the current collating sequence as defined by the **LC_COLLATE** category in the current locale.

(iv) Named character classes, like

[:alnum:] [:alpha:] [:blank:] [:cntrl:]
[:digit:] [:graph:] [:lower:] [:print:]
[:punct:] [:space:] [:upper:] [:xdigit:]

so that one can say "*[[:lower:]]*" instead of "*[a−z]*", and have things work in Denmark, too, where there are three letters past 'z' in the alphabet. These character classes are defined by the **LC_CTYPE** category in the current locale.

(v) Collating symbols, like "*[.ch.]*" or "*[.a-acute.]*", where the string between "*[.*" and ".*]*" is a collating element defined for the current locale. Note that this may be a multicharacter element.

(vi) Equivalence class expressions, like "*[=a=]*", where the string between "*[=*" and "*=]*" is any collating element from its equivalence class, as defined for the current locale. For example, "*[[=a=]]*" might be equivalent to "*[aáàäâ]*", that is, to "*[a[.a-acute.][.a-grave.][.a-umlaut.][.a-circumflex.]]*".

NAME

hier − description of the filesystem hierarchy

DESCRIPTION

A typical Linux system has, among others, the following directories:

/ This is the root directory. This is where the whole tree starts.

/bin This directory contains executable programs which are needed in single user mode and to bring the system up or repair it.

/boot Contains static files for the boot loader. This directory holds only the files which are needed during the boot process. The map installer and configuration files should go to */sbin* and */etc*. The operating system kernel (initrd for example) must be located in either / or */boot*.

/dev Special or device files, which refer to physical devices. See *mknod*(1)

/etc Contains configuration files which are local to the machine. Some larger software packages, like X11, can have their own subdirectories below */etc*. Site-wide configuration files may be placed here or in */usr/etc*. Nevertheless, programs should always look for these files in */etc* and you may have links for these files to */usr/etc*.

/etc/opt
Host-specific configuration files for add-on applications installed in */opt*.

/etc/sgml
This directory contains the configuration files for SGML (optional).

/etc/skel
When a new user account is created, files from this directory are usually copied into the user's home directory.

/etc/X11
Configuration files for the X11 window system (optional).

/etc/xml
This directory contains the configuration files for XML (optional).

/home On machines with home directories for users, these are usually beneath this directory, directly or not. The structure of this directory depends on local administration decisions (optional).

/lib This directory should hold those shared libraries that are necessary to boot the system and to run the commands in the root filesystem.

/lib<qual>
These directories are variants of */lib* on system which support more than one binary format requiring separate libraries (optional).

/lib/modules
Loadable kernel modules (optional).

/lost+found
This directory contains items lost in the filesystem. These items are usually chunks of files mangled as a consequence of a faulty disk or a system crash.

/media This directory contains mount points for removable media such as CD and DVD disks or USB sticks. On systems where more than one device exists for mounting a certain type of media, mount directories can be created by appending a digit to the name of those available above starting with '0', but the unqualified name must also exist.

/media/floppy[1−9]
Floppy drive (optional).

/media/cdrom[1−9]
CD-ROM drive (optional).

/media/cdrecorder[1−9]
CD writer (optional).

/media/zip[1−9]
: Zip drive (optional).

/media/usb[1−9]
: USB drive (optional).

/mnt
: This directory is a mount point for a temporarily mounted filesystem. In some distributions, */mnt* contains subdirectories intended to be used as mount points for several temporary filesystems.

/opt
: This directory should contain add-on packages that contain static files.

/proc
: This is a mount point for the *proc* filesystem, which provides information about running processes and the kernel. This pseudo-filesystem is described in more detail in *proc*(5).

/root
: This directory is usually the home directory for the root user (optional).

/run
: This directory contains information which describes the system since it was booted. Once this purpose was served by */var/run* and programs may continue to use it.

/sbin
: Like */bin*, this directory holds commands needed to boot the system, but which are usually not executed by normal users.

/srv
: This directory contains site-specific data that is served by this system.

/sys
: This is a mount point for the sysfs filesystem, which provides information about the kernel like */proc*, but better structured, following the formalism of kobject infrastructure.

/tmp
: This directory contains temporary files which may be deleted with no notice, such as by a regular job or at system boot up.

/usr
: This directory is usually mounted from a separate partition. It should hold only shareable, read-only data, so that it can be mounted by various machines running Linux.

/usr/X11R6
: The X−Window system, version 11 release 6 (present in FHS 2.3, removed in FHS 3.0).

/usr/X11R6/bin
: Binaries which belong to the X−Window system; often, there is a symbolic link from the more traditional */usr/bin/X11* to here.

/usr/X11R6/lib
: Data files associated with the X−Window system.

/usr/X11R6/lib/X11
: These contain miscellaneous files needed to run X; Often, there is a symbolic link from */usr/lib/X11* to this directory.

/usr/X11R6/include/X11
: Contains include files needed for compiling programs using the X11 window system. Often, there is a symbolic link from */usr/include/X11* to this directory.

/usr/bin
: This is the primary directory for executable programs. Most programs executed by normal users which are not needed for booting or for repairing the system and which are not installed locally should be placed in this directory.

/usr/bin/mh
: Commands for the MH mail handling system (optional).

/usr/bin/X11
: This is the traditional place to look for X11 executables; on Linux, it usually is a symbolic link to */usr/X11R6/bin*.

/usr/dict
: Replaced by */usr/share/dict*.

/usr/doc
: Replaced by */usr/share/doc*.

/usr/etc
: Site-wide configuration files to be shared between several machines may be stored in this directory. However, commands should always reference those files using the */etc* directory. Links from files in */etc* should point to the appropriate files in */usr/etc*.

/usr/games
: Binaries for games and educational programs (optional).

/usr/include
: Include files for the C compiler.

/usr/include/bsd
: BSD compatibility include files (optional).

/usr/include/X11
: Include files for the C compiler and the X−Window system. This is usually a symbolic link to */usr/X11R6/include/X11*.

/usr/include/asm
: Include files which declare some assembler functions. This used to be a symbolic link to */usr/src/linux/include/asm*.

/usr/include/linux
: This contains information which may change from system release to system release and used to be a symbolic link to */usr/src/linux/include/linux* to get at operating-system-specific information.

  (Note that one should have include files there that work correctly with the current libc and in user space. However, Linux kernel source is not designed to be used with user programs and does not know anything about the libc you are using. It is very likely that things will break if you let */usr/include/asm* and */usr/include/linux* point at a random kernel tree. Debian systems don't do this and use headers from a known good kernel version, provided in the libc*−dev package.)

/usr/include/g++
: Include files to use with the GNU C++ compiler.

/usr/lib Object libraries, including dynamic libraries, plus some executables which usually are not invoked directly. More complicated programs may have whole subdirectories there.

/usr/libexec
: Directory contains binaries for internal use only and they are not meant to be executed directly by users shell or scripts.

/usr/lib<qual>
: These directories are variants of */usr/lib* on system which support more than one binary format requiring separate libraries, except that the symbolic link */usr/lib*qual*/X11* is not required (optional).

/usr/lib/X11
: The usual place for data files associated with X programs, and configuration files for the X system itself. On Linux, it usually is a symbolic link to */usr/X11R6/lib/X11*.

/usr/lib/gcc−lib
: contains executables and include files for the GNU C compiler, *gcc*(1)

/usr/lib/groff
: Files for the GNU groff document formatting system.

/usr/lib/uucp
: Files for *uucp*(1)

/usr/local
: This is where programs which are local to the site typically go.

/usr/local/bin
: Binaries for programs local to the site.

/usr/local/doc
: Local documentation.

/usr/local/etc
: Configuration files associated with locally installed programs.

/usr/local/games
: Binaries for locally installed games.

/usr/local/lib
: Files associated with locally installed programs.

/usr/local/lib<qual>
: These directories are variants of */usr/local/lib* on system which support more than one binary format requiring separate libraries (optional).

/usr/local/include
: Header files for the local C compiler.

/usr/local/info
: Info pages associated with locally installed programs.

/usr/local/man
: Man pages associated with locally installed programs.

/usr/local/sbin
: Locally installed programs for system administration.

/usr/local/share
: Local application data that can be shared among different architectures of the same OS.

/usr/local/src
: Source code for locally installed software.

/usr/man
: Replaced by */usr/share/man*.

/usr/sbin
: This directory contains program binaries for system administration which are not essential for the boot process, for mounting */usr*, or for system repair.

/usr/share
: This directory contains subdirectories with specific application data, that can be shared among different architectures of the same OS. Often one finds stuff here that used to live in */usr/doc* or */usr/lib* or */usr/man*.

/usr/share/color
: Contains color management information, like International Color Consortium (ICC) Color profiles (optional).

/usr/share/dict
: Contains the word lists used by spell checkers (optional).

/usr/share/dict/words
: List of English words (optional).

/usr/share/doc
: Documentation about installed programs (optional).

/usr/share/games
: Static data files for games in */usr/games* (optional).

/usr/share/info
: Info pages go here (optional).

/usr/share/locale
: Locale information goes here (optional).

/usr/share/man
: Manual pages go here in subdirectories according to the man page sections.

*/usr/share/man/*locale*/man[1−9]*
: These directories contain manual pages for the specific locale in source code form. Systems which use a unique language and code set for all manual pages may omit the <locale> substring.

/usr/share/misc
: Miscellaneous data that can be shared among different architectures of the same OS.

/usr/share/nls
: The message catalogs for native language support go here (optional).

/usr/share/ppd
: Postscript Printer Definition (PPD) files (optional).

/usr/share/sgml
: Files for SGML (optional).

/usr/share/sgml/docbook
: DocBook DTD (optional).

/usr/share/sgml/tei
: TEI DTD (optional).

/usr/share/sgml/html
: HTML DTD (optional).

/usr/share/sgml/mathml
: MathML DTD (optional).

/usr/share/terminfo
: The database for terminfo (optional).

/usr/share/tmac
: Troff macros that are not distributed with groff (optional).

/usr/share/xml
: Files for XML (optional).

/usr/share/xml/docbook
: DocBook DTD (optional).

/usr/share/xml/xhtml
: XHTML DTD (optional).

/usr/share/xml/mathml
: MathML DTD (optional).

/usr/share/zoneinfo
: Files for timezone information (optional).

/usr/src
: Source files for different parts of the system, included with some packages for reference purposes. Don't work here with your own projects, as files below /usr should be read-only except when installing software (optional).

/usr/src/linux
: This was the traditional place for the kernel source. Some distributions put here the source for the default kernel they ship. You should probably use another directory when building your own kernel.

/usr/tmp
: Obsolete. This should be a link to */var/tmp*. This link is present only for compatibility reasons and shouldn't be used.

/var This directory contains files which may change in size, such as spool and log files.

/var/account
: Process accounting logs (optional).

/var/adm
This directory is superseded by */var/log* and should be a symbolic link to */var/log*.

/var/backups
Reserved for historical reasons.

/var/cache
Data cached for programs.

/var/cache/fonts
Locally generated fonts (optional).

/var/cache/man
Locally formatted man pages (optional).

/var/cache/www
WWW proxy or cache data (optional).

/var/cache/<package>
Package specific cache data (optional).

/var/catman/cat[1−9] or */var/cache/man/cat[1−9]*
These directories contain preformatted manual pages according to their man page section. (The use of preformatted manual pages is deprecated.)

/var/crash
System crash dumps (optional).

/var/cron
Reserved for historical reasons.

/var/games
Variable game data (optional).

/var/lib Variable state information for programs.

/var/lib/color
Variable files containing color management information (optional).

/var/lib/hwclock
State directory for hwclock (optional).

/var/lib/misc
Miscellaneous state data.

/var/lib/xdm
X display manager variable data (optional).

/var/lib/<editor>
Editor backup files and state (optional).

/var/lib/<name>
These directories must be used for all distribution packaging support.

/var/lib/<package>
State data for packages and subsystems (optional).

/var/lib/<pkgtool>
Packaging support files (optional).

/var/local
Variable data for */usr/local*.

/var/lock
Lock files are placed in this directory. The naming convention for device lock files is *LCK..<device>* where *<device>* is the device's name in the filesystem. The format used is that of HDU UUCP lock files, that is, lock files contain a PID as a 10-byte ASCII decimal number, followed by a newline character.

/var/log
Miscellaneous log files.

/var/opt
: Variable data for */opt*.

/var/mail
: Users' mailboxes. Replaces */var/spool/mail*.

/var/msgs
: Reserved for historical reasons.

/var/preserve
: Reserved for historical reasons.

/var/run
: Run-time variable files, like files holding process identifiers (PIDs) and logged user information *(utmp)*. Files in this directory are usually cleared when the system boots.

/var/spool
: Spooled (or queued) files for various programs.

/var/spool/at
: Spooled jobs for *at*(1)

/var/spool/cron
: Spooled jobs for *cron*(8)

/var/spool/lpd
: Spooled files for printing (optional).

/var/spool/lpd/printer
: Spools for a specific printer (optional).

/var/spool/mail
: Replaced by */var/mail*.

/var/spool/mqueue
: Queued outgoing mail (optional).

/var/spool/news
: Spool directory for news (optional).

/var/spool/rwho
: Spooled files for *rwhod*(8) (optional).

/var/spool/smail
: Spooled files for the *smail*(1) mail delivery program.

/var/spool/uucp
: Spooled files for *uucp*(1) (optional).

/var/tmp
: Like */tmp*, this directory holds temporary files stored for an unspecified duration.

/var/yp Database files for NIS, formerly known as the Sun Yellow Pages (YP).

The Filesystem Hierarchy Standard

NAME

hostname − hostname resolution description

DESCRIPTION

Hostnames are domains, where a domain is a hierarchical, dot-separated list of subdomains; for example, the machine "monet", in the "example" subdomain of the "com" domain would be represented as "monet.example.com".

Each element of the hostname must be from 1 to 63 characters long and the entire hostname, including the dots, can be at most 253 characters long. Valid characters for hostnames are *ASCII*(7) letters from *a* to *z*, the digits from *0* to *9*, and the hyphen (−). A hostname may not start with a hyphen.

Hostnames are often used with network client and server programs, which must generally translate the name to an address for use. (This task is generally performed by either *getaddrinfo*(3) or the obsolete *gethostbyname*(3).)

Hostnames are resolved by the NSS framework in glibc according to the **hosts** configuration in *nsswitch.conf*(5). The DNS-based name resolver (in the **dns** NSS service module) resolves them in the following fashion.

If the name consists of a single component, that is, contains no dot, and if the environment variable **HOSTALIASES** is set to the name of a file, that file is searched for any string matching the input hostname. The file should consist of lines made up of two white-space separated strings, the first of which is the hostname alias, and the second of which is the complete hostname to be substituted for that alias. If a case-insensitive match is found between the hostname to be resolved and the first field of a line in the file, the substituted name is looked up with no further processing.

If the input name ends with a trailing dot, the trailing dot is removed, and the remaining name is looked up with no further processing.

If the input name does not end with a trailing dot, it is looked up by searching through a list of domains until a match is found. The default search list includes first the local domain, then its parent domains with at least 2 name components (longest first). For example, in the domain cs.example.com, the name lithium.cchem will be checked first as lithium.cchem.cs.example and then as lithium.cchem.example.com. lithium.cchem.com will not be tried, as there is only one component remaining from the local domain. The search path can be changed from the default by a system-wide configuration file (see *resolver*(5)).

IETF RFC 1123

IETF RFC 1178

NAME

icmp − Linux IPv4 ICMP kernel module.

DESCRIPTION

This kernel protocol module implements the Internet Control Message Protocol defined in RFC 792. It is used to signal error conditions and for diagnosis. The user doesn't interact directly with this module; instead it communicates with the other protocols in the kernel and these pass the ICMP errors to the application layers. The kernel ICMP module also answers ICMP requests.

A user protocol may receive ICMP packets for all local sockets by opening a raw socket with the protocol **IPPROTO_ICMP**. See *raw*(7) for more information. The types of ICMP packets passed to the socket can be filtered using the **ICMP_FILTER** socket option. ICMP packets are always processed by the kernel too, even when passed to a user socket.

Linux limits the rate of ICMP error packets to each destination. **ICMP_REDIRECT** and **ICMP_DEST_UNREACH** are also limited by the destination route of the incoming packets.

/proc interfaces

ICMP supports a set of */proc* interfaces to configure some global IP parameters. The parameters can be accessed by reading or writing files in the directory */proc/sys/net/ipv4/*. Most of these parameters are rate limitations for specific ICMP types. Linux 2.2 uses a token bucket filter to limit ICMPs. The value is the timeout in jiffies until the token bucket filter is cleared after a burst. A jiffy is a system dependent unit, usually 10ms on i386 and about 1ms on alpha and ia64.

icmp_destunreach_rate (Linux 2.2 to Linux 2.4.9)
: Maximum rate to send ICMP Destination Unreachable packets. This limits the rate at which packets are sent to any individual route or destination. The limit does not affect sending of **ICMP_FRAG_NEEDED** packets needed for path MTU discovery.

icmp_echo_ignore_all (since Linux 2.2)
: If this value is nonzero, Linux will ignore all **ICMP_ECHO** requests.

icmp_echo_ignore_broadcasts (since Linux 2.2)
: If this value is nonzero, Linux will ignore all **ICMP_ECHO** packets sent to broadcast addresses.

icmp_echoreply_rate (Linux 2.2 to Linux 2.4.9)
: Maximum rate for sending **ICMP_ECHOREPLY** packets in response to **ICMP_ECHOREQUEST** packets.

icmp_errors_use_inbound_ifaddr (Boolean; default: disabled; since Linux 2.6.12)
: If disabled, ICMP error messages are sent with the primary address of the exiting interface.

  If enabled, the message will be sent with the primary address of the interface that received the packet that caused the ICMP error. This is the behavior that many network administrators will expect from a router. And it can make debugging complicated network layouts much easier.

  Note that if no primary address exists for the interface selected, then the primary address of the first non-loopback interface that has one will be used regardless of this setting.

icmp_ignore_bogus_error_responses (Boolean; default: disabled; since Linux 2.2)
: Some routers violate RFC1122 by sending bogus responses to broadcast frames. Such violations are normally logged via a kernel warning. If this parameter is enabled, the kernel will not give such warnings, which will avoid log file clutter.

icmp_paramprob_rate (Linux 2.2 to Linux 2.4.9)
: Maximum rate for sending **ICMP_PARAMETERPROB** packets. These packets are sent when a packet arrives with an invalid IP header.

icmp_ratelimit (integer; default: 1000; since Linux 2.4.10)
: Limit the maximum rates for sending ICMP packets whose type matches *icmp_ratemask* (see below) to specific targets. 0 to disable any limiting, otherwise the minimum space between responses in milliseconds.

icmp_ratemask (integer; default: see below; since Linux 2.4.10)
: Mask made of ICMP types for which rates are being limited.

Significant bits: IHGFEDCBA9876543210
Default mask: 0000001100000011000 (0x1818)

Bit definitions (see the Linux kernel source file *include/linux/icmp.h*):

0 Echo Reply
3 Destination Unreachable *
4 Source Quench *
5 Redirect
8 Echo Request
B Time Exceeded *
C Parameter Problem *
D Timestamp Request
E Timestamp Reply
F Info Request
G Info Reply
H Address Mask Request
I Address Mask Reply

The bits marked with an asterisk are rate limited by default (see the default mask above).

icmp_timeexceed_rate (Linux 2.2 to Linux 2.4.9)
Maximum rate for sending **ICMP_TIME_EXCEEDED** packets. These packets are sent to prevent loops when a packet has crossed too many hops.

ping_group_range (two integers; default: see below; since Linux 2.6.39)
Range of the group IDs (minimum and maximum group IDs, inclusive) that are allowed to create ICMP Echo sockets. The default is "1 0", which means no group is allowed to create ICMP Echo sockets.

VERSIONS

Support for the **ICMP_ADDRESS** request was removed in Linux 2.2.

Support for **ICMP_SOURCE_QUENCH** was removed in Linux 2.2.

NOTES

As many other implementations don't support **IPPROTO_ICMP** raw sockets, this feature should not be relied on in portable programs.

ICMP_REDIRECT packets are not sent when Linux is not acting as a router. They are also accepted only from the old gateway defined in the routing table and the redirect routes are expired after some time.

The 64-bit timestamp returned by **ICMP_TIMESTAMP** is in milliseconds since the Epoch, 1970-01-01 00:00:00 +0000 (UTC).

Linux ICMP internally uses a raw socket to send ICMPs. This raw socket may appear in *netstat*(8) output with a zero inode.

RFC 792 for a description of the ICMP protocol.

NAME

inode − file inode information

DESCRIPTION

Each file has an inode containing metadata about the file. An application can retrieve this metadata using *stat*(2) (or related calls), which returns a *stat* structure, or *statx*(2), which returns a *statx* structure.

The following is a list of the information typically found in, or associated with, the file inode, with the names of the corresponding structure fields returned by *stat*(2) and *statx*(2):

Device where inode resides
: *stat.st_dev*; *statx.stx_dev_minor* and *statx.stx_dev_major*

  Each inode (as well as the associated file) resides in a filesystem that is hosted on a device. That device is identified by the combination of its major ID (which identifies the general class of device) and minor ID (which identifies a specific instance in the general class).

Inode number
: *stat.st_ino*; *statx.stx_ino*

  Each file in a filesystem has a unique inode number. Inode numbers are guaranteed to be unique only within a filesystem (i.e., the same inode numbers may be used by different filesystems, which is the reason that hard links may not cross filesystem boundaries). This field contains the file's inode number.

File type and mode
: *stat.st_mode*; *statx.stx_mode*

  See the discussion of file type and mode, below.

Link count
: *stat.st_nlink*; *statx.stx_nlink*

  This field contains the number of hard links to the file. Additional links to an existing file are created using *link*(2).

User ID
: *stat.st_uid*; *statx.stx_uid*

  This field records the user ID of the owner of the file. For newly created files, the file user ID is the effective user ID of the creating process. The user ID of a file can be changed using *chown*(2).

Group ID
: *stat.st_gid*; *statx.stx_gid*

  The inode records the ID of the group owner of the file. For newly created files, the file group ID is either the group ID of the parent directory or the effective group ID of the creating process, depending on whether or not the set-group-ID bit is set on the parent directory (see below). The group ID of a file can be changed using *chown*(2).

Device represented by this inode
: *stat.st_rdev*; *statx.stx_rdev_minor* and *statx.stx_rdev_major*

  If this file (inode) represents a device, then the inode records the major and minor ID of that device.

File size
: *stat.st_size*; *statx.stx_size*

  This field gives the size of the file (if it is a regular file or a symbolic link) in bytes. The size of a symbolic link is the length of the pathname it contains, without a terminating null byte.

Preferred block size for I/O
: *stat.st_blksize*; *statx.stx_blksize*

  This field gives the "preferred" blocksize for efficient filesystem I/O. (Writing to a file in smaller chunks may cause an inefficient read-modify-rewrite.)

Number of blocks allocated to the file
: *stat.st_blocks*; *statx.stx_blocks*

  This field indicates the number of blocks allocated to the file, 512-byte units, (This may be smaller than *st_size*/512 when the file has holes.)

  The POSIX.1 standard notes that the unit for the *st_blocks* member of the *stat* structure is not defined by the standard. On many implementations it is 512 bytes; on a few systems, a different unit is used, such as 1024. Furthermore, the unit may differ on a per-filesystem basis.

Last access timestamp (atime)
: *stat.st_atime*; *statx.stx_atime*

  This is the file's last access timestamp. It is changed by file accesses, for example, by *execve*(2), *mknod*(2), *pipe*(2), *utime*(2), and *read*(2) (of more than zero bytes). Other interfaces, such as *mmap*(2), may or may not update the atime timestamp

  Some filesystem types allow mounting in such a way that file and/or directory accesses do not cause an update of the atime timestamp. (See *noatime*, *nodiratime*, and *relatime* in *mount*(8), and related information in *mount*(2).) In addition, the atime timestamp is not updated if a file is opened with the **O_NOATIME** flag; see *open*(2).

File creation (birth) timestamp (btime)
: (not returned in the *stat* structure); *statx.stx_btime*

  The file's creation timestamp. This is set on file creation and not changed subsequently.

  The btime timestamp was not historically present on UNIX systems and is not currently supported by most Linux filesystems.

Last modification timestamp (mtime)
: *stat.st_mtime*; *statx.stx_mtime*

  This is the file's last modification timestamp. It is changed by file modifications, for example, by *mknod*(2), *truncate*(2), *utime*(2), and *write*(2) (of more than zero bytes). Moreover, the mtime timestamp of a directory is changed by the creation or deletion of files in that directory. The mtime timestamp is *not* changed for changes in owner, group, hard link count, or mode.

Last status change timestamp (ctime)
: *stat.st_ctime*; *statx.stx_ctime*

  This is the file's last status change timestamp. It is changed by writing or by setting inode information (i.e., owner, group, link count, mode, etc.).

The timestamp fields report time measured with a zero point at the *Epoch*, 1970-01-01 00:00:00 +0000, UTC (see *time*(7)).

Nanosecond timestamps are supported on XFS, JFS, Btrfs, and ext4 (since Linux 2.6.23). Nanosecond timestamps are not supported in ext2, ext3, and Reiserfs. In order to return timestamps with nanosecond precision, the timestamp fields in the *stat* and *statx* structures are defined as structures that include a nanosecond component. See *stat*(2) and *statx*(2) for details. On filesystems that do not support subsecond timestamps, the nanosecond fields in the *stat* and *statx* structures are returned with the value 0.

The file type and mode

The *stat.st_mode* field (for *statx*(2), the *statx.stx_mode* field) contains the file type and mode.

POSIX refers to the *stat.st_mode* bits corresponding to the mask **S_IFMT** (see below) as the *file type*, the 12 bits corresponding to the mask 07777 as the *file mode bits* and the least significant 9 bits (0777) as the *file permission bits*.

The following mask values are defined for the file type:

S_IFMT	0170000	bit mask for the file type bit field
S_IFSOCK	0140000	socket
S_IFLNK	0120000	symbolic link
S_IFREG	0100000	regular file
S_IFBLK	0060000	block device
S_IFDIR	0040000	directory
S_IFCHR	0020000	character device

S_IFIFO 0010000 FIFO

Thus, to test for a regular file (for example), one could write:

```
stat(pathname, &sb);
if ((sb.st_mode & S_IFMT) == S_IFREG) {
    /* Handle regular file */
}
```

Because tests of the above form are common, additional macros are defined by POSIX to allow the test of the file type in *st_mode* to be written more concisely:

S_ISREG(m) is it a regular file?

S_ISDIR(m) directory?

S_ISCHR(m) character device?

S_ISBLK(m) block device?

S_ISFIFO(m) FIFO (named pipe)?

S_ISLNK(m) symbolic link? (Not in POSIX.1-1996.)

S_ISSOCK(m) socket? (Not in POSIX.1-1996.)

The preceding code snippet could thus be rewritten as:

```
stat(pathname, &sb);
if (S_ISREG(sb.st_mode)) {
    /* Handle regular file */
}
```

The definitions of most of the above file type test macros are provided if any of the following feature test macros is defined: **_BSD_SOURCE** (in glibc 2.19 and earlier), **_SVID_SOURCE** (in glibc 2.19 and earlier), or **_DEFAULT_SOURCE** (in glibc 2.20 and later). In addition, definitions of all of the above macros except **S_IFSOCK** and **S_ISSOCK**() are provided if **_XOPEN_SOURCE** is defined.

The definition of **S_IFSOCK** can also be exposed either by defining **_XOPEN_SOURCE** with a value of 500 or greater or (since glibc 2.24) by defining both **_XOPEN_SOURCE** and **_XOPEN_SOURCE_EXTENDED**.

The definition of **S_ISSOCK**() is exposed if any of the following feature test macros is defined: **_BSD_SOURCE** (in glibc 2.19 and earlier), **_DEFAULT_SOURCE** (in glibc 2.20 and later), **_XOPEN_SOURCE** with a value of 500 or greater, **_POSIX_C_SOURCE** with a value of 200112L or greater, or (since glibc 2.24) by defining both **_XOPEN_SOURCE** and **_XOPEN_SOURCE_EXTENDED**.

The following mask values are defined for the file mode component of the *st_mode* field:

S_ISUID 04000 set-user-ID bit (see *execve*(2))
S_ISGID 02000 set-group-ID bit (see below)
S_ISVTX 01000 sticky bit (see below)
S_IRWXU 00700 owner has read, write, and execute permission
S_IRUSR 00400 owner has read permission
S_IWUSR 00200 owner has write permission
S_IXUSR 00100 owner has execute permission
S_IRWXG 00070 group has read, write, and execute permission
S_IRGRP 00040 group has read permission
S_IWGRP 00020 group has write permission
S_IXGRP 00010 group has execute permission
S_IRWXO 00007 others (not in group) have read, write, and execute permission
S_IROTH 00004 others have read permission
S_IWOTH 00002 others have write permission
S_IXOTH 00001 others have execute permission

The set-group-ID bit (**S_ISGID**) has several special uses. For a directory, it indicates that BSD semantics are to be used for that directory: files created there inherit their group ID from the directory, not from the effective group ID of the creating process, and directories created there will also get the **S_ISGID** bit set. For an executable file, the set-group-ID bit causes the effective group ID of a process that

executes the file to change as described in *execve*(2). For a file that does not have the group execution bit (**S_IXGRP**) set, the set-group-ID bit indicates mandatory file/record locking.

The sticky bit (**S_ISVTX**) on a directory means that a file in that directory can be renamed or deleted only by the owner of the file, by the owner of the directory, and by a privileged process.

STANDARDS

POSIX.1-2008.

HISTORY

POSIX.1-2001.

POSIX.1-1990 did not describe the **S_IFMT**, **S_IFSOCK**, **S_IFLNK**, **S_IFREG**, **S_IFBLK**, **S_IFDIR**, **S_IFCHR**, **S_IFIFO**, and **S_ISVTX** constants, but instead specified the use of the macros **S_ISDIR**() and so on.

The **S_ISLNK**() and **S_ISSOCK**() macros were not in POSIX.1-1996; the former is from SVID 4, the latter from SUSv2.

UNIX V7 (and later systems) had **S_IREAD**, **S_IWRITE**, **S_IEXEC**, and where POSIX prescribes the synonyms **S_IRUSR**, **S_IWUSR**, and **S_IXUSR**.

NOTES

For pseudofiles that are autogenerated by the kernel, the file size (*stat.st_size*; *statx.stx_size*) reported by the kernel is not accurate. For example, the value 0 is returned for many files under the */proc* directory, while various files under */sys* report a size of 4096 bytes, even though the file content is smaller. For such files, one should simply try to read as many bytes as possible (and append '\0' to the returned buffer if it is to be interpreted as a string).

NAME

inotify − monitoring filesystem events

DESCRIPTION

The *inotify* API provides a mechanism for monitoring filesystem events. Inotify can be used to monitor individual files, or to monitor directories. When a directory is monitored, inotify will return events for the directory itself, and for files inside the directory.

The following system calls are used with this API:

- *inotify_init*(2) creates an inotify instance and returns a file descriptor referring to the inotify instance. The more recent *inotify_init1*(2) is like *inotify_init*(2), but has a *flags* argument that provides access to some extra functionality.
- *inotify_add_watch*(2) manipulates the "watch list" associated with an inotify instance. Each item ("watch") in the watch list specifies the pathname of a file or directory, along with some set of events that the kernel should monitor for the file referred to by that pathname. *inotify_add_watch*(2) either creates a new watch item, or modifies an existing watch. Each watch has a unique "watch descriptor", an integer returned by *inotify_add_watch*(2) when the watch is created.
- When events occur for monitored files and directories, those events are made available to the application as structured data that can be read from the inotify file descriptor using *read*(2) (see below).
- *inotify_rm_watch*(2) removes an item from an inotify watch list.
- When all file descriptors referring to an inotify instance have been closed (using *close*(2)), the underlying object and its resources are freed for reuse by the kernel; all associated watches are automatically freed.

With careful programming, an application can use inotify to efficiently monitor and cache the state of a set of filesystem objects. However, robust applications should allow for the fact that bugs in the monitoring logic or races of the kind described below may leave the cache inconsistent with the filesystem state. It is probably wise to do some consistency checking, and rebuild the cache when inconsistencies are detected.

Reading events from an inotify file descriptor

To determine what events have occurred, an application *read*(2)s from the inotify file descriptor. If no events have so far occurred, then, assuming a blocking file descriptor, *read*(2) will block until at least one event occurs (unless interrupted by a signal, in which case the call fails with the error **EINTR**; see *signal*(7)).

Each successful *read*(2) returns a buffer containing one or more of the following structures:

```
struct inotify_event {
    int      wd;       /* Watch descriptor */
    uint32_t mask;     /* Mask describing event */
    uint32_t cookie;   /* Unique cookie associating related
                          events (for rename(2)) */
    uint32_t len;      /* Size of name field */
    char     name[];   /* Optional null-terminated name */
};
```

wd identifies the watch for which this event occurs. It is one of the watch descriptors returned by a previous call to *inotify_add_watch*(2).

mask contains bits that describe the event that occurred (see below).

cookie is a unique integer that connects related events. Currently, this is used only for rename events, and allows the resulting pair of **IN_MOVED_FROM** and **IN_MOVED_TO** events to be connected by the application. For all other event types, *cookie* is set to 0.

The *name* field is present only when an event is returned for a file inside a watched directory; it identifies the filename within the watched directory. This filename is null-terminated, and may include further null bytes ('\0') to align subsequent reads to a suitable address boundary.

The *len* field counts all of the bytes in *name*, including the null bytes; the length of each *inotify_event* structure is thus *sizeof(struct inotify_event)+len*.

The behavior when the buffer given to *read*(2) is too small to return information about the next event

depends on the kernel version: before Linux 2.6.21, *read*(2) returns 0; since Linux 2.6.21, *read*(2) fails with the error **EINVAL**. Specifying a buffer of size

```
sizeof(struct inotify_event) + NAME_MAX + 1
```

will be sufficient to read at least one event.

inotify events

The *inotify_add_watch*(2) *mask* argument and the *mask* field of the *inotify_event* structure returned when *read*(2)ing an inotify file descriptor are both bit masks identifying inotify events. The following bits can be specified in *mask* when calling *inotify_add_watch*(2) and may be returned in the *mask* field returned by *read*(2):

IN_ACCESS (+)
File was accessed (e.g., *read*(2), *execve*(2)).

IN_ATTRIB (*)
Metadata changed—for example, permissions (e.g., *chmod*(2)), timestamps (e.g., *utimensat*(2)), extended attributes (**setxattr**(2)), link count (since Linux 2.6.25; e.g., for the target of *link*(2) and for *unlink*(2)), and user/group ID (e.g., *chown*(2)).

IN_CLOSE_WRITE (+)
File opened for writing was closed.

IN_CLOSE_NOWRITE (*)
File or directory not opened for writing was closed.

IN_CREATE (+)
File/directory created in watched directory (e.g., *open*(2) **O_CREAT**, *mkdir*(2), *link*(2), *symlink*(2), *bind*(2) on a UNIX domain socket).

IN_DELETE (+)
File/directory deleted from watched directory.

IN_DELETE_SELF
Watched file/directory was itself deleted. (This event also occurs if an object is moved to another filesystem, since *mv*(1) in effect copies the file to the other filesystem and then deletes it from the original filesystem.) In addition, an **IN_IGNORED** event will subsequently be generated for the watch descriptor.

IN_MODIFY (+)
File was modified (e.g., *write*(2), *truncate*(2)).

IN_MOVE_SELF
Watched file/directory was itself moved.

IN_MOVED_FROM (+)
Generated for the directory containing the old filename when a file is renamed.

IN_MOVED_TO (+)
Generated for the directory containing the new filename when a file is renamed.

IN_OPEN (*)
File or directory was opened.

Inotify monitoring is inode-based: when monitoring a file (but not when monitoring the directory containing a file), an event can be generated for activity on any link to the file (in the same or a different directory).

When monitoring a directory:

- the events marked above with an asterisk (*) can occur both for the directory itself and for objects inside the directory; and
- the events marked with a plus sign (+) occur only for objects inside the directory (not for the directory itself).

Note: when monitoring a directory, events are not generated for the files inside the directory when the events are performed via a pathname (i.e., a link) that lies outside the monitored directory.

When events are generated for objects inside a watched directory, the *name* field in the returned

inotify_event structure identifies the name of the file within the directory.

The **IN_ALL_EVENTS** macro is defined as a bit mask of all of the above events. This macro can be used as the *mask* argument when calling *inotify_add_watch*(2).

Two additional convenience macros are defined:

IN_MOVE
Equates to **IN_MOVED_FROM | IN_MOVED_TO**.

IN_CLOSE
Equates to **IN_CLOSE_WRITE | IN_CLOSE_NOWRITE**.

The following further bits can be specified in *mask* when calling *inotify_add_watch*(2):

IN_DONT_FOLLOW (since Linux 2.6.15)
Don't dereference *pathname* if it is a symbolic link.

IN_EXCL_UNLINK (since Linux 2.6.36)
By default, when watching events on the children of a directory, events are generated for children even after they have been unlinked from the directory. This can result in large numbers of uninteresting events for some applications (e.g., if watching */tmp*, in which many applications create temporary files whose names are immediately unlinked). Specifying **IN_EXCL_UNLINK** changes the default behavior, so that events are not generated for children after they have been unlinked from the watched directory.

IN_MASK_ADD
If a watch instance already exists for the filesystem object corresponding to *pathname*, add (OR) the events in *mask* to the watch mask (instead of replacing the mask); the error **EINVAL** results if **IN_MASK_CREATE** is also specified.

IN_ONESHOT
Monitor the filesystem object corresponding to *pathname* for one event, then remove from watch list.

IN_ONLYDIR (since Linux 2.6.15)
Watch *pathname* only if it is a directory; the error **ENOTDIR** results if *pathname* is not a directory. Using this flag provides an application with a race-free way of ensuring that the monitored object is a directory.

IN_MASK_CREATE (since Linux 4.18)
Watch *pathname* only if it does not already have a watch associated with it; the error **EEXIST** results if *pathname* is already being watched.

Using this flag provides an application with a way of ensuring that new watches do not modify existing ones. This is useful because multiple paths may refer to the same inode, and multiple calls to *inotify_add_watch*(2) without this flag may clobber existing watch masks.

The following bits may be set in the *mask* field returned by *read*(2):

IN_IGNORED
Watch was removed explicitly (**inotify_rm_watch**(2)) or automatically (file was deleted, or filesystem was unmounted). See also BUGS.

IN_ISDIR
Subject of this event is a directory.

IN_Q_OVERFLOW
Event queue overflowed (*wd* is −1 for this event).

IN_UNMOUNT
Filesystem containing watched object was unmounted. In addition, an **IN_IGNORED** event will subsequently be generated for the watch descriptor.

Examples

Suppose an application is watching the directory *dir* and the file *dir/myfile* for all events. The examples below show some events that will be generated for these two objects.

fd = open("dir/myfile", O_RDWR);
: Generates **IN_OPEN** events for both *dir* and *dir/myfile*.

read(fd, buf, count);
: Generates **IN_ACCESS** events for both *dir* and *dir/myfile*.

write(fd, buf, count);
: Generates **IN_MODIFY** events for both *dir* and *dir/myfile*.

fchmod(fd, mode);
: Generates **IN_ATTRIB** events for both *dir* and *dir/myfile*.

close(fd);
: Generates **IN_CLOSE_WRITE** events for both *dir* and *dir/myfile*.

Suppose an application is watching the directories *dir1* and *dir2*, and the file *dir1/myfile*. The following examples show some events that may be generated.

link("dir1/myfile", "dir2/new");
: Generates an **IN_ATTRIB** event for *myfile* and an **IN_CREATE** event for *dir2*.

rename("dir1/myfile", "dir2/myfile");
: Generates an **IN_MOVED_FROM** event for *dir1*, an **IN_MOVED_TO** event for *dir2*, and an **IN_MOVE_SELF** event for *myfile*. The **IN_MOVED_FROM** and **IN_MOVED_TO** events will have the same *cookie* value.

Suppose that *dir1/xx* and *dir2/yy* are (the only) links to the same file, and an application is watching *dir1*, *dir2*, *dir1/xx*, and *dir2/yy*. Executing the following calls in the order given below will generate the following events:

unlink("dir2/yy");
: Generates an **IN_ATTRIB** event for *xx* (because its link count changes) and an **IN_DELETE** event for *dir2*.

unlink("dir1/xx");
: Generates **IN_ATTRIB**, **IN_DELETE_SELF**, and **IN_IGNORED** events for *xx*, and an **IN_DELETE** event for *dir1*.

Suppose an application is watching the directory *dir* and (the empty) directory *dir/subdir*. The following examples show some events that may be generated.

mkdir("dir/new", mode);
: Generates an **IN_CREATE | IN_ISDIR** event for *dir*.

rmdir("dir/subdir");
: Generates **IN_DELETE_SELF** and **IN_IGNORED** events for *subdir*, and an **IN_DELETE | IN_ISDIR** event for *dir*.

/proc interfaces

The following interfaces can be used to limit the amount of kernel memory consumed by inotify:

/proc/sys/fs/inotify/max_queued_events
: The value in this file is used when an application calls *inotify_init*(2) to set an upper limit on the number of events that can be queued to the corresponding inotify instance. Events in excess of this limit are dropped, but an **IN_Q_OVERFLOW** event is always generated.

/proc/sys/fs/inotify/max_user_instances
: This specifies an upper limit on the number of inotify instances that can be created per real user ID.

/proc/sys/fs/inotify/max_user_watches
: This specifies an upper limit on the number of watches that can be created per real user ID.

STANDARDS

Linux.

HISTORY

Inotify was merged into Linux 2.6.13. The required library interfaces were added in glibc 2.4. (**IN_DONT_FOLLOW**, **IN_MASK_ADD**, and **IN_ONLYDIR** were added in glibc 2.5.)

NOTES

Inotify file descriptors can be monitored using *select*(2), *poll*(2), and *epoll*(7). When an event is available, the file descriptor indicates as readable.

Since Linux 2.6.25, signal-driven I/O notification is available for inotify file descriptors; see the discussion of **F_SETFL** (for setting the **O_ASYNC** flag), **F_SETOWN**, and **F_SETSIG** in *fcntl*(2). The *siginfo_t* structure (described in *sigaction*(2)) that is passed to the signal handler has the following fields set: *si_fd* is set to the inotify file descriptor number; *si_signo* is set to the signal number; *si_code* is set to **POLL_IN**; and **POLLIN** is set in *si_band*.

If successive output inotify events produced on the inotify file descriptor are identical (same *wd*, *mask*, *cookie*, and *name*), then they are coalesced into a single event if the older event has not yet been read (but see BUGS). This reduces the amount of kernel memory required for the event queue, but also means that an application can't use inotify to reliably count file events.

The events returned by reading from an inotify file descriptor form an ordered queue. Thus, for example, it is guaranteed that when renaming from one directory to another, events will be produced in the correct order on the inotify file descriptor.

The set of watch descriptors that is being monitored via an inotify file descriptor can be viewed via the entry for the inotify file descriptor in the process's */proc/*pid*/fdinfo* directory. See *proc*(5) for further details. The **FIONREAD** *ioctl*(2) returns the number of bytes available to read from an inotify file descriptor.

Limitations and caveats

The inotify API provides no information about the user or process that triggered the inotify event. In particular, there is no easy way for a process that is monitoring events via inotify to distinguish events that it triggers itself from those that are triggered by other processes.

Inotify reports only events that a user-space program triggers through the filesystem API. As a result, it does not catch remote events that occur on network filesystems. (Applications must fall back to polling the filesystem to catch such events.) Furthermore, various pseudo-filesystems such as */proc*, */sys*, and */dev/pts* are not monitorable with inotify.

The inotify API does not report file accesses and modifications that may occur because of *mmap*(2), *msync*(2), and *munmap*(2).

The inotify API identifies affected files by filename. However, by the time an application processes an inotify event, the filename may already have been deleted or renamed.

The inotify API identifies events via watch descriptors. It is the application's responsibility to cache a mapping (if one is needed) between watch descriptors and pathnames. Be aware that directory renamings may affect multiple cached pathnames.

Inotify monitoring of directories is not recursive: to monitor subdirectories under a directory, additional watches must be created. This can take a significant amount time for large directory trees.

If monitoring an entire directory subtree, and a new subdirectory is created in that tree or an existing directory is renamed into that tree, be aware that by the time you create a watch for the new subdirectory, new files (and subdirectories) may already exist inside the subdirectory. Therefore, you may want to scan the contents of the subdirectory immediately after adding the watch (and, if desired, recursively add watches for any subdirectories that it contains).

Note that the event queue can overflow. In this case, events are lost. Robust applications should handle the possibility of lost events gracefully. For example, it may be necessary to rebuild part or all of the application cache. (One simple, but possibly expensive, approach is to close the inotify file descriptor, empty the cache, create a new inotify file descriptor, and then re-create watches and cache entries for the objects to be monitored.)

If a filesystem is mounted on top of a monitored directory, no event is generated, and no events are generated for objects immediately under the new mount point. If the filesystem is subsequently unmounted, events will subsequently be generated for the directory and the objects it contains.

Dealing with rename() events

As noted above, the **IN_MOVED_FROM** and **IN_MOVED_TO** event pair that is generated by *rename*(2) can be matched up via their shared cookie value. However, the task of matching has some challenges.

These two events are usually consecutive in the event stream available when reading from the inotify file descriptor. However, this is not guaranteed. If multiple processes are triggering events for monitored objects, then (on rare occasions) an arbitrary number of other events may appear between the **IN_MOVED_FROM** and **IN_MOVED_TO** events. Furthermore, it is not guaranteed that the event pair is atomically inserted into the queue: there may be a brief interval where the **IN_MOVED_FROM** has appeared, but the **IN_MOVED_TO** has not.

Matching up the **IN_MOVED_FROM** and **IN_MOVED_TO** event pair generated by *rename*(2) is thus inherently racy. (Don't forget that if an object is renamed outside of a monitored directory, there may not even be an **IN_MOVED_TO** event.) Heuristic approaches (e.g., assume the events are always consecutive) can be used to ensure a match in most cases, but will inevitably miss some cases, causing the application to perceive the **IN_MOVED_FROM** and **IN_MOVED_TO** events as being unrelated. If watch descriptors are destroyed and re-created as a result, then those watch descriptors will be inconsistent with the watch descriptors in any pending events. (Re-creating the inotify file descriptor and rebuilding the cache may be useful to deal with this scenario.)

Applications should also allow for the possibility that the **IN_MOVED_FROM** event was the last event that could fit in the buffer returned by the current call to *read*(2), and the accompanying **IN_MOVED_TO** event might be fetched only on the next *read*(2), which should be done with a (small) timeout to allow for the fact that insertion of the **IN_MOVED_FROM**+**IN_MOVED_TO** event pair is not atomic, and also the possibility that there may not be any **IN_MOVED_TO** event.

BUGS

Before Linux 3.19, *fallocate*(2) did not create any inotify events. Since Linux 3.19, calls to *fallocate*(2) generate **IN_MODIFY** events.

Before Linux 2.6.16, the **IN_ONESHOT** *mask* flag does not work.

As originally designed and implemented, the **IN_ONESHOT** flag did not cause an **IN_IGNORED** event to be generated when the watch was dropped after one event. However, as an unintended effect of other changes, since Linux 2.6.36, an **IN_IGNORED** event is generated in this case.

Before Linux 2.6.25, the kernel code that was intended to coalesce successive identical events (i.e., the two most recent events could potentially be coalesced if the older had not yet been read) instead checked if the most recent event could be coalesced with the *oldest* unread event.

When a watch descriptor is removed by calling *inotify_rm_watch*(2) (or because a watch file is deleted or the filesystem that contains it is unmounted), any pending unread events for that watch descriptor remain available to read. As watch descriptors are subsequently allocated with *inotify_add_watch*(2), the kernel cycles through the range of possible watch descriptors (1 to **INT_MAX**) incrementally. When allocating a free watch descriptor, no check is made to see whether that watch descriptor number has any pending unread events in the inotify queue. Thus, it can happen that a watch descriptor is reallocated even when pending unread events exist for a previous incarnation of that watch descriptor number, with the result that the application might then read those events and interpret them as belonging to the file associated with the newly recycled watch descriptor. In practice, the likelihood of hitting this bug may be extremely low, since it requires that an application cycle through **INT_MAX** watch descriptors, release a watch descriptor while leaving unread events for that watch descriptor in the queue, and then recycle that watch descriptor. For this reason, and because there have been no reports of the bug occurring in real-world applications, as of Linux 3.15, no kernel changes have yet been made to eliminate this possible bug.

EXAMPLES

The following program demonstrates the usage of the inotify API. It marks the directories passed as a command-line arguments and waits for events of type **IN_OPEN**, **IN_CLOSE_NOWRITE**, and **IN_CLOSE_WRITE**.

The following output was recorded while editing the file */home/user/temp/foo* and listing directory */tmp*. Before the file and the directory were opened, **IN_OPEN** events occurred. After the file was closed, an **IN_CLOSE_WRITE** event occurred. After the directory was closed, an **IN_CLOSE_NOWRITE** event occurred. Execution of the program ended when the user pressed the ENTER key.

Example output

```
$ ./a.out /tmp /home/user/temp
Press enter key to terminate.
```

```
    Listening for events.
    IN_OPEN: /home/user/temp/foo [file]
    IN_CLOSE_WRITE: /home/user/temp/foo [file]
    IN_OPEN: /tmp/ [directory]
    IN_CLOSE_NOWRITE: /tmp/ [directory]

    Listening for events stopped.
```

NAME

ip − Linux IPv4 protocol implementation

SYNOPSIS

#include <sys/socket.h>
#include <netinet/in.h>
#include <netinet/ip.h> /* superset of previous */

tcp_socket = **socket(AF_INET, SOCK_STREAM, 0);**
udp_socket = **socket(AF_INET, SOCK_DGRAM, 0);**
raw_socket = **socket(AF_INET, SOCK_RAW,** *protocol***);**

DESCRIPTION

Linux implements the Internet Protocol, version 4, described in RFC 791 and RFC 1122. **ip** contains a level 2 multicasting implementation conforming to RFC 1112. It also contains an IP router including a packet filter.

The programming interface is BSD-sockets compatible. For more information on sockets, see *socket*(7).

An IP socket is created using *socket*(2):

```
socket(AF_INET, socket_type, protocol);
```

Valid socket types include **SOCK_STREAM** to open a stream socket, **SOCK_DGRAM** to open a datagram socket, and **SOCK_RAW** to open a *raw*(7) socket to access the IP protocol directly.

protocol is the IP protocol in the IP header to be received or sent. Valid values for *protocol* include:

- 0 and **IPPROTO_TCP** for *tcp*(7) stream sockets;
- 0 and **IPPROTO_UDP** for *udp*(7) datagram sockets;
- **IPPROTO_SCTP** for *sctp*(7) stream sockets; and
- **IPPROTO_UDPLITE** for *udplite*(7) datagram sockets.

For **SOCK_RAW** you may specify a valid IANA IP protocol defined in RFC 1700 assigned numbers.

When a process wants to receive new incoming packets or connections, it should bind a socket to a local interface address using *bind*(2). In this case, only one IP socket may be bound to any given local (address, port) pair. When **INADDR_ANY** is specified in the bind call, the socket will be bound to *all* local interfaces. When *listen*(2) is called on an unbound socket, the socket is automatically bound to a random free port with the local address set to **INADDR_ANY**. When *connect*(2) is called on an unbound socket, the socket is automatically bound to a random free port or to a usable shared port with the local address set to **INADDR_ANY**.

A TCP local socket address that has been bound is unavailable for some time after closing, unless the **SO_REUSEADDR** flag has been set. Care should be taken when using this flag as it makes TCP less reliable.

Address format

An IP socket address is defined as a combination of an IP interface address and a 16-bit port number. The basic IP protocol does not supply port numbers, they are implemented by higher level protocols like *udp*(7) and *tcp*(7). On raw sockets *sin_port* is set to the IP protocol.

```
struct sockaddr_in {
    sa_family_t    sin_family; /* address family: AF_INET */
    in_port_t      sin_port;   /* port in network byte order */
    struct in_addr sin_addr;   /* internet address */
};

/* Internet address */
struct in_addr {
    uint32_t       s_addr;     /* address in network byte order */
};
```

sin_family is always set to **AF_INET**. This is required; in Linux 2.2 most networking functions return **EINVAL** when this setting is missing. *sin_port* contains the port in network byte order. The port

numbers below 1024 are called *privileged ports* (or sometimes: *reserved ports*). Only a privileged process (on Linux: a process that has the **CAP_NET_BIND_SERVICE** capability in the user namespace governing its network namespace) may *bind*(2) to these sockets. Note that the raw IPv4 protocol as such has no concept of a port, they are implemented only by higher protocols like *tcp*(7) and *udp*(7).

sin_addr is the IP host address. The *s_addr* member of *struct in_addr* contains the host interface address in network byte order. *in_addr* should be assigned one of the **INADDR_*** values (e.g., **INADDR_LOOPBACK**) using *htonl*(3) or set using the *inet_aton*(3), *inet_addr*(3), *inet_makeaddr*(3) library functions or directly with the name resolver (see *gethostbyname*(3)).

IPv4 addresses are divided into unicast, broadcast, and multicast addresses. Unicast addresses specify a single interface of a host, broadcast addresses specify all hosts on a network, and multicast addresses address all hosts in a multicast group. Datagrams to broadcast addresses can be sent or received only when the **SO_BROADCAST** socket flag is set. In the current implementation, connection-oriented sockets are allowed to use only unicast addresses.

Note that the address and the port are always stored in network byte order. In particular, this means that you need to call *htons*(3) on the number that is assigned to a port. All address/port manipulation functions in the standard library work in network byte order.

Special and reserved addresses

There are several special addresses:

INADDR_LOOPBACK (127.0.0.1)
: always refers to the local host via the loopback device;

INADDR_ANY (0.0.0.0)
: means any address for socket binding;

INADDR_BROADCAST (255.255.255.255)
: has the same effect on *bind*(2) as **INADDR_ANY** for historical reasons. A packet addressed to **INADDR_BROADCAST** through a socket which has **SO_BROADCAST** set will be broadcast to all hosts on the local network segment, as long as the link is broadcast-capable.

Highest-numbered address
Lowest-numbered address
: On any locally-attached non-point-to-point IP subnet with a link type that supports broadcasts, the highest-numbered address (e.g., the .255 address on a subnet with netmask 255.255.255.0) is designated as a broadcast address. It cannot usefully be assigned to an individual interface, and can only be addressed with a socket on which the **SO_BROADCAST** option has been set. Internet standards have historically also reserved the lowest-numbered address (e.g., the .0 address on a subnet with netmask 255.255.255.0) for broadcast, though they call it "obsolete" for this purpose. (Some sources also refer to this as the "network address.") Since Linux 5.14, it is treated as an ordinary unicast address and can be assigned to an interface.

Internet standards have traditionally also reserved various addresses for particular uses, though Linux no longer treats some of these specially.

[0.0.0.1, 0.255.255.255]
[240.0.0.0, 255.255.255.254]
: Addresses in these ranges (0/8 and 240/4) are reserved globally. Since Linux 5.3 and Linux 2.6.25, respectively, the 0/8 and 240/4 addresses, other than **INADDR_ANY** and **INADDR_BROADCAST**, are treated as ordinary unicast addresses. Systems that follow the traditional behaviors may not interoperate with these historically reserved addresses.

[127.0.0.1, 127.255.255.254]
: Addresses in this range (127/8) are treated as loopback addresses akin to the standardized local loopback address **INADDR_LOOPBACK** (127.0.0.1);

[224.0.0.0, 239.255.255.255]
: Addresses in this range (224/4) are dedicated to multicast use.

Socket options

IP supports some protocol-specific socket options that can be set with *setsockopt*(2) and read with *getsockopt*(2). The socket option level for IP is **IPPROTO_IP**. A boolean integer flag is zero when it is false, otherwise true.

When an invalid socket option is specified, *getsockopt*(2) and *setsockopt*(2) fail with the error **ENOPROTOOPT**.

IP_ADD_MEMBERSHIP (since Linux 1.2)
Join a multicast group. Argument is an *ip_mreqn* structure.

```
struct ip_mreqn {
    struct in_addr imr_multiaddr; /* IP multicast group
                                     address */
    struct in_addr imr_address;   /* IP address of local
                                     interface */
    int            imr_ifindex;   /* interface index */
};
```

imr_multiaddr contains the address of the multicast group the application wants to join or leave. It must be a valid multicast address (or *setsockopt*(2) fails with the error **EINVAL**). *imr_address* is the address of the local interface with which the system should join the multicast group; if it is equal to **INADDR_ANY**, an appropriate interface is chosen by the system. *imr_ifindex* is the interface index of the interface that should join/leave the *imr_multiaddr* group, or 0 to indicate any interface.

The *ip_mreqn* structure is available only since Linux 2.2. For compatibility, the old *ip_mreq* structure (present since Linux 1.2) is still supported; it differs from *ip_mreqn* only by not including the *imr_ifindex* field. (The kernel determines which structure is being passed based on the size passed in *optlen*.)

IP_ADD_MEMBERSHIP is valid only for *setsockopt*(2).

IP_ADD_SOURCE_MEMBERSHIP (since Linux 2.4.22 / Linux 2.5.68)
Join a multicast group and allow receiving data only from a specified source. Argument is an *ip_mreq_source* structure.

```
struct ip_mreq_source {
    struct in_addr imr_multiaddr;  /* IP multicast group
                                      address */
    struct in_addr imr_interface;  /* IP address of local
                                      interface */
    struct in_addr imr_sourceaddr; /* IP address of
                                      multicast source */
};
```

The *ip_mreq_source* structure is similar to *ip_mreqn* described under **IP_ADD_MEMBERSHIP**. The *imr_multiaddr* field contains the address of the multicast group the application wants to join or leave. The *imr_interface* field is the address of the local interface with which the system should join the multicast group. Finally, the *imr_sourceaddr* field contains the address of the source the application wants to receive data from.

This option can be used multiple times to allow receiving data from more than one source.

IP_BIND_ADDRESS_NO_PORT (since Linux 4.2)
Inform the kernel to not reserve an ephemeral port when using *bind*(2) with a port number of 0. The port will later be automatically chosen at *connect*(2) time, in a way that allows sharing a source port as long as the 4-tuple is unique.

IP_BLOCK_SOURCE (since Linux 2.4.22 / 2.5.68)
Stop receiving multicast data from a specific source in a given group. This is valid only after the application has subscribed to the multicast group using either **IP_ADD_MEMBERSHIP** or **IP_ADD_SOURCE_MEMBERSHIP**.

Argument is an *ip_mreq_source* structure as described under **IP_ADD_SOURCE_MEMBERSHIP**.

IP_DROP_MEMBERSHIP (since Linux 1.2)
Leave a multicast group. Argument is an *ip_mreqn* or *ip_mreq* structure similar to **IP_ADD_MEMBERSHIP**.

IP_DROP_SOURCE_MEMBERSHIP (since Linux 2.4.22 / 2.5.68)
Leave a source-specific group—that is, stop receiving data from a given multicast group that come from a given source. If the application has subscribed to multiple sources within the same group, data from the remaining sources will still be delivered. To stop receiving data from all sources at once, use **IP_DROP_MEMBERSHIP**.

Argument is an *ip_mreq_source* structure as described under **IP_ADD_SOURCE_MEMBERSHIP**.

IP_FREEBIND (since Linux 2.4)
If enabled, this boolean option allows binding to an IP address that is nonlocal or does not (yet) exist. This permits listening on a socket, without requiring the underlying network interface or the specified dynamic IP address to be up at the time that the application is trying to bind to it. This option is the per-socket equivalent of the *ip_nonlocal_bind /proc* interface described below.

IP_HDRINCL (since Linux 2.0)
If enabled, the user supplies an IP header in front of the user data. Valid only for **SOCK_RAW** sockets; see *raw*(7) for more information. When this flag is enabled, the values set by **IP_OPTIONS**, **IP_TTL**, and **IP_TOS** are ignored.

IP_LOCAL_PORT_RANGE (since Linux 6.3)
Set or get the per-socket default local port range. This option can be used to clamp down the global local port range, defined by the *ip_local_port_range /proc* interface described below, for a given socket.

The option takes an *uint32_t* value with the high 16 bits set to the upper range bound, and the low 16 bits set to the lower range bound. Range bounds are inclusive. The 16-bit values should be in host byte order.

The lower bound has to be less than the upper bound when both bounds are not zero. Otherwise, setting the option fails with EINVAL.

If either bound is outside of the global local port range, or is zero, then that bound has no effect.

To reset the setting, pass zero as both the upper and the lower bound.

IP_MSFILTER (since Linux 2.4.22 / 2.5.68)
This option provides access to the advanced full-state filtering API. Argument is an *ip_msfilter* structure.

```
struct ip_msfilter {
    struct in_addr imsf_multiaddr; /* IP multicast group
                                      address */
    struct in_addr imsf_interface; /* IP address of local
                                      interface */
    uint32_t       imsf_fmode;     /* Filter-mode */

    uint32_t       imsf_numsrc;    /* Number of sources in
                                      the following array */
    struct in_addr imsf_slist[1];  /* Array of source
                                      addresses */
};
```

There are two macros, **MCAST_INCLUDE** and **MCAST_EXCLUDE**, which can be used to specify the filtering mode. Additionally, the *IP_MSFILTER_SIZE*(n) macro exists to determine how much memory is needed to store *ip_msfilter* structure with *n* sources in the source list.

For the full description of multicast source filtering refer to RFC 3376.

IP_MTU (since Linux 2.2)
Retrieve the current known path MTU of the current socket. Returns an integer.

IP_MTU is valid only for *getsockopt*(2) and can be employed only when the socket has been connected.

IP_MTU_DISCOVER (since Linux 2.2)
Set or receive the Path MTU Discovery setting for a socket. When enabled, Linux will perform Path MTU Discovery as defined in RFC 1191 on **SOCK_STREAM** sockets. For non-**SOCK_STREAM** sockets, **IP_PMTUDISC_DO** forces the don't-fragment flag to be set on all outgoing packets. It is the user's responsibility to packetize the data in MTU-sized chunks and to do the retransmits if necessary. The kernel will reject (with **EMSGSIZE**) datagrams that are bigger than the known path MTU. **IP_PMTUDISC_WANT** will fragment a datagram if needed according to the path MTU, or will set the don't-fragment flag otherwise.

The system-wide default can be toggled between **IP_PMTUDISC_WANT** and **IP_PMTUDISC_DONT** by writing (respectively, zero and nonzero values) to the */proc/sys/net/ipv4/ip_no_pmtu_disc* file.

Path MTU discovery value	Meaning
IP_PMTUDISC_WANT	Use per-route settings.
IP_PMTUDISC_DONT	Never do Path MTU Discovery.
IP_PMTUDISC_DO	Always do Path MTU Discovery.
IP_PMTUDISC_PROBE	Set DF but ignore Path MTU.

When PMTU discovery is enabled, the kernel automatically keeps track of the path MTU per destination host. When it is connected to a specific peer with *connect*(2), the currently known path MTU can be retrieved conveniently using the **IP_MTU** socket option (e.g., after an **EMSGSIZE** error occurred). The path MTU may change over time. For connectionless sockets with many destinations, the new MTU for a given destination can also be accessed using the error queue (see **IP_RECVERR**). A new error will be queued for every incoming MTU update.

While MTU discovery is in progress, initial packets from datagram sockets may be dropped. Applications using UDP should be aware of this and not take it into account for their packet retransmit strategy.

To bootstrap the path MTU discovery process on unconnected sockets, it is possible to start with a big datagram size (headers up to 64 kilobytes long) and let it shrink by updates of the path MTU.

To get an initial estimate of the path MTU, connect a datagram socket to the destination address using *connect*(2) and retrieve the MTU by calling *getsockopt*(2) with the **IP_MTU** option.

It is possible to implement RFC 4821 MTU probing with **SOCK_DGRAM** or **SOCK_RAW** sockets by setting a value of **IP_PMTUDISC_PROBE** (available since Linux 2.6.22). This is also particularly useful for diagnostic tools such as *tracepath*(8) that wish to deliberately send probe packets larger than the observed Path MTU.

IP_MULTICAST_ALL (since Linux 2.6.31)
This option can be used to modify the delivery policy of multicast messages. The argument is a boolean integer (defaults to 1). If set to 1, the socket will receive messages from all the groups that have been joined globally on the whole system. Otherwise, it will deliver messages only from the groups that have been explicitly joined (for example via the **IP_ADD_MEMBERSHIP** option) on this particular socket.

IP_MULTICAST_IF (since Linux 1.2)
Set the local device for a multicast socket. The argument for *setsockopt*(2) is an *ip_mreqn* or (since Linux 3.5) *ip_mreq* structure similar to **IP_ADD_MEMBERSHIP**, or an *in_addr* structure. (The kernel determines which structure is being passed based on the size passed in *optlen*.) For *getsockopt*(2), the argument is an *in_addr* structure.

IP_MULTICAST_LOOP (since Linux 1.2)
Set or read a boolean integer argument that determines whether sent multicast packets should be looped back to the local sockets.

IP_MULTICAST_TTL (since Linux 1.2)
Set or read the time-to-live value of outgoing multicast packets for this socket. It is very important for multicast packets to set the smallest TTL possible. The default is 1 which means that multicast packets don't leave the local network unless the user program explicitly requests it. Argument is an integer.

IP_NODEFRAG (since Linux 2.6.36)
If enabled (argument is nonzero), the reassembly of outgoing packets is disabled in the netfilter layer. The argument is an integer.

This option is valid only for **SOCK_RAW** sockets.

IP_OPTIONS (since Linux 2.0)
Set or get the IP options to be sent with every packet from this socket. The arguments are a pointer to a memory buffer containing the options and the option length. The *setsockopt*(2) call sets the IP options associated with a socket. The maximum option size for IPv4 is 40 bytes. See RFC 791 for the allowed options. When the initial connection request packet for a **SOCK_STREAM** socket contains IP options, the IP options will be set automatically to the options from the initial packet with routing headers reversed. Incoming packets are not allowed to change options after the connection is established. The processing of all incoming source routing options is disabled by default and can be enabled by using the *accept_source_route /proc* interface. Other options like timestamps are still handled. For datagram sockets, IP options can be set only by the local user. Calling *getsockopt*(2) with **IP_OPTIONS** puts the current IP options used for sending into the supplied buffer.

IP_PASSSEC (since Linux 2.6.17)
If labeled IPSEC or NetLabel is configured on the sending and receiving hosts, this option enables receiving of the security context of the peer socket in an ancillary message of type **SCM_SECURITY** retrieved using *recvmsg*(2). This option is supported only for UDP sockets; for TCP or SCTP sockets, see the description of the **SO_PEERSEC** option below.

The value given as an argument to *setsockopt*(2) and returned as the result of *getsockopt*(2) is an integer boolean flag.

The security context returned in the **SCM_SECURITY** ancillary message is of the same format as the one described under the **SO_PEERSEC** option below.

Note: the reuse of the **SCM_SECURITY** message type for the **IP_PASSSEC** socket option was likely a mistake, since other IP control messages use their own numbering scheme in the IP namespace and often use the socket option value as the message type. There is no conflict currently since the IP option with the same value as **SCM_SECURITY** is **IP_HDRINCL** and this is never used for a control message type.

IP_PKTINFO (since Linux 2.2)
Pass an **IP_PKTINFO** ancillary message that contains a *pktinfo* structure that supplies some information about the incoming packet. This works only for datagram oriented sockets. The argument is a flag that tells the socket whether the **IP_PKTINFO** message should be passed or not. The message itself can be sent/retrieved only as a control message with a packet using *recvmsg*(2) or *sendmsg*(2).

```
struct in_pktinfo {
    unsigned int   ipi_ifindex;  /* Interface index */
    struct in_addr ipi_spec_dst; /* Local address */
    struct in_addr ipi_addr;     /* Header Destination
                                    address */
};
```

ipi_ifindex is the unique index of the interface the packet was received on. *ipi_spec_dst* is the local address of the packet and *ipi_addr* is the destination address in the packet header. If **IP_PKTINFO** is passed to *sendmsg*(2) and *ipi_spec_dst* is not zero, then it is used as the local source address for the routing table lookup and for setting up IP source route options. When *ipi_ifindex* is not zero, the primary local address of the interface specified by the index overwrites *ipi_spec_dst* for the routing table lookup.

Not supported for **SOCK_STREAM** sockets.

IP_RECVERR (since Linux 2.2)
Enable extended reliable error message passing. When enabled on a datagram socket, all generated errors will be queued in a per-socket error queue. When the user receives an error from a socket operation, the errors can be received by calling *recvmsg*(2) with the **MSG_ERRQUEUE** flag set. The *sock_extended_err* structure describing the error will be passed in an

ancillary message with the type **IP_RECVERR** and the level **IPPROTO_IP**. This is useful for reliable error handling on unconnected sockets. The received data portion of the error queue contains the error packet.

The **IP_RECVERR** control message contains a *sock_extended_err* structure:

```
#define SO_EE_ORIGIN_NONE    0
#define SO_EE_ORIGIN_LOCAL   1
#define SO_EE_ORIGIN_ICMP    2
#define SO_EE_ORIGIN_ICMP6   3

struct sock_extended_err {
    uint32_t ee_errno;   /* error number */
    uint8_t  ee_origin;  /* where the error originated */
    uint8_t  ee_type;    /* type */
    uint8_t  ee_code;    /* code */
    uint8_t  ee_pad;
    uint32_t ee_info;    /* additional information */
    uint32_t ee_data;    /* other data */
    /* More data may follow */
};

struct sockaddr *SO_EE_OFFENDER(struct sock_extended_err *);
```

ee_errno contains the *errno* number of the queued error. *ee_origin* is the origin code of where the error originated. The other fields are protocol-specific. The macro **SO_EE_OFFENDER** returns a pointer to the address of the network object where the error originated from given a pointer to the ancillary message. If this address is not known, the *sa_family* member of the *sockaddr* contains **AF_UNSPEC** and the other fields of the *sockaddr* are undefined.

IP uses the *sock_extended_err* structure as follows: *ee_origin* is set to **SO_EE_ORIGIN_ICMP** for errors received as an ICMP packet, or **SO_EE_ORIGIN_LOCAL** for locally generated errors. Unknown values should be ignored. *ee_type* and *ee_code* are set from the type and code fields of the ICMP header. *ee_info* contains the discovered MTU for **EMSGSIZE** errors. The message also contains the *sockaddr_in of the node* caused the error, which can be accessed with the **SO_EE_OFFENDER** macro. The *sin_family* field of the **SO_EE_OFFENDER** address is **AF_UNSPEC** when the source was unknown. When the error originated from the network, all IP options (**IP_OPTIONS**, **IP_TTL**, etc.) enabled on the socket and contained in the error packet are passed as control messages. The payload of the packet causing the error is returned as normal payload. Note that TCP has no error queue; **MSG_ERRQUEUE** is not permitted on **SOCK_STREAM** sockets. **IP_RECVERR** is valid for TCP, but all errors are returned by socket function return or **SO_ERROR** only.

For raw sockets, **IP_RECVERR** enables passing of all received ICMP errors to the application, otherwise errors are reported only on connected sockets

It sets or retrieves an integer boolean flag. **IP_RECVERR** defaults to off.

IP_RECVOPTS (since Linux 2.2)
Pass all incoming IP options to the user in a **IP_OPTIONS** control message. The routing header and other options are already filled in for the local host. Not supported for **SOCK_STREAM** sockets.

IP_RECVORIGDSTADDR (since Linux 2.6.29)
This boolean option enables the **IP_ORIGDSTADDR** ancillary message in *recvmsg*(2), in which the kernel returns the original destination address of the datagram being received. The ancillary message contains a *struct sockaddr_in*. Not supported for **SOCK_STREAM** sockets.

IP_RECVTOS (since Linux 2.2)
If enabled, the **IP_TOS** ancillary message is passed with incoming packets. It contains a byte which specifies the Type of Service/Precedence field of the packet header. Expects a boolean integer flag. Not supported for **SOCK_STREAM** sockets.

IP_RECVTTL (since Linux 2.2)
When this flag is set, pass a **IP_TTL** control message with the time-to-live field of the received packet as a 32 bit integer. Not supported for **SOCK_STREAM** sockets.

IP_RETOPTS (since Linux 2.2)
Identical to **IP_RECVOPTS**, but returns raw unprocessed options with timestamp and route record options not filled in for this hop. Not supported for **SOCK_STREAM** sockets.

IP_ROUTER_ALERT (since Linux 2.2)
Pass all to-be forwarded packets with the IP Router Alert option set to this socket. Valid only for raw sockets. This is useful, for instance, for user-space RSVP daemons. The tapped packets are not forwarded by the kernel; it is the user's responsibility to send them out again. Socket binding is ignored, such packets are filtered only by protocol. Expects an integer flag.

IP_TOS (since Linux 1.0)
Set or receive the Type-Of-Service (TOS) field that is sent with every IP packet originating from this socket. It is used to prioritize packets on the network. TOS is a byte. There are some standard TOS flags defined: **IPTOS_LOWDELAY** to minimize delays for interactive traffic, **IPTOS_THROUGHPUT** to optimize throughput, **IPTOS_RELIABILITY** to optimize for reliability, **IPTOS_MINCOST** should be used for "filler data" where slow transmission doesn't matter. At most one of these TOS values can be specified. Other bits are invalid and shall be cleared. Linux sends **IPTOS_LOWDELAY** datagrams first by default, but the exact behavior depends on the configured queueing discipline. Some high-priority levels may require superuser privileges (the **CAP_NET_ADMIN** capability).

IP_TRANSPARENT (since Linux 2.6.24)
Setting this boolean option enables transparent proxying on this socket. This socket option allows the calling application to bind to a nonlocal IP address and operate both as a client and a server with the foreign address as the local endpoint. NOTE: this requires that routing be set up in a way that packets going to the foreign address are routed through the TProxy box (i.e., the system hosting the application that employs the **IP_TRANSPARENT** socket option). Enabling this socket option requires superuser privileges (the **CAP_NET_ADMIN** capability).

TProxy redirection with the iptables TPROXY target also requires that this option be set on the redirected socket.

IP_TTL (since Linux 1.0)
Set or retrieve the current time-to-live field that is used in every packet sent from this socket.

IP_UNBLOCK_SOURCE (since Linux 2.4.22 / 2.5.68)
Unblock previously blocked multicast source. Returns **EADDRNOTAVAIL** when given source is not being blocked.

Argument is an *ip_mreq_source* structure as described under **IP_ADD_SOURCE_MEMBERSHIP**.

SO_PEERSEC (since Linux 2.6.17)
If labeled IPSEC or NetLabel is configured on both the sending and receiving hosts, this read-only socket option returns the security context of the peer socket connected to this socket. By default, this will be the same as the security context of the process that created the peer socket unless overridden by the policy or by a process with the required permissions.

The argument to *getsockopt*(2) is a pointer to a buffer of the specified length in bytes into which the security context string will be copied. If the buffer length is less than the length of the security context string, then *getsockopt*(2) returns −1, sets *errno* to **ERANGE**, and returns the required length via *optlen*. The caller should allocate at least **NAME_MAX** bytes for the buffer initially, although this is not guaranteed to be sufficient. Resizing the buffer to the returned length and retrying may be necessary.

The security context string may include a terminating null character in the returned length, but is not guaranteed to do so: a security context "foo" might be represented as either {'f','o','o'} of length 3 or {'f','o','o','\0'} of length 4, which are considered to be interchangeable. The string is printable, does not contain non-terminating null characters, and is in an unspecified encoding (in particular, it is not guaranteed to be ASCII or UTF-8).

The use of this option for sockets in the **AF_INET** address family is supported since Linux 2.6.17 for TCP sockets, and since Linux 4.17 for SCTP sockets.

For SELinux, NetLabel conveys only the MLS portion of the security context of the peer across the wire, defaulting the rest of the security context to the values defined in the policy for the netmsg initial security identifier (SID). However, NetLabel can be configured to pass full security contexts over loopback. Labeled IPSEC always passes full security contexts as part of establishing the security association (SA) and looks them up based on the association for each packet.

/proc interfaces

The IP protocol supports a set of */proc* interfaces to configure some global parameters. The parameters can be accessed by reading or writing files in the directory */proc/sys/net/ipv4/*. Interfaces described as *Boolean* take an integer value, with a nonzero value ("true") meaning that the corresponding option is enabled, and a zero value ("false") meaning that the option is disabled.

ip_always_defrag (Boolean; since Linux 2.2.13)

[New with Linux 2.2.13; in earlier kernel versions this feature was controlled at compile time by the **CONFIG_IP_ALWAYS_DEFRAG** option; this option is not present in Linux 2.4.x and later]

When this boolean flag is enabled (not equal 0), incoming fragments (parts of IP packets that arose when some host between origin and destination decided that the packets were too large and cut them into pieces) will be reassembled (defragmented) before being processed, even if they are about to be forwarded.

Enable only if running either a firewall that is the sole link to your network or a transparent proxy; never ever use it for a normal router or host. Otherwise, fragmented communication can be disturbed if the fragments travel over different links. Defragmentation also has a large memory and CPU time cost.

This is automagically turned on when masquerading or transparent proxying are configured.

ip_autoconfig (since Linux 2.2 to Linux 2.6.17)

Not documented.

ip_default_ttl (integer; default: 64; since Linux 2.2)

Set the default time-to-live value of outgoing packets. This can be changed per socket with the **IP_TTL** option.

ip_dynaddr (Boolean; default: disabled; since Linux 2.0.31)

Enable dynamic socket address and masquerading entry rewriting on interface address change. This is useful for dialup interface with changing IP addresses. 0 means no rewriting, 1 turns it on and 2 enables verbose mode.

ip_forward (Boolean; default: disabled; since Linux 1.2)

Enable IP forwarding with a boolean flag. IP forwarding can be also set on a per-interface basis.

ip_local_port_range (since Linux 2.2)

This file contains two integers that define the default local port range allocated to sockets that are not explicitly bound to a port number—that is, the range used for *ephemeral ports*. An ephemeral port is allocated to a socket in the following circumstances:

- the port number in a socket address is specified as 0 when calling *bind*(2);
- *listen*(2) is called on a stream socket that was not previously bound;
- *connect*(2) was called on a socket that was not previously bound;
- *sendto*(2) is called on a datagram socket that was not previously bound.

Allocation of ephemeral ports starts with the first number in *ip_local_port_range* and ends with the second number. If the range of ephemeral ports is exhausted, then the relevant system call returns an error (but see BUGS).

Note that the port range in *ip_local_port_range* should not conflict with the ports used by masquerading (although the case is handled). Also, arbitrary choices may cause problems with some firewall packet filters that make assumptions about the local ports in use. The first

number should be at least greater than 1024, or better, greater than 4096, to avoid clashes with well known ports and to minimize firewall problems.

ip_no_pmtu_disc (Boolean; default: disabled; since Linux 2.2)
: If enabled, don't do Path MTU Discovery for TCP sockets by default. Path MTU discovery may fail if misconfigured firewalls (that drop all ICMP packets) or misconfigured interfaces (e.g., a point-to-point link where the both ends don't agree on the MTU) are on the path. It is better to fix the broken routers on the path than to turn off Path MTU Discovery globally, because not doing it incurs a high cost to the network.

ip_nonlocal_bind (Boolean; default: disabled; since Linux 2.4)
: If set, allows processes to *bind*(2) to nonlocal IP addresses, which can be quite useful, but may break some applications.

ip6frag_time (integer; default: 30)
: Time in seconds to keep an IPv6 fragment in memory.

ip6frag_secret_interval (integer; default: 600)
: Regeneration interval (in seconds) of the hash secret (or lifetime for the hash secret) for IPv6 fragments.

ipfrag_high_thresh (integer)
ipfrag_low_thresh (integer)
: If the amount of queued IP fragments reaches *ipfrag_high_thresh*, the queue is pruned down to *ipfrag_low_thresh*. Contains an integer with the number of bytes.

*neigh/** See *arp*(7).

Ioctls

All ioctls described in *socket*(7) apply to **ip**.

Ioctls to configure generic device parameters are described in *netdevice*(7).

ERRORS

EACCES
: The user tried to execute an operation without the necessary permissions. These include: sending a packet to a broadcast address without having the **SO_BROADCAST** flag set; sending a packet via a *prohibit* route; modifying firewall settings without superuser privileges (the **CAP_NET_ADMIN** capability); binding to a privileged port without superuser privileges (the **CAP_NET_BIND_SERVICE** capability).

EADDRINUSE
: Tried to bind to an address already in use.

EADDRNOTAVAIL
: A nonexistent interface was requested or the requested source address was not local.

EAGAIN
: Operation on a nonblocking socket would block.

EALREADY
: A connection operation on a nonblocking socket is already in progress.

ECONNABORTED
: A connection was closed during an *accept*(2).

EHOSTUNREACH
: No valid routing table entry matches the destination address. This error can be caused by an ICMP message from a remote router or for the local routing table.

EINVAL
: Invalid argument passed. For send operations this can be caused by sending to a *blackhole* route.

EISCONN
: *connect*(2) was called on an already connected socket.

EMSGSIZE
Datagram is bigger than an MTU on the path and it cannot be fragmented.

ENOBUFS
ENOMEM
Not enough free memory. This often means that the memory allocation is limited by the socket buffer limits, not by the system memory, but this is not 100% consistent.

ENOENT
SIOCGSTAMP was called on a socket where no packet arrived.

ENOPKG
A kernel subsystem was not configured.

ENOPROTOOPT and **EOPNOTSUPP**
Invalid socket option passed.

ENOTCONN
The operation is defined only on a connected socket, but the socket wasn't connected.

EPERM
User doesn't have permission to set high priority, change configuration, or send signals to the requested process or group.

EPIPE The connection was unexpectedly closed or shut down by the other end.

ESOCKTNOSUPPORT
The socket is not configured or an unknown socket type was requested.

Other errors may be generated by the overlaying protocols; see *tcp*(7), *raw*(7), *udp*(7), and *socket*(7).

NOTES

IP_FREEBIND, **IP_MSFILTER**, **IP_MTU**, **IP_MTU_DISCOVER**, **IP_RECVORIGDSTADDR**, **IP_PASSSEC**, **IP_PKTINFO**, **IP_RECVERR**, **IP_ROUTER_ALERT**, and **IP_TRANSPARENT** are Linux-specific.

Be very careful with the **SO_BROADCAST** option − it is not privileged in Linux. It is easy to overload the network with careless broadcasts. For new application protocols it is better to use a multicast group instead of broadcasting. Broadcasting is discouraged. See RFC 6762 for an example of a protocol (mDNS) using the more modern multicast approach to communicating with an open-ended group of hosts on the local network.

Some other BSD sockets implementations provide **IP_RCVDSTADDR** and **IP_RECVIF** socket options to get the destination address and the interface of received datagrams. Linux has the more general **IP_PKTINFO** for the same task.

Some BSD sockets implementations also provide an **IP_RECVTTL** option, but an ancillary message with type **IP_RECVTTL** is passed with the incoming packet. This is different from the **IP_TTL** option used in Linux.

Using the **SOL_IP** socket options level isn't portable; BSD-based stacks use the **IPPROTO_IP** level.

INADDR_ANY (0.0.0.0) and **INADDR_BROADCAST** (255.255.255.255) are byte-order-neutral. This means *htonl*(3) has no effect on them.

Compatibility

For compatibility with Linux 2.0, the obsolete **socket(AF_INET, SOCK_PACKET,** *protocol***)** syntax is still supported to open a *packet*(7) socket. This is deprecated and should be replaced by **socket(AF_PACKET, SOCK_RAW,** *protocol***)** instead. The main difference is the new *sockaddr_ll* address structure for generic link layer information instead of the old **sockaddr_pkt**.

BUGS

There are too many inconsistent error values.

The error used to diagnose exhaustion of the ephemeral port range differs across the various system calls (**connect**(2), *bind*(2), *listen*(2), *sendto*(2)) that can assign ephemeral ports.

The ioctls to configure IP-specific interface options and ARP tables are not described.

Receiving the original destination address with **MSG_ERRQUEUE** in *msg_name* by *recvmsg*(2) does not work in some Linux 2.2 kernels.

NAME

ipc_namespaces − overview of Linux IPC namespaces

DESCRIPTION

IPC namespaces isolate certain IPC resources, namely, System V IPC objects (see *sysvipc*(7)) and (since Linux 2.6.30) POSIX message queues (see *mq_overview*(7)). The common characteristic of these IPC mechanisms is that IPC objects are identified by mechanisms other than filesystem pathnames.

Each IPC namespace has its own set of System V IPC identifiers and its own POSIX message queue filesystem. Objects created in an IPC namespace are visible to all other processes that are members of that namespace, but are not visible to processes in other IPC namespaces.

The following */proc* interfaces are distinct in each IPC namespace:

- The POSIX message queue interfaces in */proc/sys/fs/mqueue*.
- The System V IPC interfaces in */proc/sys/kernel*, namely: *msgmax*, *msgmnb*, *msgmni*, *sem*, *shmall*, *shmmax*, *shmmni*, and *shm_rmid_forced*.
- The System V IPC interfaces in */proc/sysvipc*.

When an IPC namespace is destroyed (i.e., when the last process that is a member of the namespace terminates), all IPC objects in the namespace are automatically destroyed.

Use of IPC namespaces requires a kernel that is configured with the **CONFIG_IPC_NS** option.

NAME

ipv6 − Linux IPv6 protocol implementation

SYNOPSIS

#include <sys/socket.h>
#include <netinet/in.h>

tcp6_socket = **socket(AF_INET6, SOCK_STREAM, 0);**
raw6_socket = **socket(AF_INET6, SOCK_RAW,** *protocol***);**
udp6_socket = **socket(AF_INET6, SOCK_DGRAM,** *protocol***);**

DESCRIPTION

Linux 2.2 optionally implements the Internet Protocol, version 6. This man page contains a description of the IPv6 basic API as implemented by the Linux kernel and glibc 2.1. The interface is based on the BSD sockets interface; see *socket*(7).

The IPv6 API aims to be mostly compatible with the IPv4 API (see *ip*(7)). Only differences are described in this man page.

To bind an **AF_INET6** socket to any process, the local address should be copied from the *in6addr_any* variable which has *in6_addr* type. In static initializations, **IN6ADDR_ANY_INIT** may also be used, which expands to a constant expression. Both of them are in network byte order.

The IPv6 loopback address (::1) is available in the global *in6addr_loopback* variable. For initializations, **IN6ADDR_LOOPBACK_INIT** should be used.

IPv4 connections can be handled with the v6 API by using the v4-mapped-on-v6 address type; thus a program needs to support only this API type to support both protocols. This is handled transparently by the address handling functions in the C library.

IPv4 and IPv6 share the local port space. When you get an IPv4 connection or packet to an IPv6 socket, its source address will be mapped to v6.

Address format

```
struct sockaddr_in6 {
    sa_family_t     sin6_family;   /* AF_INET6 */
    in_port_t       sin6_port;     /* port number */
    uint32_t        sin6_flowinfo; /* IPv6 flow information */
    struct in6_addr sin6_addr;     /* IPv6 address */
    uint32_t        sin6_scope_id; /* Scope ID (new in Linux 2.4) */
};

struct in6_addr {
    unsigned char   s6_addr[16];   /* IPv6 address */
};
```

sin6_family is always set to **AF_INET6**; *sin6_port* is the protocol port (see *sin_port* in *ip*(7)); *sin6_flowinfo* is the IPv6 flow identifier; *sin6_addr* is the 128-bit IPv6 address. *sin6_scope_id* is an ID depending on the scope of the address. It is new in Linux 2.4. Linux supports it only for link-local addresses, in that case *sin6_scope_id* contains the interface index (see *netdevice*(7))

IPv6 supports several address types: unicast to address a single host, multicast to address a group of hosts, anycast to address the nearest member of a group of hosts (not implemented in Linux), IPv4-on-IPv6 to address an IPv4 host, and other reserved address types.

The address notation for IPv6 is a group of 8 4-digit hexadecimal numbers, separated with a ':'. "::" stands for a string of 0 bits. Special addresses are ::1 for loopback and ::FFFF:<IPv4 address> for IPv4-mapped-on-IPv6.

The port space of IPv6 is shared with IPv4.

Socket options

IPv6 supports some protocol-specific socket options that can be set with *setsockopt*(2) and read with *getsockopt*(2). The socket option level for IPv6 is **IPPROTO_IPV6**. A boolean integer flag is zero when it is false, otherwise true.

IPV6_ADDRFORM
Turn an **AF_INET6** socket into a socket of a different address family. Only **AF_INET** is currently supported for that. It is allowed only for IPv6 sockets that are connected and bound to a v4-mapped-on-v6 address. The argument is a pointer to an integer containing **AF_INET**. This is useful to pass v4-mapped sockets as file descriptors to programs that don't know how to deal with the IPv6 API.

IPV6_ADD_MEMBERSHIP, IPV6_DROP_MEMBERSHIP
Control membership in multicast groups. Argument is a pointer to a *struct ipv6_mreq*.

IPV6_MTU
getsockopt(): Retrieve the current known path MTU of the current socket. Valid only when the socket has been connected. Returns an integer.

setsockopt(): Set the MTU to be used for the socket. The MTU is limited by the device MTU or the path MTU when path MTU discovery is enabled. Argument is a pointer to integer.

IPV6_MTU_DISCOVER
Control path-MTU discovery on the socket. See **IP_MTU_DISCOVER** in *ip*(7) for details.

IPV6_MULTICAST_HOPS
Set the multicast hop limit for the socket. Argument is a pointer to an integer. −1 in the value means use the route default, otherwise it should be between 0 and 255.

IPV6_MULTICAST_IF
Set the device for outgoing multicast packets on the socket. This is allowed only for **SOCK_DGRAM** and **SOCK_RAW** socket. The argument is a pointer to an interface index (see *netdevice*(7)) in an integer.

IPV6_MULTICAST_LOOP
Control whether the socket sees multicast packets that it has send itself. Argument is a pointer to boolean.

IPV6_RECVPKTINFO (since Linux 2.6.14)
Set delivery of the **IPV6_PKTINFO** control message on incoming datagrams. Such control messages contain a *struct in6_pktinfo*, as per RFC 3542. Allowed only for **SOCK_DGRAM** or **SOCK_RAW** sockets. Argument is a pointer to a boolean value in an integer.

IPV6_RTHDR, IPV6_AUTHHDR, IPV6_DSTOPTS, IPV6_HOPOPTS, IPV6_FLOWINFO, IPV6_HOPLIMIT
Set delivery of control messages for incoming datagrams containing extension headers from the received packet. **IPV6_RTHDR** delivers the routing header, **IPV6_AUTHHDR** delivers the authentication header, **IPV6_DSTOPTS** delivers the destination options, **IPV6_HOPOPTS** delivers the hop options, **IPV6_FLOWINFO** delivers an integer containing the flow ID, **IPV6_HOPLIMIT** delivers an integer containing the hop count of the packet. The control messages have the same type as the socket option. All these header options can also be set for outgoing packets by putting the appropriate control message into the control buffer of *sendmsg*(2). Allowed only for **SOCK_DGRAM** or **SOCK_RAW** sockets. Argument is a pointer to a boolean value.

IPV6_RECVERR
Control receiving of asynchronous error options. See **IP_RECVERR** in *ip*(7) for details. Argument is a pointer to boolean.

IPV6_ROUTER_ALERT
Pass forwarded packets containing a router alert hop-by-hop option to this socket. Allowed only for **SOCK_RAW** sockets. The tapped packets are not forwarded by the kernel, it is the user's responsibility to send them out again. Argument is a pointer to an integer. A positive integer indicates a router alert option value to intercept. Packets carrying a router alert option with a value field containing this integer will be delivered to the socket. A negative integer disables delivery of packets with router alert options to this socket.

IPV6_UNICAST_HOPS
Set the unicast hop limit for the socket. Argument is a pointer to an integer. −1 in the value means use the route default, otherwise it should be between 0 and 255.

IPV6_V6ONLY (since Linux 2.4.21 and 2.6)
If this flag is set to true (nonzero), then the socket is restricted to sending and receiving IPv6 packets only. In this case, an IPv4 and an IPv6 application can bind to a single port at the same time.

If this flag is set to false (zero), then the socket can be used to send and receive packets to and from an IPv6 address or an IPv4-mapped IPv6 address.

The argument is a pointer to a boolean value in an integer.

The default value for this flag is defined by the contents of the file */proc/sys/net/ipv6/bindv6only*. The default value for that file is 0 (false).

ERRORS

ENODEV
The user tried to *bind*(2) to a link-local IPv6 address, but the *sin6_scope_id* in the supplied *sockaddr_in6* structure is not a valid interface index.

VERSIONS

Linux 2.4 will break binary compatibility for the *sockaddr_in6* for 64-bit hosts by changing the alignment of *in6_addr* and adding an additional *sin6_scope_id* field. The kernel interfaces stay compatible, but a program including *sockaddr_in6* or *in6_addr* into other structures may not be. This is not a problem for 32-bit hosts like i386.

The *sin6_flowinfo* field is new in Linux 2.4. It is transparently passed/read by the kernel when the passed address length contains it. Some programs that pass a longer address buffer and then check the outgoing address length may break.

NOTES

The *sockaddr_in6* structure is bigger than the generic *sockaddr*. Programs that assume that all address types can be stored safely in a *struct sockaddr* need to be changed to use *struct sockaddr_storage* for that instead.

SOL_IP, **SOL_IPV6**, **SOL_ICMPV6**, and other **SOL_*** socket options are nonportable variants of **IPPROTO_***. See also *ip*(7).

BUGS

The IPv6 extended API as in RFC 2292 is currently only partly implemented; although the 2.2 kernel has near complete support for receiving options, the macros for generating IPv6 options are missing in glibc 2.1.

IPSec support for EH and AH headers is missing.

Flow label management is not complete and not documented here.

This man page is not complete.

NAME

iso_8859-1 − ISO/IEC 8859-1 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-1 encodes the characters used in many West European languages.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-1 characters

The following table displays the characters in ISO/IEC 8859-1 that are printable and unlisted in the *ascii*(7) manual page.

NAME

iso_8859-3 − ISO/IEC 8859-3 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-3 encodes the characters used in certain Southeast European languages.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-3 characters

The following table displays the characters in ISO/IEC 8859-3 that are printable and unlisted in the *ascii*(7) manual page.

Oct	Dec	Hex	Char	Description

NAME

iso_8859-4 − ISO/IEC 8859-4 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-4 encodes the characters used in Scandinavian and Baltic languages.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-4 characters

The following table displays the characters in ISO/IEC 8859-4 that are printable and unlisted in the *ascii*(7) manual page.

NAME

iso_8859-5 − ISO/IEC 8859-5 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-5 encodes the Cyrillic characters used in many East European languages.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-5 characters

NAME

iso_8859-6 − ISO/IEC 8859-6 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-6 encodes the characters used in the Arabic language.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-6 characters

The following table displays the characters in ISO/IEC 8859-6 that are printable and unlisted in the *ascii*(7) manual page.

NAME

iso_8859-7 − ISO/IEC 8859-7 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-7 encodes the characters used in modern monotonic Greek.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-7 characters

NAME

iso_8859-10 − ISO/IEC 8859-10 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-10 encodes the characters used in Nordic languages.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-10 characters

The following table displays the characters in ISO/IEC 8859-10 that are printable and unlisted in the *ascii*(7) manual page.

Oct	Dec	Hex	Char	Description
240	160	A0		NO-BREAK SPACE
241	161	A1	Ą	LATIN CAPITAL LETTER A WITH OGONEK
242	162	A2	Ē	LATIN CAPITAL LETTER E WITH MACRON
243	163	A3	Ģ	LATIN CAPITAL LETTER G WITH CEDILLA
244	164	A4	Ī	LATIN CAPITAL LETTER I WITH MACRON
245	165	A5	Ĩ	LATIN CAPITAL LETTER I WITH TILDE
246	166	A6	Ķ	LATIN CAPITAL LETTER K WITH CEDILLA
247	167	A7	§	SECTION SIGN
250	168	A8	Ļ	LATIN CAPITAL LETTER L WITH CEDILLA
251	169	A9	Đ	LATIN CAPITAL LETTER D WITH STROKE
252	170	AA	Š	LATIN CAPITAL LETTER S WITH CARON
253	171	AB	Ŧ	LATIN CAPITAL LETTER T WITH STROKE
254	172	AC	Ž	LATIN CAPITAL LETTER Z WITH CARON
255	173	AD		SOFT HYPHEN
256	174	AE	Ū	LATIN CAPITAL LETTER U WITH MACRON
257	175	AF	Ŋ	LATIN CAPITAL LETTER ENG
260	176	B0	°	DEGREE SIGN
261	177	B1	ą	LATIN SMALL LETTER A WITH OGONEK
262	178	B2	ē	LATIN SMALL LETTER E WITH MACRON
263	179	B3	ģ	LATIN SMALL LETTER G WITH CEDILLA
264	180	B4	ī	LATIN SMALL LETTER I WITH MACRON
265	181	B5	ĩ	LATIN SMALL LETTER I WITH TILDE
266	182	B6	ķ	LATIN SMALL LETTER K WITH CEDILLA
267	183	B7	·	MIDDLE DOT
270	184	B8	ļ	LATIN SMALL LETTER L WITH CEDILLA
271	185	B9	đ	LATIN SMALL LETTER D WITH STROKE
272	186	BA	š	LATIN SMALL LETTER S WITH CARON
273	187	BB	ŧ	LATIN SMALL LETTER T WITH STROKE
274	188	BC	ž	LATIN SMALL LETTER Z WITH CARON
275	189	BD	―	HORIZONTAL BAR

276	190	BE	ū	LATIN SMALL LETTER U WITH MACRON
277	191	BF	ŋ	LATIN SMALL LETTER ENG
300	192	C0	Ā	LATIN CAPITAL LETTER A WITH MACRON
301	193	C1	Á	LATIN CAPITAL LETTER A WITH ACUTE
302	194	C2	Â	LATIN CAPITAL LETTER A WITH CIRCUMFLEX
303	195	C3	Ã	LATIN CAPITAL LETTER A WITH TILDE
304	196	C4	Ä	LATIN CAPITAL LETTER A WITH DIAERESIS
305	197	C5	Å	LATIN CAPITAL LETTER A WITH RING ABOVE
306	198	C6	Æ	LATIN CAPITAL LETTER AE
307	199	C7	Į	LATIN CAPITAL LETTER I WITH OGONEK
310	200	C8	Č	LATIN CAPITAL LETTER C WITH CARON
311	201	C9	É	LATIN CAPITAL LETTER E WITH ACUTE
312	202	CA	Ę	LATIN CAPITAL LETTER E WITH OGONEK
312	202	CB	Ë	LATIN CAPITAL LETTER E WITH DIAERESIS
314	204	CC	Ė	LATIN CAPITAL LETTER E WITH DOT ABOVE
315	205	CD	Í	LATIN CAPITAL LETTER I WITH ACUTE
316	206	CE	Î	LATIN CAPITAL LETTER I WITH CIRCUMFLEX
317	207	CF	Ï	LATIN CAPITAL LETTER I WITH DIAERESIS
320	208	D0	Đ	LATIN CAPITAL LETTER ETH
321	209	D1	Ņ	LATIN CAPITAL LETTER N WITH CEDILLA
322	210	D2	Ō	LATIN CAPITAL LETTER O WITH MACRON
323	211	D3	Ó	LATIN CAPITAL LETTER O WITH ACUTE
324	212	D4	Ô	LATIN CAPITAL LETTER O WITH CIRCUMFLEX
325	213	D5	Õ	LATIN CAPITAL LETTER O WITH TILDE
326	214	D6	Ö	LATIN CAPITAL LETTER O WITH DIAERESIS
327	215	D7	Ũ	LATIN CAPITAL LETTER U WITH TILDE
330	216	D8	Ø	LATIN CAPITAL LETTER O WITH STROKE
331	217	D9	Ų	LATIN CAPITAL LETTER U WITH OGONEK
332	218	DA	Ú	LATIN CAPITAL LETTER U WITH ACUTE
333	219	DB	Û	LATIN CAPITAL LETTER U WITH CIRCUMFLEX
334	220	DC	Ü	LATIN CAPITAL LETTER U WITH DIAERESIS
335	221	DD	Ý	LATIN CAPITAL LETTER Y WITH ACUTE
336	222	DE	Þ	LATIN CAPITAL LETTER THORN
337	223	DF	ß	LATIN SMALL LETTER SHARP S
340	224	E0	ā	LATIN SMALL LETTER A WITH MACRON
341	225	E1	á	LATIN SMALL LETTER A WITH ACUTE
342	226	E2	â	LATIN SMALL LETTER A WITH CIRCUMFLEX
343	227	E3	ã	LATIN SMALL LETTER A WITH TILDE
344	228	E4	ä	LATIN SMALL LETTER A WITH DIAERESIS
345	229	E5	å	LATIN SMALL LETTER A WITH RING ABOVE
346	230	E6	æ	LATIN SMALL LETTER AE
347	231	E7	į	LATIN SMALL LETTER I WITH OGONEK
350	232	E8	č	LATIN SMALL LETTER C WITH CARON
351	233	E9	é	LATIN SMALL LETTER E WITH ACUTE
352	234	EA	ę	LATIN SMALL LETTER E WITH OGONEK
353	235	EB	ë	LATIN SMALL LETTER E WITH DIAERESIS
354	236	EC	ė	LATIN SMALL LETTER E WITH DOT ABOVE
355	237	ED	í	LATIN SMALL LETTER I WITH ACUTE
356	238	EE	î	LATIN SMALL LETTER I WITH CIRCUMFLEX
357	239	EF	ï	LATIN SMALL LETTER I WITH DIAERESIS
360	240	F0	ð	LATIN SMALL LETTER ETH
361	241	F1	ņ	LATIN SMALL LETTER N WITH CEDILLA
362	242	F2	ō	LATIN SMALL LETTER O WITH MACRON
363	243	F3	ó	LATIN SMALL LETTER O WITH ACUTE
364	244	F4	ô	LATIN SMALL LETTER O WITH CIRCUMFLEX
365	245	F5	õ	LATIN SMALL LETTER O WITH TILDE
366	246	F6	ö	LATIN SMALL LETTER O WITH DIAERESIS
367	247	F7	ũ	LATIN SMALL LETTER U WITH TILDE

370	248	F8	ø	LATIN SMALL LETTER O WITH STROKE
371	249	F9	ų	LATIN SMALL LETTER U WITH OGONEK
372	250	FA	ú	LATIN SMALL LETTER U WITH ACUTE
373	251	FB	û	LATIN SMALL LETTER U WITH CIRCUMFLEX
374	252	FC	ü	LATIN SMALL LETTER U WITH DIAERESIS
375	253	FD	ý	LATIN SMALL LETTER Y WITH ACUTE
376	254	FE	þ	LATIN SMALL LETTER THORN
377	255	FF	ĸ	LATIN SMALL LETTER KRA

NOTES

ISO/IEC 8859-10 is also known as Latin-6.

NAME

iso_8859-11 − ISO/IEC 8859-11 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-11 encodes the characters used in the Thai language.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-11 characters

The following table displays the characters in ISO/IEC 8859-11 that are printable and unlisted in the *ascii*(7) manual page.

Oct	Dec	Hex	Char	Description
240	160	A0		NO-BREAK SPACE
241	161	A1		THAI CHARACTER KO KAI
242	162	A2		THAI CHARACTER KHO KHAI
243	163	A3		THAI CHARACTER KHO KHUAT
244	164	A4		THAI CHARACTER KHO KHWAI
245	165	A5		THAI CHARACTER KHO KHON
246	166	A6		THAI CHARACTER KHO RAKHANG
247	167	A7		THAI CHARACTER NGO NGU
250	168	A8		THAI CHARACTER CHO CHAN
251	169	A9		THAI CHARACTER CHO CHING
252	170	AA		THAI CHARACTER CHO CHANG
253	171	AB		THAI CHARACTER SO SO
254	172	AC		THAI CHARACTER CHO CHOE
255	173	AD		THAI CHARACTER YO YING
256	174	AE		THAI CHARACTER DO CHADA
257	175	AF		THAI CHARACTER TO PATAK
260	176	B0		THAI CHARACTER THO THAN
261	177	B1		THAI CHARACTER THO NANGMONTHO
262	178	B2		THAI CHARACTER THO PHUTHAO
263	179	B3		THAI CHARACTER NO NEN
264	180	B4		THAI CHARACTER DO DEK
265	181	B5		THAI CHARACTER TO TAO
266	182	B6		THAI CHARACTER THO THUNG
267	183	B7		THAI CHARACTER THO THAHAN
270	184	B8		THAI CHARACTER THO THONG
271	185	B9		THAI CHARACTER NO NU
272	186	BA		THAI CHARACTER BO BAIMAI
273	187	BB		THAI CHARACTER PO PLA
274	188	BC		THAI CHARACTER PHO PHUNG
275	189	BD		THAI CHARACTER FO FA

276	190	BE	THAI CHARACTER PHO PHAN
277	191	BF	THAI CHARACTER FO FAN
300	192	C0	THAI CHARACTER PHO SAMPHAO
301	193	C1	THAI CHARACTER MO MA
302	194	C2	THAI CHARACTER YO YAK
303	195	C3	THAI CHARACTER RO RUA
304	196	C4	THAI CHARACTER RU
305	197	C5	THAI CHARACTER LO LING
306	198	C6	THAI CHARACTER LU
307	199	C7	THAI CHARACTER WO WAEN
310	200	C8	THAI CHARACTER SO SALA
311	201	C9	THAI CHARACTER SO RUSI
312	202	CA	THAI CHARACTER SO SUA
313	203	CB	THAI CHARACTER HO HIP
314	204	CC	THAI CHARACTER LO CHULA
315	205	CD	THAI CHARACTER O ANG
316	206	CE	THAI CHARACTER HO NOKHUK
317	207	CF	THAI CHARACTER PAIYANNOI
320	208	D0	THAI CHARACTER SARA A
321	209	D1	THAI CHARACTER MAI HAN-AKAT
322	210	D2	THAI CHARACTER SARA AA
323	211	D3	THAI CHARACTER SARA AM
324	212	D4	THAI CHARACTER SARA I
325	213	D5	THAI CHARACTER SARA II
326	214	D6	THAI CHARACTER SARA UE
327	215	D7	THAI CHARACTER SARA UEE
330	216	D8	THAI CHARACTER SARA U
331	217	D9	THAI CHARACTER SARA UU
332	218	DA	THAI CHARACTER PHINTHU
337	223	DF	THAI CURRENCY SYMBOL BAHT
340	224	E0	THAI CHARACTER SARA E
341	225	E1	THAI CHARACTER SARA AE
342	226	E2	THAI CHARACTER SARA O
343	227	E3	THAI CHARACTER SARA AI MAIMUAN
344	228	E4	THAI CHARACTER SARA AI MAIMALAI
345	229	E5	THAI CHARACTER LAKKHANGYAO
346	230	E6	THAI CHARACTER MAIYAMOK
347	231	E7	THAI CHARACTER MAITAIKHU
350	232	E8	THAI CHARACTER MAI EK
351	233	E9	THAI CHARACTER MAI THO
352	234	EA	THAI CHARACTER MAI TRI
353	235	EB	THAI CHARACTER MAI CHATTAWA
354	236	EC	THAI CHARACTER THANTHAKHAT
355	237	ED	THAI CHARACTER NIKHAHIT
356	238	EE	THAI CHARACTER YAMAKKAN
357	239	EF	THAI CHARACTER FONGMAN
360	240	F0	THAI DIGIT ZERO
361	241	F1	THAI DIGIT ONE
362	242	F2	THAI DIGIT TWO
363	243	F3	THAI DIGIT THREE
364	244	F4	THAI DIGIT FOUR
365	245	F5	THAI DIGIT FIVE
366	246	F6	THAI DIGIT SIX
367	247	F7	THAI DIGIT SEVEN
370	248	F8	THAI DIGIT EIGHT
371	249	F9	THAI DIGIT NINE
372	250	FA	THAI CHARACTER ANGKHANKHU
373	251	FB	THAI CHARACTER KHOMUT

NOTES

ISO/IEC 8859-11 is the same as TIS (Thai Industrial Standard) 620-2253, commonly known as TIS-620, except for the character in position A0: ISO/IEC 8859-11 defines this as NO-BREAK SPACE, while TIS-620 leaves it undefined.

NAME

iso_8859-13 − ISO/IEC 8859-13 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-13 encodes the characters used in Baltic Rim languages.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-13 characters

The following table displays the characters in ISO/IEC 8859-13 that are printable and unlisted in the *ascii*(7) manual page.

Oct	Dec	Hex	Char	Description
240	160	A0		NO-BREAK SPACE
241	161	A1	”	RIGHT DOUBLE QUOTATION MARK
242	162	A2	¢	CENT SIGN
243	163	A3	£	POUND SIGN
244	164	A4	¤	CURRENCY SIGN
245	165	A5	„	DOUBLE LOW-9 QUOTATION MARK
246	166	A6	¦	BROKEN BAR
247	167	A7	§	SECTION SIGN
250	168	A8	Ø	LATIN CAPITAL LETTER O WITH STROKE
251	169	A9	©	COPYRIGHT SIGN
252	170	AA	Ŗ	LATIN CAPITAL LETTER R WITH CEDILLA
253	171	AB	«	LEFT-POINTING DOUBLE ANGLE QUOTATION MARK
254	172	AC	¬	NOT SIGN
255	173	AD		SOFT HYPHEN
256	174	AE	®	REGISTERED SIGN
257	175	AF	Æ	LATIN CAPITAL LETTER AE
260	176	B0	°	DEGREE SIGN
261	177	B1	±	PLUS-MINUS SIGN
262	178	B2	²	SUPERSCRIPT TWO
263	179	B3	³	SUPERSCRIPT THREE
264	180	B4	“	LEFT DOUBLE QUOTATION MARK
265	181	B5	µ	MICRO SIGN
266	182	B6	¶	PILCROW SIGN
267	183	B7	·	MIDDLE DOT
270	184	B8	ø	LATIN SMALL LETTER O WITH STROKE
271	185	B9	¹	SUPERSCRIPT ONE
272	186	BA	ŗ	LATIN SMALL LETTER R WITH CEDILLA
273	187	BB	»	RIGHT-POINTING DOUBLE ANGLE QUOTATION MARK
274	188	BC	¼	VULGAR FRACTION ONE QUARTER
275	189	BD	½	VULGAR FRACTION ONE HALF

NAME

iso_8859-15 − ISO/IEC 8859-15 character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

The ISO/IEC 8859 standard includes several 8-bit extensions to the ASCII character set (also known as ISO/IEC 646-IRV). ISO/IEC 8859-15 encodes the characters used in many West European languages and adds the Euro sign.

ISO/IEC 8859 alphabets

The full set of ISO/IEC 8859 alphabets includes:

ISO/IEC 8859-1	West European languages (Latin-1)
ISO/IEC 8859-2	Central and East European languages (Latin-2)
ISO/IEC 8859-3	Southeast European and miscellaneous languages (Latin-3)
ISO/IEC 8859-4	Scandinavian/Baltic languages (Latin-4)
ISO/IEC 8859-5	Latin/Cyrillic
ISO/IEC 8859-6	Latin/Arabic
ISO/IEC 8859-7	Latin/Greek
ISO/IEC 8859-8	Latin/Hebrew
ISO/IEC 8859-9	Latin-1 modification for Turkish (Latin-5)
ISO/IEC 8859-10	Lappish/Nordic/Eskimo languages (Latin-6)
ISO/IEC 8859-11	Latin/Thai
ISO/IEC 8859-13	Baltic Rim languages (Latin-7)
ISO/IEC 8859-14	Celtic (Latin-8)
ISO/IEC 8859-15	West European languages (Latin-9)
ISO/IEC 8859-16	Romanian (Latin-10)

ISO/IEC 8859-15 characters

The following table displays the characters in ISO/IEC 8859-15 that are printable and unlisted in the *ascii*(7) manual page.

NAME

kernel_lockdown − kernel image access prevention feature

DESCRIPTION

The Kernel Lockdown feature is designed to prevent both direct and indirect access to a running kernel image, attempting to protect against unauthorized modification of the kernel image and to prevent access to security and cryptographic data located in kernel memory, whilst still permitting driver modules to be loaded.

If a prohibited or restricted feature is accessed or used, the kernel will emit a message that looks like:

```
Lockdown: X: Y is restricted, see man kernel_lockdown.7
```

where X indicates the process name and Y indicates what is restricted.

On an EFI-enabled x86 or arm64 machine, lockdown will be automatically enabled if the system boots in EFI Secure Boot mode.

Coverage

When lockdown is in effect, a number of features are disabled or have their use restricted. This includes special device files and kernel services that allow direct access of the kernel image:

/dev/mem
/dev/kmem
/dev/kcore
/dev/ioports
BPF
kprobes

and the ability to directly configure and control devices, so as to prevent the use of a device to access or modify a kernel image:

- The use of module parameters that directly specify hardware parameters to drivers through the kernel command line or when loading a module.
- The use of direct PCI BAR access.
- The use of the ioperm and iopl instructions on x86.
- The use of the KD*IO console ioctls.
- The use of the TIOCSSERIAL serial ioctl.
- The alteration of MSR registers on x86.
- The replacement of the PCMCIA CIS.
- The overriding of ACPI tables.
- The use of ACPI error injection.
- The specification of the ACPI RDSP address.
- The use of ACPI custom methods.

Certain facilities are restricted:

- Only validly signed modules may be loaded (waived if the module file being loaded is vouched for by IMA appraisal).
- Only validly signed binaries may be kexec’d (waived if the binary image file to be executed is vouched for by IMA appraisal).
- Unencrypted hibernation/suspend to swap are disallowed as the kernel image is saved to a medium that can then be accessed.
- Use of debugfs is not permitted as this allows a whole range of actions including direct configuration of, access to and driving of hardware.
- IMA requires the addition of the "secure_boot" rules to the policy, whether or not they are specified on the command line, for both the built-in and custom policies in secure boot lockdown mode.

VERSIONS

The Kernel Lockdown feature was added in Linux 5.4.

NOTES

The Kernel Lockdown feature is enabled by CONFIG_SECURITY_LOCKDOWN_LSM. The *lsm=lsm1,...,lsmN* command line parameter controls the sequence of the initialization of Linux Security Modules. It must contain the string *lockdown* to enable the Kernel Lockdown feature. If the command line parameter is not specified, the initialization falls back to the value of the deprecated *security=* command line parameter and further to the value of CONFIG_LSM.

NAME

keyrings − in-kernel key management and retention facility

DESCRIPTION

The Linux key-management facility is primarily a way for various kernel components to retain or cache security data, authentication keys, encryption keys, and other data in the kernel.

System call interfaces are provided so that user-space programs can manage those objects and also use the facility for their own purposes; see *add_key*(2), *request_key*(2), and *keyctl*(2).

A library and some user-space utilities are provided to allow access to the facility. See *keyctl*(1), *keyctl*(3), and *keyutils*(7) for more information.

Keys

A key has the following attributes:

Serial number (ID)
: This is a unique integer handle by which a key is referred to in system calls. The serial number is sometimes synonymously referred as the key ID. Programmatically, key serial numbers are represented using the type *key_serial_t*.

Type
: A key's type defines what sort of data can be held in the key, how the proposed content of the key will be parsed, and how the payload will be used.

  There are a number of general-purpose types available, plus some specialist types defined by specific kernel components.

Description (name)
: The key description is a printable string that is used as the search term for the key (in conjunction with the key type) as well as a display name. During searches, the description may be partially matched or exactly matched.

Payload (data)
: The payload is the actual content of a key. This is usually set when a key is created, but it is possible for the kernel to upcall to user space to finish the instantiation of a key if that key wasn't already known to the kernel when it was requested. For further details, see *request_key*(2).

  A key's payload can be read and updated if the key type supports it and if suitable permission is granted to the caller.

Access rights
: Much as files do, each key has an owning user ID, an owning group ID, and a security label. Each key also has a set of permissions, though there are more than for a normal UNIX file, and there is an additional category—possessor—beyond the usual user, group, and other (see *Possession*, below).

  Note that keys are quota controlled, since they require unswappable kernel memory. The owning user ID specifies whose quota is to be debited.

Expiration time
: Each key can have an expiration time set. When that time is reached, the key is marked as being expired and accesses to it fail with the error **EKEYEXPIRED**. If not deleted, updated, or replaced, then, after a set amount of time, an expired key is automatically removed (garbage collected) along with all links to it, and attempts to access the key fail with the error **ENOKEY**.

Reference count
: Each key has a reference count. Keys are referenced by keyrings, by currently active users, and by a process's credentials. When the reference count reaches zero, the key is scheduled for garbage collection.

Key types

The kernel provides several basic types of key:

"keyring"
: Keyrings are special keys which store a set of links to other keys (including other keyrings), analogous to a directory holding links to files. The main purpose of a keyring is to prevent

other keys from being garbage collected because nothing refers to them.

Keyrings with descriptions (names) that begin with a period ('.') are reserved to the implementation.

"user" This is a general-purpose key type. The key is kept entirely within kernel memory. The payload may be read and updated by user-space applications.

The payload for keys of this type is a blob of arbitrary data of up to 32,767 bytes.

The description may be any valid string, though it is preferred that it start with a colon-delimited prefix representing the service to which the key is of interest (for instance *"afs:mykey"*).

"logon" (since Linux 3.3)
This key type is essentially the same as *"user"*, but it does not provide reading (i.e., the *keyctl*(2) **KEYCTL_READ** operation), meaning that the key payload is never visible from user space. This is suitable for storing username-password pairs that should not be readable from user space.

The description of a *"logon"* key *must* start with a non-empty colon-delimited prefix whose purpose is to identify the service to which the key belongs. (Note that this differs from keys of the *"user"* type, where the inclusion of a prefix is recommended but is not enforced.)

"big_key" (since Linux 3.13)
This key type is similar to the *"user"* key type, but it may hold a payload of up to 1 MiB in size. This key type is useful for purposes such as holding Kerberos ticket caches.

The payload data may be stored in a tmpfs filesystem, rather than in kernel memory, if the data size exceeds the overhead of storing the data in the filesystem. (Storing the data in a filesystem requires filesystem structures to be allocated in the kernel. The size of these structures determines the size threshold above which the tmpfs storage method is used.) Since Linux 4.8, the payload data is encrypted when stored in tmpfs, thereby preventing it from being written unencrypted into swap space.

There are more specialized key types available also, but they aren't discussed here because they aren't intended for normal user-space use.

Key type names that begin with a period ('.') are reserved to the implementation.

Keyrings

As previously mentioned, keyrings are a special type of key that contain links to other keys (which may include other keyrings). Keys may be linked to by multiple keyrings. Keyrings may be considered as analogous to UNIX directories where each directory contains a set of hard links to files.

Various operations (system calls) may be applied only to keyrings:

Adding A key may be added to a keyring by system calls that create keys. This prevents the new key from being immediately deleted when the system call releases its last reference to the key.

Linking
A link may be added to a keyring pointing to a key that is already known, provided this does not create a self-referential cycle.

Unlinking
A link may be removed from a keyring. When the last link to a key is removed, that key will be scheduled for deletion by the garbage collector.

Clearing
All the links may be removed from a keyring.

Searching
A keyring may be considered the root of a tree or subtree in which keyrings form the branches and non-keyrings the leaves. This tree may be searched for a key matching a particular type and description.

See *keyctl_clear*(3), *keyctl_link*(3), *keyctl_search*(3), and *keyctl_unlink*(3) for more information.

Anchoring keys

To prevent a key from being garbage collected, it must be anchored to keep its reference count elevated when it is not in active use by the kernel.

Keyrings are used to anchor other keys: each link is a reference on a key. Note that keyrings themselves are just keys and are also subject to the same anchoring requirement to prevent them being garbage collected.

The kernel makes available a number of anchor keyrings. Note that some of these keyrings will be created only when first accessed.

Process keyrings
: Process credentials themselves reference keyrings with specific semantics. These keyrings are pinned as long as the set of credentials exists, which is usually as long as the process exists.

  There are three keyrings with different inheritance/sharing rules: the *session-keyring*(7) (inherited and shared by all child processes), the *process-keyring*(7) (shared by all threads in a process) and the *thread-keyring*(7) (specific to a particular thread).

  As an alternative to using the actual keyring IDs, in calls to *add_key*(2), *keyctl*(2), and *request_key*(2), the special keyring values **KEY_SPEC_SESSION_KEYRING**, **KEY_SPEC_PROCESS_KEYRING**, and **KEY_SPEC_THREAD_KEYRING** can be used to refer to the caller's own instances of these keyrings.

User keyrings
: Each UID known to the kernel has a record that contains two keyrings: the *user-keyring*(7) and the *user-session-keyring*(7). These exist for as long as the UID record in the kernel exists.

  As an alternative to using the actual keyring IDs, in calls to *add_key*(2), *keyctl*(2), and *request_key*(2), the special keyring values **KEY_SPEC_USER_KEYRING** and **KEY_SPEC_USER_SESSION_KEYRING** can be used to refer to the caller's own instances of these keyrings.

  A link to the user keyring is placed in a new session keyring by *pam_keyinit*(8) when a new login session is initiated.

Persistent keyrings
: There is a *persistent-keyring*(7) available to each UID known to the system. It may persist beyond the life of the UID record previously mentioned, but has an expiration time set such that it is automatically cleaned up after a set time. The persistent keyring permits, for example, *cron*(8) scripts to use credentials that are left in the persistent keyring after the user logs out.

  Note that the expiration time of the persistent keyring is reset every time the persistent key is requested.

Special keyrings
: There are special keyrings owned by the kernel that can anchor keys for special purposes. An example of this is the *system keyring* used for holding encryption keys for module signature verification.

  These special keyrings are usually closed to direct alteration by user space.

An originally planned "group keyring", for storing keys associated with each GID known to the kernel, is not so far implemented, is unlikely to be implemented. Nevertheless, the constant **KEY_SPEC_GROUP_KEYRING** has been defined for this keyring.

Possession

The concept of possession is important to understanding the keyrings security model. Whether a thread possesses a key is determined by the following rules:

(1) Any key or keyring that does not grant *search* permission to the caller is ignored in all the following rules.

(2) A thread possesses its *session-keyring*(7), *process-keyring*(7), and *thread-keyring*(7) directly because those keyrings are referred to by its credentials.

(3) If a keyring is possessed, then any key it links to is also possessed.

(4) If any key a keyring links to is itself a keyring, then rule (3) applies recursively.

(5) If a process is upcalled from the kernel to instantiate a key (see *request_key*(2)), then it also possesses the requester's keyrings as in rule (1) as if it were the requester.

Note that possession is not a fundamental property of a key, but must rather be calculated each time the

key is needed.

Possession is designed to allow set-user-ID programs run from, say a user's shell to access the user's keys. Granting permissions to the key possessor while denying them to the key owner and group allows the prevention of access to keys on the basis of UID and GID matches.

When it creates the session keyring, *pam_keyinit*(8) adds a link to the *user-keyring*(7), thus making the user keyring and anything it contains possessed by default.

Access rights

Each key has the following security-related attributes:

- The owning user ID
- The ID of a group that is permitted to access the key
- A security label
- A permissions mask

The permissions mask contains four sets of rights. The first three sets are mutually exclusive. One and only one will be in force for a particular access check. In order of descending priority, these three sets are:

user The set specifies the rights granted if the key's user ID matches the caller's filesystem user ID.

group The set specifies the rights granted if the user ID didn't match and the key's group ID matches the caller's filesystem GID or one of the caller's supplementary group IDs.

other The set specifies the rights granted if neither the key's user ID nor group ID matched.

The fourth set of rights is:

possessor
The set specifies the rights granted if a key is determined to be possessed by the caller.

The complete set of rights for a key is the union of whichever of the first three sets is applicable plus the fourth set if the key is possessed.

The set of rights that may be granted in each of the four masks is as follows:

view The attributes of the key may be read. This includes the type, description, and access rights (excluding the security label).

read For a key: the payload of the key may be read. For a keyring: the list of serial numbers (keys) to which the keyring has links may be read.

write The payload of the key may be updated and the key may be revoked. For a keyring, links may be added to or removed from the keyring, and the keyring may be cleared completely (all links are removed),

search For a key (or a keyring): the key may be found by a search. For a keyring: keys and keyrings that are linked to by the keyring may be searched.

link Links may be created from keyrings to the key. The initial link to a key that is established when the key is created doesn't require this permission.

setattr The ownership details and security label of the key may be changed, the key's expiration time may be set, and the key may be revoked.

In addition to access rights, any active Linux Security Module (LSM) may prevent access to a key if its policy so dictates. A key may be given a security label or other attribute by the LSM; this label is retrievable via *keyctl_get_security*(3)

See *keyctl_chown*(3), *keyctl_describe*(3), *keyctl_get_security*(3), *keyctl_setperm*(3), and *selinux*(8) for more information.

Searching for keys

One of the key features of the Linux key-management facility is the ability to find a key that a process is retaining. The *request_key*(2) system call is the primary point of access for user-space applications to find a key. (Internally, the kernel has something similar available for use by internal components that make use of keys.)

The search algorithm works as follows:

(1) The process keyrings are searched in the following order: the *thread-keyring*(7) if it exists, the *process-keyring*(7) if it exists, and then either the *session-keyring*(7) if it exists or the *user-session-keyring*(7) if that exists.

(2) If the caller was a process that was invoked by the *request_key*(2) upcall mechanism, then the keyrings of the original caller of *request_key*(2) will be searched as well.

(3) The search of a keyring tree is in breadth-first order: each keyring is searched first for a match, then the keyrings referred to by that keyring are searched.

(4) If a matching key is found that is valid, then the search terminates and that key is returned.

(5) If a matching key is found that has an error state attached, that error state is noted and the search continues.

(6) If no valid matching key is found, then the first noted error state is returned; otherwise, an **ENOKEY** error is returned.

It is also possible to search a specific keyring, in which case only steps (3) to (6) apply.

See *request_key*(2) and *keyctl_search*(3) for more information.

On-demand key creation

If a key cannot be found, *request_key*(2) will, if given a *callout_info* argument, create a new key and then upcall to user space to instantiate the key. This allows keys to be created on an as-needed basis.

Typically, this will involve the kernel creating a new process that executes the *request-key*(8) program, which will then execute the appropriate handler based on its configuration.

The handler is passed a special authorization key that allows it and only it to instantiate the new key. This is also used to permit searches performed by the handler program to also search the requester's keyrings.

See *request_key*(2), *keyctl_assume_authority*(3), *keyctl_instantiate*(3), *keyctl_negate*(3), *keyctl_reject*(3), *request-key*(8), and *request-key.conf* (5) for more information.

/proc files

The kernel provides various */proc* files that expose information about keys or define limits on key usage.

/proc/keys (since Linux 2.6.10)

This file exposes a list of the keys for which the reading thread has *view* permission, providing various information about each key. The thread need not possess the key for it to be visible in this file.

The only keys included in the list are those that grant *view* permission to the reading process (regardless of whether or not it possesses them). LSM security checks are still performed, and may filter out further keys that the process is not authorized to view.

An example of the data that one might see in this file (with the columns numbered for easy reference below) is the following:

```
  (1)     (2)     (3)(4)    (5)     (6)   (7)   (8)        (9)
009a2028 I--Q---   1 perm 3f010000  1000  1000 user     krb_ccache:primary: 12
1806c4ba I--Q---   1 perm 3f010000  1000  1000 keyring  _pid: 2
25d3a08f I--Q---   1 perm 1f3f0000  1000 65534 keyring  _uid_ses.1000: 1
28576bd8 I--Q---   3 perm 3f010000  1000  1000 keyring  _krb: 1
2c546d21 I--Q--- 190 perm 3f030000  1000  1000 keyring  _ses: 2
30a4e0be I------   4   2d 1f030000  1000 65534 keyring  _persistent.1000: 1
32100fab I--Q---   4 perm 1f3f0000  1000 65534 keyring  _uid.1000: 2
32a387ea I--Q---   1 perm 3f010000  1000  1000 keyring  _pid: 2
3ce56aea I--Q---   5 perm 3f030000  1000  1000 keyring  _ses: 1
```

The fields shown in each line of this file are as follows:

ID (1) The ID (serial number) of the key, expressed in hexadecimal.

Flags (2)

A set of flags describing the state of the key:

I The key has been instantiated.

R The key has been revoked.

D The key is dead (i.e., the key type has been unregistered). (A key may be briefly in this state during garbage collection.)

Q The key contributes to the user's quota.

U The key is under construction via a callback to user space; see *request-key*(2)

N The key is negatively instantiated.

i The key has been invalidated.

Usage (3)
: This is a count of the number of kernel credential structures that are pinning the key (approximately: the number of threads and open file references that refer to this key).

Timeout (4)
: The amount of time until the key will expire, expressed in human-readable form (weeks, days, hours, minutes, and seconds). The string *perm* here means that the key is permanent (no timeout). The string *expd* means that the key has already expired, but has not yet been garbage collected.

Permissions (5)
: The key permissions, expressed as four hexadecimal bytes containing, from left to right, the possessor, user, group, and other permissions. Within each byte, the permission bits are as follows:

0x01	*view*
0x02	*read*
0x04	*write*
0x08	*search*
0x10	*link*
0x20	*setattr*

UID (6)
: The user ID of the key owner.

GID (7)
: The group ID of the key. The value −1 here means that the key has no group ID; this can occur in certain circumstances for keys created by the kernel.

Type (8)
: The key type (user, keyring, etc.)

Description (9)
: The key description (name). This field contains descriptive information about the key. For most key types, it has the form

```
name[: extra-info]
```

The *name* subfield is the key's description (name). The optional *extra−info* field provides some further information about the key. The information that appears here depends on the key type, as follows:

"user" and *"logon"*
: The size in bytes of the key payload (expressed in decimal).

"keyring"
: The number of keys linked to the keyring, or the string *empty* if there are no keys linked to the keyring.

"big_key"
: The payload size in bytes, followed either by the string *[file]*, if the key payload exceeds the threshold that means that the payload is stored in a (swappable) *tmpfs*(5) filesystem, or otherwise the string *[buff]*, indicating that the key is small enough to reside in kernel memory.

For the *".request_key_auth"* key type (authorization key; see *request_key*(2)), the description field has the form shown in the following example:

```
key:c9a9b19 pid:28880 ci:10
```

The three subfields are as follows:

key The hexadecimal ID of the key being instantiated in the requesting program.

pid The PID of the requesting program.

ci The length of the callout data with which the requested key should be instantiated (i.e., the length of the payload associated with the authorization key).

/proc/key−users (since Linux 2.6.10)
This file lists various information for each user ID that has at least one key on the system. An example of the data that one might see in this file is the following:

```
    0:    10 9/9 2/1000000 22/25000000
   42:     9 9/9 8/200 106/20000
 1000:    11 11/11 10/200 271/20000
```

The fields shown in each line are as follows:

uid The user ID.

usage This is a kernel-internal usage count for the kernel structure used to record key users.

nkeys/*nikeys*
The total number of keys owned by the user, and the number of those keys that have been instantiated.

qnkeys/*maxkeys*
The number of keys owned by the user, and the maximum number of keys that the user may own.

qnbytes/*maxbytes*
The number of bytes consumed in payloads of the keys owned by this user, and the upper limit on the number of bytes in key payloads for that user.

/proc/sys/kernel/keys/gc_delay (since Linux 2.6.32)
The value in this file specifies the interval, in seconds, after which revoked and expired keys will be garbage collected. The purpose of having such an interval is so that there is a window of time where user space can see an error (respectively **EKEYREVOKED** and **EKEYEXPIRED**) that indicates what happened to the key.

The default value in this file is 300 (i.e., 5 minutes).

/proc/sys/kernel/keys/persistent_keyring_expiry (since Linux 3.13)
This file defines an interval, in seconds, to which the persistent keyring's expiration timer is reset each time the keyring is accessed (via *keyctl_get_persistent*(3) or the *keyctl*(2) **KEYCTL_GET_PERSISTENT** operation.)

The default value in this file is 259200 (i.e., 3 days).

The following files (which are writable by privileged processes) are used to enforce quotas on the number of keys and number of bytes of data that can be stored in key payloads:

/proc/sys/kernel/keys/maxbytes (since Linux 2.6.26)
This is the maximum number of bytes of data that a nonroot user can hold in the payloads of the keys owned by the user.

The default value in this file is 20,000.

/proc/sys/kernel/keys/maxkeys (since Linux 2.6.26)
This is the maximum number of keys that a nonroot user may own.

The default value in this file is 200.

/proc/sys/kernel/keys/root_maxbytes (since Linux 2.6.26)
This is the maximum number of bytes of data that the root user (UID 0 in the root user namespace) can hold in the payloads of the keys owned by root.

The default value in this file is 25,000,000 (20,000 before Linux 3.17).

/proc/sys/kernel/keys/root_maxkeys (since Linux 2.6.26)
This is the maximum number of keys that the root user (UID 0 in the root user namespace) may own.

The default value in this file is 1,000,000 (200 before Linux 3.17).

With respect to keyrings, note that each link in a keyring consumes 4 bytes of the keyring payload.

Users

The Linux key-management facility has a number of users and usages, but is not limited to those that already exist.

In-kernel users of this facility include:

Network filesystems - DNS
The kernel uses the upcall mechanism provided by the keys to upcall to user space to do DNS lookups and then to cache the results.

AF_RXRPC and kAFS - Authentication
The AF_RXRPC network protocol and the in-kernel AFS filesystem use keys to store the ticket needed to do secured or encrypted traffic. These are then looked up by network operations on AF_RXRPC and filesystem operations on kAFS.

NFS - User ID mapping
The NFS filesystem uses keys to store mappings of foreign user IDs to local user IDs.

CIFS - Password
The CIFS filesystem uses keys to store passwords for accessing remote shares.

Module verification
The kernel build process can be made to cryptographically sign modules. That signature is then checked when a module is loaded.

User-space users of this facility include:

Kerberos key storage
The MIT Kerberos 5 facility (libkrb5) can use keys to store authentication tokens which can be made to be automatically cleaned up a set time after the user last uses them, but until then permits them to hang around after the user has logged out so that *cron*(8) scripts can use them.

NAME

koi8-r − Russian character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

RFC 1489 defines an 8-bit character set, KOI8-R. KOI8-R encodes the characters used in Russian.

KOI8-R characters

The following table displays the characters in KOI8-R that are printable and unlisted in the *ascii*(7) manual page.

Oct	Dec	Hex	Char	Description
200	128	80	─	BOX DRAWINGS LIGHT HORIZONTAL
201	129	81	│	BOX DRAWINGS LIGHT VERTICAL

NAME

koi8-u − Ukrainian character set encoded in octal, decimal, and hexadecimal

DESCRIPTION

RFC 2310 defines an 8-bit character set, KOI8-U. KOI8-U encodes the characters used in Ukrainian and Byelorussian.

KOI8-U characters

The following table displays the characters in KOI8-U that are printable and unlisted in the *ascii*(7) manual page.

Oct	Dec	Hex	Char	Description
200	128	80	─	BOX DRAWINGS LIGHT HORIZONTAL

NAME

Landlock − unprivileged access-control

DESCRIPTION

Landlock is an access-control system that enables any processes to securely restrict themselves and their future children. Because Landlock is a stackable Linux Security Module (LSM), it makes it possible to create safe security sandboxes as new security layers in addition to the existing system-wide access-controls. This kind of sandbox is expected to help mitigate the security impact of bugs, and unexpected or malicious behaviors in applications.

A Landlock security policy is a set of access rights (e.g., open a file in read-only, make a directory, etc.) tied to a file hierarchy. Such policy can be configured and enforced by processes for themselves using three system calls:

- *landlock_create_ruleset*(2) creates a new ruleset;
- *landlock_add_rule*(2) adds a new rule to a ruleset;
- *landlock_restrict_self*(2) enforces a ruleset on the calling thread.

To be able to use these system calls, the running kernel must support Landlock and it must be enabled at boot time.

Landlock rules

A Landlock rule describes an action on an object. An object is currently a file hierarchy, and the related filesystem actions are defined with access rights (see *landlock_add_rule*(2)). A set of rules is aggregated in a ruleset, which can then restrict the thread enforcing it, and its future children.

Filesystem actions

These flags enable to restrict a sandboxed process to a set of actions on files and directories. Files or directories opened before the sandboxing are not subject to these restrictions. See *landlock_add_rule*(2) and *landlock_create_ruleset*(2) for more context.

A file can only receive these access rights:

LANDLOCK_ACCESS_FS_EXECUTE
: Execute a file.

LANDLOCK_ACCESS_FS_WRITE_FILE
: Open a file with write access.

  When opening files for writing, you will often additionally need the **LANDLOCK_ACCESS_FS_TRUNCATE** right. In many cases, these system calls truncate existing files when overwriting them (e.g., *creat*(2)).

LANDLOCK_ACCESS_FS_READ_FILE
: Open a file with read access.

LANDLOCK_ACCESS_FS_TRUNCATE
: Truncate a file with *truncate*(2), *ftruncate*(2), *creat*(2), or *open*(2) with **O_TRUNC**. Whether an opened file can be truncated with *ftruncate*(2) is determined during *open*(2), in the same way as read and write permissions are checked during *open*(2) using **LANDLOCK_ACCESS_FS_READ_FILE** and **LANDLOCK_ACCESS_FS_WRITE_FILE**. This access right is available since the third version of the Landlock ABI.

A directory can receive access rights related to files or directories. The following access right is applied to the directory itself, and the directories beneath it:

LANDLOCK_ACCESS_FS_READ_DIR
: Open a directory or list its content.

However, the following access rights only apply to the content of a directory, not the directory itself:

LANDLOCK_ACCESS_FS_REMOVE_DIR
: Remove an empty directory or rename one.

LANDLOCK_ACCESS_FS_REMOVE_FILE
: Unlink (or rename) a file.

LANDLOCK_ACCESS_FS_MAKE_CHAR
Create (or rename or link) a character device.

LANDLOCK_ACCESS_FS_MAKE_DIR
Create (or rename) a directory.

LANDLOCK_ACCESS_FS_MAKE_REG
Create (or rename or link) a regular file.

LANDLOCK_ACCESS_FS_MAKE_SOCK
Create (or rename or link) a UNIX domain socket.

LANDLOCK_ACCESS_FS_MAKE_FIFO
Create (or rename or link) a named pipe.

LANDLOCK_ACCESS_FS_MAKE_BLOCK
Create (or rename or link) a block device.

LANDLOCK_ACCESS_FS_MAKE_SYM
Create (or rename or link) a symbolic link.

LANDLOCK_ACCESS_FS_REFER
Link or rename a file from or to a different directory (i.e., reparent a file hierarchy).

This access right is available since the second version of the Landlock ABI.

This is the only access right which is denied by default by any ruleset, even if the right is not specified as handled at ruleset creation time. The only way to make a ruleset grant this right is to explicitly allow it for a specific directory by adding a matching rule to the ruleset.

In particular, when using the first Landlock ABI version, Landlock will always deny attempts to reparent files between different directories.

In addition to the source and destination directories having the **LANDLOCK_ACCESS_FS_REFER** access right, the attempted link or rename operation must meet the following constraints:

- The reparented file may not gain more access rights in the destination directory than it previously had in the source directory. If this is attempted, the operation results in an **EXDEV** error.
- When linking or renaming, the **LANDLOCK_ACCESS_FS_MAKE_*** right for the respective file type must be granted for the destination directory. Otherwise, the operation results in an **EACCES** error.
- When renaming, the **LANDLOCK_ACCESS_FS_REMOVE_*** right for the respective file type must be granted for the source directory. Otherwise, the operation results in an **EACCES** error.

If multiple requirements are not met, the **EACCES** error code takes precedence over **EXDEV**.

Layers of file path access rights
Each time a thread enforces a ruleset on itself, it updates its Landlock domain with a new layer of policy. Indeed, this complementary policy is composed with the potentially other rulesets already restricting this thread. A sandboxed thread can then safely add more constraints to itself with a new enforced ruleset.

One policy layer grants access to a file path if at least one of its rules encountered on the path grants the access. A sandboxed thread can only access a file path if all its enforced policy layers grant the access as well as all the other system access controls (e.g., filesystem DAC, other LSM policies, etc.).

Bind mounts and OverlayFS
Landlock enables restricting access to file hierarchies, which means that these access rights can be propagated with bind mounts (cf. *mount_namespaces*(7)) but not with OverlayFS.

A bind mount mirrors a source file hierarchy to a destination. The destination hierarchy is then composed of the exact same files, on which Landlock rules can be tied, either via the source or the destination path. These rules restrict access when they are encountered on a path, which means that they can restrict access to multiple file hierarchies at the same time, whether these hierarchies are the result of bind mounts or not.

An OverlayFS mount point consists of upper and lower layers. These layers are combined in a merge directory, result of the mount point. This merge hierarchy may include files from the upper and lower layers, but modifications performed on the merge hierarchy only reflect on the upper layer. From a Landlock policy point of view, each of the OverlayFS layers and merge hierarchies is standalone and contains its own set of files and directories, which is different from a bind mount. A policy restricting an OverlayFS layer will not restrict the resulted merged hierarchy, and vice versa. Landlock users should then only think about file hierarchies they want to allow access to, regardless of the underlying filesystem.

Inheritance

Every new thread resulting from a *clone*(2) inherits Landlock domain restrictions from its parent. This is similar to the *seccomp*(2) inheritance or any other LSM dealing with tasks' *credentials*(7). For instance, one process's thread may apply Landlock rules to itself, but they will not be automatically applied to other sibling threads (unlike POSIX thread credential changes, cf. *nptl*(7)).

When a thread sandboxes itself, we have the guarantee that the related security policy will stay enforced on all this thread's descendants. This allows creating standalone and modular security policies per application, which will automatically be composed between themselves according to their run-time parent policies.

Ptrace restrictions

A sandboxed process has less privileges than a non-sandboxed process and must then be subject to additional restrictions when manipulating another process. To be allowed to use *ptrace*(2) and related syscalls on a target process, a sandboxed process should have a subset of the target process rules, which means the tracee must be in a sub-domain of the tracer.

Truncating files

The operations covered by **LANDLOCK_ACCESS_FS_WRITE_FILE** and **LANDLOCK_ACCESS_FS_TRUNCATE** both change the contents of a file and sometimes overlap in non-intuitive ways. It is recommended to always specify both of these together.

A particularly surprising example is *creat*(2). The name suggests that this system call requires the rights to create and write files. However, it also requires the truncate right if an existing file under the same name is already present.

It should also be noted that truncating files does not require the **LANDLOCK_ACCESS_FS_WRITE_FILE** right. Apart from the *truncate*(2) system call, this can also be done through *open*(2) with the flags *O_RDONLY* | *O_TRUNC*.

When opening a file, the availability of the **LANDLOCK_ACCESS_FS_TRUNCATE** right is associated with the newly created file descriptor and will be used for subsequent truncation attempts using *ftruncate*(2). The behavior is similar to opening a file for reading or writing, where permissions are checked during *open*(2), but not during the subsequent *read*(2) and *write*(2) calls.

As a consequence, it is possible to have multiple open file descriptors for the same file, where one grants the right to truncate the file and the other does not. It is also possible to pass such file descriptors between processes, keeping their Landlock properties, even when these processes do not have an enforced Landlock ruleset.

VERSIONS

Landlock was introduced in Linux 5.13.

To determine which Landlock features are available, users should query the Landlock ABI version:

ABI	Kernel	Newly introduced access rights
1	5.13	**LANDLOCK_ACCESS_FS_EXECUTE** **LANDLOCK_ACCESS_FS_WRITE_FILE** **LANDLOCK_ACCESS_FS_READ_FILE** **LANDLOCK_ACCESS_FS_READ_DIR** **LANDLOCK_ACCESS_FS_REMOVE_DIR** **LANDLOCK_ACCESS_FS_REMOVE_FILE** **LANDLOCK_ACCESS_FS_MAKE_CHAR** **LANDLOCK_ACCESS_FS_MAKE_DIR** **LANDLOCK_ACCESS_FS_MAKE_REG** **LANDLOCK_ACCESS_FS_MAKE_SOCK** **LANDLOCK_ACCESS_FS_MAKE_FIFO** **LANDLOCK_ACCESS_FS_MAKE_BLOCK** **LANDLOCK_ACCESS_FS_MAKE_SYM**
2	5.19	**LANDLOCK_ACCESS_FS_REFER**
3	6.2	**LANDLOCK_ACCESS_FS_TRUNCATE**

Users should use the Landlock ABI version rather than the kernel version to determine which features are available. The mainline kernel versions listed here are only included for orientation. Kernels from other sources may contain backported features, and their version numbers may not match.

To query the running kernel's Landlock ABI version, programs may pass the **LANDLOCK_CREATE_RULESET_VERSION** flag to *landlock_create_ruleset*(2).

When building fallback mechanisms for compatibility with older kernels, users are advised to consider the special semantics of the **LANDLOCK_ACCESS_FS_REFER** access right: In ABI v1, linking and moving of files between different directories is always forbidden, so programs relying on such operations are only compatible with Landlock ABI v2 and higher.

NOTES

Landlock is enabled by **CONFIG_SECURITY_LANDLOCK**. The *lsm=lsm1,...,lsmN* command line parameter controls the sequence of the initialization of Linux Security Modules. It must contain the string *landlock* to enable Landlock. If the command line parameter is not specified, the initialization falls back to the value of the deprecated *security=* command line parameter and further to the value of **CONFIG_LSM**. We can check that Landlock is enabled by looking for *landlock: Up and running.* in kernel logs.

CAVEATS

It is currently not possible to restrict some file-related actions accessible through these system call families: *chdir*(2), *stat*(2), *flock*(2), *chmod*(2), *chown*(2), *setxattr*(2), *utime*(2), *ioctl*(2), *fcntl*(2), *access*(2). Future Landlock evolutions will enable to restrict them.

EXAMPLES

We first need to create the ruleset that will contain our rules.

For this example, the ruleset will contain rules that only allow read actions, but write actions will be denied. The ruleset then needs to handle both of these kinds of actions. See the **DESCRIPTION** section for the description of filesystem actions.

```
struct landlock_ruleset_attr attr = {0};
int ruleset_fd;

attr.handled_access_fs =
        LANDLOCK_ACCESS_FS_EXECUTE |
        LANDLOCK_ACCESS_FS_WRITE_FILE |
        LANDLOCK_ACCESS_FS_READ_FILE |
        LANDLOCK_ACCESS_FS_READ_DIR |
        LANDLOCK_ACCESS_FS_REMOVE_DIR |
        LANDLOCK_ACCESS_FS_REMOVE_FILE |
        LANDLOCK_ACCESS_FS_MAKE_CHAR |
        LANDLOCK_ACCESS_FS_MAKE_DIR |
        LANDLOCK_ACCESS_FS_MAKE_REG |
        LANDLOCK_ACCESS_FS_MAKE_SOCK |
```

```
            LANDLOCK_ACCESS_FS_MAKE_FIFO |
            LANDLOCK_ACCESS_FS_MAKE_BLOCK |
            LANDLOCK_ACCESS_FS_MAKE_SYM |
            LANDLOCK_ACCESS_FS_REFER |
            LANDLOCK_ACCESS_FS_TRUNCATE;
```

To be compatible with older Linux versions, we detect the available Landlock ABI version, and only use the available subset of access rights:

```
/*
 * Table of available file system access rights by ABI version,
 * numbers hardcoded to keep the example short.
 */
__u64 landlock_fs_access_rights[] = {
    (LANDLOCK_ACCESS_FS_MAKE_SYM << 1) - 1,  /* v1                */
    (LANDLOCK_ACCESS_FS_REFER    << 1) - 1,  /* v2: add "refer"   */
    (LANDLOCK_ACCESS_FS_TRUNCATE << 1) - 1,  /* v3: add "truncate" */
};

int abi = landlock_create_ruleset(NULL, 0,
                                  LANDLOCK_CREATE_RULESET_VERSION);
if (abi == -1) {
    /*
     * Kernel too old, not compiled with Landlock,
     * or Landlock was not enabled at boot time.
     */
    perror("Unable to use Landlock");
    return;  /* Graceful fallback: Do nothing. */
}
abi = MIN(abi, 3);

/* Only use the available rights in the ruleset. */
attr.handled_access_fs &= landlock_fs_access_rights[abi - 1];
```

The available access rights for each ABI version are listed in the **VERSIONS** section.

If our program needed to create hard links or rename files between different directories (**LANDLOCK_ACCESS_FS_REFER**), we would require the following change to the backwards compatibility logic: Directory reparenting is not possible in a process restricted with Landlock ABI version 1. Therefore, if the program needed to do file reparenting, and if only Landlock ABI version 1 was available, we could not restrict the process.

Now that the ruleset attributes are determined, we create the Landlock ruleset and acquire a file descriptor as a handle to it, using *landlock_create_ruleset*(2):

```
ruleset_fd = landlock_create_ruleset(&attr, sizeof(attr), 0);
if (ruleset_fd == -1) {
    perror("Failed to create a ruleset");
    exit(EXIT_FAILURE);
}
```

We can now add a new rule to the ruleset through the ruleset's file descriptor. The requested access rights must be a subset of the access rights which were specified in *attr.handled_access_fs* at ruleset creation time.

In this example, the rule will only allow reading the file hierarchy */usr*. Without another rule, write actions would then be denied by the ruleset. To add */usr* to the ruleset, we open it with the *O_PATH* flag and fill the *struct landlock_path_beneath_attr* with this file descriptor.

```
struct landlock_path_beneath_attr path_beneath = {0};
int err;

path_beneath.allowed_access =
        LANDLOCK_ACCESS_FS_EXECUTE |
```

```
            LANDLOCK_ACCESS_FS_READ_FILE |
            LANDLOCK_ACCESS_FS_READ_DIR;

    path_beneath.parent_fd = open("/usr", O_PATH | O_CLOEXEC);
    if (path_beneath.parent_fd == -1) {
        perror("Failed to open file");
        close(ruleset_fd);
        exit(EXIT_FAILURE);
    }
    err = landlock_add_rule(ruleset_fd, LANDLOCK_RULE_PATH_BENEATH,
                            &path_beneath, 0);
    close(path_beneath.parent_fd);
    if (err) {
        perror("Failed to update ruleset");
        close(ruleset_fd);
        exit(EXIT_FAILURE);
    }
```

We now have a ruleset with one rule allowing read access to */usr* while denying all other handled accesses for the filesystem. The next step is to restrict the current thread from gaining more privileges (e.g., thanks to a set-user-ID binary).

```
    if (prctl(PR_SET_NO_NEW_PRIVS, 1, 0, 0, 0)) {
        perror("Failed to restrict privileges");
        close(ruleset_fd);
        exit(EXIT_FAILURE);
    }
```

The current thread is now ready to sandbox itself with the ruleset.

```
    if (landlock_restrict_self(ruleset_fd, 0)) {
        perror("Failed to enforce ruleset");
        close(ruleset_fd);
        exit(EXIT_FAILURE);
    }
    close(ruleset_fd);
```

If the *landlock_restrict_self*(2) system call succeeds, the current thread is now restricted and this policy will be enforced on all its subsequently created children as well. Once a thread is landlocked, there is no way to remove its security policy; only adding more restrictions is allowed. These threads are now in a new Landlock domain, merge of their parent one (if any) with the new ruleset.

Full working code can be found in

NAME

libc − overview of standard C libraries on Linux

DESCRIPTION

The term "libc" is commonly used as a shorthand for the "standard C library" a library of standard functions that can be used by all C programs (and sometimes by programs in other languages). Because of some history (see below), use of the term "libc" to refer to the standard C library is somewhat ambiguous on Linux.

glibc

By far the most widely used C library on Linux is the GNU C Library, often referred to as *glibc*. This is the C library that is nowadays used in all major Linux distributions. It is also the C library whose details are documented in the relevant pages of the *man-pages* project (primarily in Section 3 of the manual). Documentation of glibc is also available in the glibc manual, available via the command *info libc*. Release 1.0 of glibc was made in September 1992. (There were earlier 0.x releases.) The next major release of glibc was 2.0, at the beginning of 1997.

The pathname */lib/libc.so.6* (or something similar) is normally a symbolic link that points to the location of the glibc library, and executing this pathname will cause glibc to display various information about the version installed on your system.

Linux libc

In the early to mid 1990s, there was for a while *Linux libc*, a fork of glibc 1.x created by Linux developers who felt that glibc development at the time was not sufficing for the needs of Linux. Often, this library was referred to (ambiguously) as just "libc". Linux libc released major versions 2, 3, 4, and 5, as well as many minor versions of those releases. Linux libc4 was the last version to use the a.out binary format, and the first version to provide (primitive) shared library support. Linux libc 5 was the first version to support the ELF binary format; this version used the shared library soname *libc.so.5*. For a while, Linux libc was the standard C library in many Linux distributions.

However, notwithstanding the original motivations of the Linux libc effort, by the time glibc 2.0 was released (in 1997), it was clearly superior to Linux libc, and all major Linux distributions that had been using Linux libc soon switched back to glibc. To avoid any confusion with Linux libc versions, glibc 2.0 and later used the shared library soname *libc.so.6*.

Since the switch from Linux libc to glibc 2.0 occurred long ago, *man-pages* no longer takes care to document Linux libc details. Nevertheless, the history is visible in vestiges of information about Linux libc that remain in a few manual pages, in particular, references to *libc4* and *libc5*.

Other C libraries

There are various other less widely used C libraries for Linux. These libraries are generally smaller than glibc, both in terms of features and memory footprint, and often intended for building small binaries, perhaps targeted at development for embedded Linux systems. Among such libraries are *uClibc*, *dietlibc*, and *musl libc*. Details of these libraries are covered by the *man-pages* project, where they are known.

NAME

locale − description of multilanguage support

SYNOPSIS

#include <locale.h>

DESCRIPTION

A locale is a set of language and cultural rules. These cover aspects such as language for messages, different character sets, lexicographic conventions, and so on. A program needs to be able to determine its locale and act accordingly to be portable to different cultures.

The header <*locale.h*> declares data types, functions, and macros which are useful in this task.

The functions it declares are *setlocale*(3) to set the current locale, and *localeconv*(3) to get information about number formatting.

There are different categories for locale information a program might need; they are declared as macros. Using them as the first argument to the *setlocale*(3) function, it is possible to set one of these to the desired locale:

LC_ADDRESS (GNU extension, since glibc 2.2)
: Change settings that describe the formats (e.g., postal addresses) used to describe locations and geography-related items. Applications that need this information can use *nl_langinfo*(3) to retrieve nonstandard elements, such as **_NL_ADDRESS_COUNTRY_NAME** (country name, in the language of the locale) and **_NL_ADDRESS_LANG_NAME** (language name, in the language of the locale), which return strings such as "Deutschland" and "Deutsch" (for German-language locales). (Other element names are listed in <*langinfo.h*>.)

LC_COLLATE
: This category governs the collation rules used for sorting and regular expressions, including character equivalence classes and multicharacter collating elements. This locale category changes the behavior of the functions *strcoll*(3) and *strxfrm*(3), which are used to compare strings in the local alphabet. For example, the German sharp s is sorted as "ss".

LC_CTYPE
: This category determines the interpretation of byte sequences as characters (e.g., single versus multibyte characters), character classifications (e.g., alphabetic or digit), and the behavior of character classes. On glibc systems, this category also determines the character transliteration rules for *iconv*(1) and *iconv*(3). It changes the behavior of the character handling and classification functions, such as *isupper*(3) and *toupper*(3), and the multibyte character functions such as *mblen*(3) or *wctomb*(3).

LC_IDENTIFICATION (GNU extension, since glibc 2.2)
: Change settings that relate to the metadata for the locale. Applications that need this information can use *nl_langinfo*(3) to retrieve nonstandard elements, such as **_NL_IDENTIFICATION_TITLE** (title of this locale document) and **_NL_IDENTIFICATION_TERRITORY** (geographical territory to which this locale document applies), which might return strings such as "English locale for the USA" and "USA". (Other element names are listed in <*langinfo.h*>.)

LC_MONETARY
: This category determines the formatting used for monetary-related numeric values. This changes the information returned by *localeconv*(3), which describes the way numbers are usually printed, with details such as decimal point versus decimal comma. This information is internally used by the function *strfmon*(3).

LC_MESSAGES
: This category affects the language in which messages are displayed and what an affirmative or negative answer looks like. The GNU C library contains the *gettext*(3), *ngettext*(3), and *rpmatch*(3) functions to ease the use of this information. The GNU gettext family of functions also obey the environment variable **LANGUAGE** (containing a colon-separated list of locales) if the category is set to a valid locale other than **"C"**. This category also affects the behavior of *catopen*(3).

LC_MEASUREMENT (GNU extension, since glibc 2.2)
: Change the settings relating to the measurement system in the locale (i.e., metric versus US customary units). Applications can use *nl_langinfo*(3) to retrieve the nonstandard **_NL_MEASUREMENT_MEASUREMENT** element, which returns a pointer to a character that has the value 1 (metric) or 2 (US customary units).

LC_NAME (GNU extension, since glibc 2.2)
: Change settings that describe the formats used to address persons. Applications that need this information can use *nl_langinfo*(3) to retrieve nonstandard elements, such as **_NL_NAME_NAME_MR** (general salutation for men) and **_NL_NAME_NAME_MS** (general salutation for women) elements, which return strings such as "Herr" and "Frau" (for German-language locales). (Other element names are listed in <*langinfo.h*>.)

LC_NUMERIC
: This category determines the formatting rules used for nonmonetary numeric values—for example, the thousands separator and the radix character (a period in most English-speaking countries, but a comma in many other regions). It affects functions such as *printf*(3), *scanf*(3), and *strtod*(3). This information can also be read with the *localeconv*(3) function.

LC_PAPER (GNU extension, since glibc 2.2)
: Change the settings relating to the dimensions of the standard paper size (e.g., US letter versus A4). Applications that need the dimensions can obtain them by using *nl_langinfo*(3) to retrieve the nonstandard **_NL_PAPER_WIDTH** and **_NL_PAPER_HEIGHT** elements, which return *int* values specifying the dimensions in millimeters.

LC_TELEPHONE (GNU extension, since glibc 2.2)
: Change settings that describe the formats to be used with telephone services. Applications that need this information can use *nl_langinfo*(3) to retrieve nonstandard elements, such as **_NL_TELEPHONE_INT_PREFIX** (international prefix used to call numbers in this locale), which returns a string such as "49" (for Germany). (Other element names are listed in <*langinfo.h*>.)

LC_TIME
: This category governs the formatting used for date and time values. For example, most of Europe uses a 24-hour clock versus the 12-hour clock used in the United States. The setting of this category affects the behavior of functions such as *strftime*(3) and *strptime*(3).

LC_ALL
: All of the above.

If the second argument to *setlocale*(3) is an empty string, "", for the default locale, it is determined using the following steps:

(1) If there is a non-null environment variable **LC_ALL**, the value of **LC_ALL** is used.

(2) If an environment variable with the same name as one of the categories above exists and is non-null, its value is used for that category.

(3) If there is a non-null environment variable **LANG**, the value of **LANG** is used.

Values about local numeric formatting is made available in a *struct lconv* returned by the *localeconv*(3) function, which has the following declaration:

```
struct lconv {

    /* Numeric (nonmonetary) information */

    char *decimal_point;     /* Radix character */
    char *thousands_sep;     /* Separator for digit groups to left
                                of radix character */
    char *grouping;     /* Each element is the number of digits in
                           a group; elements with higher indices
                           are further left.  An element with value
                           CHAR_MAX means that no further grouping
                           is done.  An element with value 0 means
                           that the previous element is used for
```

```
                                all groups further left. */

            /* Remaining fields are for monetary information */

            char *int_curr_symbol;   /* First three chars are a currency
                                        symbol from ISO 4217.  Fourth char
                                        is the separator.  Fifth char
                                        is '\0'. */
            char *currency_symbol;   /* Local currency symbol */
            char *mon_decimal_point; /* Radix character */
            char *mon_thousands_sep; /* Like thousands_sep above */
            char *mon_grouping;      /* Like grouping above */
            char *positive_sign;     /* Sign for positive values */
            char *negative_sign;     /* Sign for negative values */
            char  int_frac_digits;   /* International fractional digits */
            char  frac_digits;       /* Local fractional digits */
            char  p_cs_precedes;     /* 1 if currency_symbol precedes a
                                        positive value, 0 if succeeds */
            char  p_sep_by_space;    /* 1 if a space separates
                                        currency_symbol from a positive
                                        value */
            char  n_cs_precedes;     /* 1 if currency_symbol precedes a
                                        negative value, 0 if succeeds */
            char  n_sep_by_space;    /* 1 if a space separates
                                        currency_symbol from a negative
                                        value */
            /* Positive and negative sign positions:
               0 Parentheses surround the quantity and currency_symbol.
               1 The sign string precedes the quantity and currency_symbol.
               2 The sign string succeeds the quantity and currency_symbol.
               3 The sign string immediately precedes the currency_symbol.
               4 The sign string immediately succeeds the currency_symbol. */
            char  p_sign_posn;
            char  n_sign_posn;
        };
```

POSIX.1-2008 extensions to the locale API

POSIX.1-2008 standardized a number of extensions to the locale API, based on implementations that first appeared in glibc 2.3. These extensions are designed to address the problem that the traditional locale APIs do not mix well with multithreaded applications and with applications that must deal with multiple locales.

The extensions take the form of new functions for creating and manipulating locale objects (**newlocale**(3), *freelocale*(3), *duplocale*(3), and *uselocale*(3)) and various new library functions with the suffix "_l" (e.g., *toupper_l*(3)) that extend the traditional locale-dependent APIs (e.g., *toupper*(3)) to allow the specification of a locale object that should apply when executing the function.

ENVIRONMENT

The following environment variable is used by *newlocale*(3) and *setlocale*(3), and thus affects all unprivileged localized programs:

LOCPATH

A list of pathnames, separated by colons (':'), that should be used to find locale data. If this variable is set, only the individual compiled locale data files from **LOCPATH** and the system default locale data path are used; any available locale archives are not used (see *localedef*(1)). The individual compiled locale data files are searched for under subdirectories which depend on the currently used locale. For example, when *en_GB.UTF−8* is used for a category, the following subdirectories are searched for, in this order: *en_GB.UTF−8*, *en_GB.utf8*, *en_GB*, *en.UTF−8*, *en.utf8*, and *en*.

FILES

/usr/lib/locale/locale−archive
: Usual default locale archive location.

/usr/lib/locale
: Usual default path for compiled individual locale files.

STANDARDS

POSIX.1-2001.

NAME

mailaddr − mail addressing description

DESCRIPTION

This manual page gives a brief introduction to SMTP mail addresses, as used on the Internet. These addresses are in the general format

```
user@domain
```

where a domain is a hierarchical dot-separated list of subdomains. These examples are valid forms of the same address:

```
john.doe@monet.example.com
John Doe <john.doe@monet.example.com>
john.doe@monet.example.com (John Doe)
```

The domain part ("monet.example.com") is a mail-accepting domain. It can be a host and in the past it usually was, but it doesn't have to be. The domain part is not case sensitive.

The local part ("john.doe") is often a username, but its meaning is defined by the local software. Sometimes it is case sensitive, although that is unusual. If you see a local-part that looks like garbage, it is usually because of a gateway between an internal e-mail system and the net, here are some examples:

```
"surname/admd=telemail/c=us/o=hp/prmd=hp"@some.where
USER%SOMETHING@some.where
machine!machine!name@some.where
I2461572@some.where
```

(These are, respectively, an X.400 gateway, a gateway to an arbitrary internal mail system that lacks proper internet support, an UUCP gateway, and the last one is just boring username policy.)

The real-name part ("John Doe") can either be placed before <>, or in () at the end. (Strictly speaking the two aren't the same, but the difference is beyond the scope of this page.) The name may have to be quoted using "", for example, if it contains ".":

```
"John Q. Doe" <john.doe@monet.example.com>
```

Abbreviation

Some mail systems let users abbreviate the domain name. For instance, users at example.com may get away with "john.doe@monet" to send mail to John Doe. *This behavior is deprecated.* Sometimes it works, but you should not depend on it.

Route-addrs

In the past, sometimes one had to route a message through several hosts to get it to its final destination. Addresses which show these relays are termed "route-addrs". These use the syntax:

```
<@hosta,@hostb:user@hostc>
```

This specifies that the message should be sent to hosta, from there to hostb, and finally to hostc. Many hosts disregard route-addrs and send directly to hostc.

Route-addrs are very unusual now. They occur sometimes in old mail archives. It is generally possible to ignore all but the "user@hostc" part of the address to determine the actual address.

Postmaster

Every site is required to have a user or user alias designated "postmaster" to which problems with the mail system may be addressed. The "postmaster" address is not case sensitive.

FILES

/etc/aliases
~/.forward

IETF RFC 5322

NAME

man-pages − conventions for writing Linux man pages

SYNOPSIS

man [*section*] *title*

DESCRIPTION

This page describes the conventions that should be employed when writing man pages for the Linux *man-pages* project, which documents the user-space API provided by the Linux kernel and the GNU C library. The project thus provides most of the pages in Section 2, many of the pages that appear in Sections 3, 4, and 7, and a few of the pages that appear in Sections 1, 5, and 8 of the man pages on a Linux system. The conventions described on this page may also be useful for authors writing man pages for other projects.

Sections of the manual pages

The manual Sections are traditionally defined as follows:

1 User commands (Programs)
Commands that can be executed by the user from within a shell.

2 System calls
Functions which wrap operations performed by the kernel.

3 Library calls
All library functions excluding the system call wrappers (Most of the *libc* functions).

4 Special files (devices)
Files found in */dev* which allow to access to devices through the kernel.

5 File formats and configuration files
Describes various human-readable file formats and configuration files.

6 Games
Games and funny little programs available on the system.

7 Overview, conventions, and miscellaneous
Overviews or descriptions of various topics, conventions, and protocols, character set standards, the standard filesystem layout, and miscellaneous other things.

8 System management commands
Commands like *mount*(8), many of which only root can execute.

Macro package

New manual pages should be marked up using the **groff an.tmac** package described in *man*(7). This choice is mainly for consistency: the vast majority of existing Linux manual pages are marked up using these macros.

Conventions for source file layout

Please limit source code line length to no more than about 75 characters wherever possible. This helps avoid line-wrapping in some mail clients when patches are submitted inline.

Title line

The first command in a man page should be a **TH** command:

.TH *title section date source manual-section*

The arguments of the command are as follows:

title The title of the man page, written in all caps (e.g., *MAN-PAGES*).

section The section number in which the man page should be placed (e.g., *7*).

date The date of the last nontrivial change that was made to the man page. (Within the *man-pages* project, the necessary updates to these timestamps are handled automatically by scripts, so there is no need to manually update them as part of a patch.) Dates should be written in the form YYYY-MM-DD.

source The name and version of the project that provides the manual page (not necessarily the package that provides the functionality).

manual-section
Normally, this should be empty, since the default value will be good.

Sections within a manual page
The list below shows conventional or suggested sections. Most manual pages should include at least the **highlighted** sections. Arrange a new manual page so that sections are placed in the order shown in the list.

NAME	
LIBRARY	[Normally only in Sections 2, 3]
SYNOPSIS	
CONFIGURATION	[Normally only in Section 4]
DESCRIPTION	
OPTIONS	[Normally only in Sections 1, 8]
EXIT STATUS	[Normally only in Sections 1, 8]
RETURN VALUE	[Normally only in Sections 2, 3]
ERRORS	[Typically only in Sections 2, 3]
ENVIRONMENT	
FILES	
ATTRIBUTES	[Normally only in Sections 2, 3]
VERSIONS	[Normally only in Sections 2, 3]
STANDARDS	
HISTORY	
NOTES	
CAVEATS	
BUGS	
EXAMPLES	
AUTHORS	[Discouraged]
REPORTING BUGS	[Not used in man-pages]
COPYRIGHT	[Not used in man-pages]
SEE ALSO	

Where a traditional heading would apply, please use it; this kind of consistency can make the information easier to understand. If you must, you can create your own headings if they make things easier to understand (this can be especially useful for pages in Sections 4 and 5). However, before doing this, consider whether you could use the traditional headings, with some subsections (*.SS*) within those sections.

The following list elaborates on the contents of each of the above sections.

NAME The name of this manual page.

See *man*(7) for important details of the line(s) that should follow the **.SH NAME** command. All words in this line (including the word immediately following the "\−") should be in lowercase, except where English or technical terminological convention dictates otherwise.

LIBRARY
The library providing a symbol.

It shows the common name of the library, and in parentheses, the name of the library file and, if needed, the linker flag needed to link a program against it: (*libfoo*[, −*lfoo*]).

SYNOPSIS
A brief summary of the command or function's interface.

For commands, this shows the syntax of the command and its arguments (including options); boldface is used for as-is text and italics are used to indicate replaceable arguments. Brackets ([]) surround optional arguments, vertical bars (|) separate choices, and ellipses (...) can be repeated. For functions, it shows any required data declarations or **#include** directives, followed by the function declaration.

Where a feature test macro must be defined in order to obtain the declaration of a function (or a variable) from a header file, then the SYNOPSIS should indicate this, as described in *feature_test_macros*(7).

CONFIGURATION
Configuration details for a device.

This section normally appears only in Section 4 pages.

DESCRIPTION
An explanation of what the program, function, or format does.

Discuss how it interacts with files and standard input, and what it produces on standard output or standard error. Omit internals and implementation details unless they're critical for understanding the interface. Describe the usual case; for information on command-line options of a program use the **OPTIONS** section.

When describing new behavior or new flags for a system call or library function, be careful to note the kernel or C library version that introduced the change. The preferred method of noting this information for flags is as part of a **.TP** list, in the following form (here, for a new system call flag):

XYZ_FLAG (since Linux 3.7)
Description of flag...

Including version information is especially useful to users who are constrained to using older kernel or C library versions (which is typical in embedded systems, for example).

OPTIONS
A description of the command-line options accepted by a program and how they change its behavior.

This section should appear only for Section 1 and 8 manual pages.

EXIT STATUS
A list of the possible exit status values of a program and the conditions that cause these values to be returned.

This section should appear only for Section 1 and 8 manual pages.

RETURN VALUE
For Section 2 and 3 pages, this section gives a list of the values the library routine will return to the caller and the conditions that cause these values to be returned.

ERRORS
For Section 2 and 3 manual pages, this is a list of the values that may be placed in *errno* in the event of an error, along with information about the cause of the errors.

Where several different conditions produce the same error, the preferred approach is to create separate list entries (with duplicate error names) for each of the conditions. This makes the separate conditions clear, may make the list easier to read, and allows metainformation (e.g., kernel version number where the condition first became applicable) to be more easily marked for each condition.

The error list should be in alphabetical order.

ENVIRONMENT
A list of all environment variables that affect the program or function and how they affect it.

FILES A list of the files the program or function uses, such as configuration files, startup files, and files the program directly operates on.

Give the full pathname of these files, and use the installation process to modify the directory part to match user preferences. For many programs, the default installation location is in */usr/local*, so your base manual page should use */usr/local* as the base.

ATTRIBUTES
A summary of various attributes of the function(s) documented on this page. See *attributes*(7) for further details.

VERSIONS
A summary of systems where the API performs differently, or where there's a similar API.

STANDARDS

A description of any standards or conventions that relate to the function or command described by the manual page.

The preferred terms to use for the various standards are listed as headings in *standards*(7).

This section should note the current standards to which the API conforms to.

If the API is not governed by any standards but commonly exists on other systems, note them. If the call is Linux-specific or GNU-specific, note this. If it's available in the BSDs, note that.

If this section consists of just a list of standards (which it commonly does), terminate the list with a period ('.').

HISTORY

A brief summary of the Linux kernel or glibc versions where a system call or library function appeared, or changed significantly in its operation.

As a general rule, every new interface should include a HISTORY section in its manual page. Unfortunately, many existing manual pages don't include this information (since there was no policy to do so when they were written). Patches to remedy this are welcome, but, from the perspective of programmers writing new code, this information probably matters only in the case of kernel interfaces that have been added in Linux 2.4 or later (i.e., changes since Linux 2.2), and library functions that have been added to glibc since glibc 2.1 (i.e., changes since glibc 2.0).

The *syscalls*(2) manual page also provides information about kernel versions in which various system calls first appeared.

Old versions of standards should be mentioned here, rather than in STANDARDS, for example, SUS, SUSv2, and XPG, or the SVr4 and 4.xBSD implementation standards.

NOTES

Miscellaneous notes.

For Section 2 and 3 man pages you may find it useful to include subsections (**SS**) named *Linux Notes* and *glibc Notes*.

In Section 2, use the heading *C library/kernel differences* to mark off notes that describe the differences (if any) between the C library wrapper function for a system call and the raw system call interface provided by the kernel.

CAVEATS

Warnings about typical user misuse of an API, that don't constitute an API bug or design defect.

BUGS A list of limitations, known defects or inconveniences, and other questionable activities.

EXAMPLES

One or more examples demonstrating how this function, file, or command is used.

For details on writing example programs, see *Example programs* below.

AUTHORS

A list of authors of the documentation or program.

Use of an AUTHORS section is strongly discouraged. Generally, it is better not to clutter every page with a list of (over time potentially numerous) authors; if you write or significantly amend a page, add a copyright notice as a comment in the source file. If you are the author of a device driver and want to include an address for reporting bugs, place this under the BUGS section.

REPORTING BUGS

The *man-pages* project doesn't use a REPORTING BUGS section in manual pages. Information on reporting bugs is instead supplied in the script-generated COLOPHON section. However, various projects do use a REPORTING BUGS section. It is recommended to place it near the foot of the page.

COPYRIGHT

The *man-pages* project doesn't use a COPYRIGHT section in manual pages. Copyright information is instead maintained in the page source. In pages where this section is present, it is recommended to place it near the foot of the page, just above SEE ALSO.

SEE ALSO

A comma-separated list of related man pages, possibly followed by other related pages or documents.

The list should be ordered by section number and then alphabetically by name. Do not terminate this list with a period.

Where the SEE ALSO list contains many long manual page names, to improve the visual result of the output, it may be useful to employ the *.ad l* (don't right justify) and *.nh* (don't hyphenate) directives. Hyphenation of individual page names can be prevented by preceding words with the string "\%".

Given the distributed, autonomous nature of FOSS projects and their documentation, it is sometimes necessary—and in many cases desirable—that the SEE ALSO section includes references to manual pages provided by other projects.

FORMATTING AND WORDING CONVENTIONS

The following subsections note some details for preferred formatting and wording conventions in various sections of the pages in the *man-pages* project.

SYNOPSIS

Wrap the function prototype(s) in a *.nf*/*.fi* pair to prevent filling.

In general, where more than one function prototype is shown in the SYNOPSIS, the prototypes should *not* be separated by blank lines. However, blank lines (achieved using *.P*) may be added in the following cases:

- to separate long lists of function prototypes into related groups (see for example *list*(3));
- in other cases that may improve readability.

In the SYNOPSIS, a long function prototype may need to be continued over to the next line. The continuation line is indented according to the following rules:

(1) If there is a single such prototype that needs to be continued, then align the continuation line so that when the page is rendered on a fixed-width font device (e.g., on an xterm) the continuation line starts just below the start of the argument list in the line above. (Exception: the indentation may be adjusted if necessary to prevent a very long continuation line or a further continuation line where the function prototype is very long.) As an example:

```
int tcsetattr(int fd, int optional_actions,
              const struct termios *termios_p);
```

(2) But, where multiple functions in the SYNOPSIS require continuation lines, and the function names have different lengths, then align all continuation lines to start in the same column. This provides a nicer rendering in PDF output (because the SYNOPSIS uses a variable width font where spaces render narrower than most characters). As an example:

```
int getopt(int argc, char * const argv[],
           const char *optstring);
int getopt_long(int argc, char * const argv[],
           const char *optstring,
           const struct option *longopts, int *longindex);
```

RETURN VALUE

The preferred wording to describe how *errno* is set is "*errno* is set to indicate the error" or similar. This wording is consistent with the wording used in both POSIX.1 and FreeBSD.

ATTRIBUTES

Note the following:

- Wrap the table in this section in a *.ad l*/*.ad* pair to disable text filling and a *.nh*/*.hy* pair to disable hyphenation.

- Ensure that the table occupies the full page width through the use of an *lbx* description for one of the columns (usually the first column, though in some cases the last column if it contains a lot of text).
- Make free use of *T{/T}* macro pairs to allow table cells to be broken over multiple lines (also bearing in mind that pages may sometimes be rendered to a width of less than 80 columns).

For examples of all of the above, see the source code of various pages.

STYLE GUIDE

The following subsections describe the preferred style for the *man-pages* project. For details not covered below, the Chicago Manual of Style is usually a good source; try also grepping for preexisting usage in the project source tree.

Use of gender-neutral language

As far as possible, use gender-neutral language in the text of man pages. Use of "they" ("them", "themself", "their") as a gender-neutral singular pronoun is acceptable.

Formatting conventions for manual pages describing commands

For manual pages that describe a command (typically in Sections 1 and 8), the arguments are always specified using italics, *even in the SYNOPSIS section*.

The name of the command, and its options, should always be formatted in bold.

Formatting conventions for manual pages describing functions

For manual pages that describe functions (typically in Sections 2 and 3), the arguments are always specified using italics, *even in the SYNOPSIS section*, where the rest of the function is specified in bold:

int myfunction(int *argc***, char *****argv***);**

Variable names should, like argument names, be specified in italics.

Any reference to the subject of the current manual page should be written with the name in bold followed by a pair of parentheses in Roman (normal) font. For example, in the *fcntl*(2) man page, references to the subject of the page would be written as: **fcntl**(). The preferred way to write this in the source file is:

```
.BR fcntl ()
```

(Using this format, rather than the use of "\fB...\fP()" makes it easier to write tools that parse man page source files.)

Use semantic newlines

In the source of a manual page, new sentences should be started on new lines, long sentences should be split into lines at clause breaks (commas, semicolons, colons, and so on), and long clauses should be split at phrase boundaries. This convention, sometimes known as "semantic newlines", makes it easier to see the effect of patches, which often operate at the level of individual sentences, clauses, or phrases.

Lists

There are different kinds of lists:

Tagged paragraphs

These are used for a list of tags and their descriptions. When the tags are constants (either macros or numbers) they are in bold. Use the **.TP** macro.

An example is this "Tagged paragraphs" subsection is itself.

Ordered lists

Elements are preceded by a number in parentheses (1), (2). These represent a set of steps that have an order.

When there are substeps, they will be numbered like (4.2).

Positional lists

Elements are preceded by a number (index) in square brackets [4], [5]. These represent fields in a set. The first index will be:

0 When it represents fields of a C data structure, to be consistent with arrays.
1 When it represents fields of a file, to be consistent with tools like *cut*(1)

Alternatives list
: Elements are preceded by a letter in parentheses (a), (b). These represent a set of (normally) exclusive alternatives.

Bullet lists
: Elements are preceded by bullet symbols (**\[bu]**). Anything that doesn't fit elsewhere is usually covered by this type of list.

Numbered notes
: Not really a list, but the syntax is identical to "positional lists".

There should always be exactly 2 spaces between the list symbol and the elements. This doesn't apply to "tagged paragraphs", which use the default indentation rules.

Formatting conventions (general)

Paragraphs should be separated by suitable markers (usually either *.P* or *.IP*). Do *not* separate paragraphs using blank lines, as this results in poor rendering in some output formats (such as PostScript and PDF).

Filenames (whether pathnames, or references to header files) are always in italics (e.g., <*stdio.h*>), except in the SYNOPSIS section, where included files are in bold (e.g., **#include <stdio.h>**). When referring to a standard header file include, specify the header file surrounded by angle brackets, in the usual C way (e.g., <*stdio.h*>).

Special macros, which are usually in uppercase, are in bold (e.g., **MAXINT**). Exception: don't boldface NULL.

When enumerating a list of error codes, the codes are in bold (this list usually uses the **.TP** macro).

Complete commands should, if long, be written as an indented line on their own, with a blank line before and after the command, for example

```
man 7 man-pages
```

If the command is short, then it can be included inline in the text, in italic format, for example, *man 7 man-pages*. In this case, it may be worth using nonbreaking spaces (\[ti]) at suitable places in the command. Command options should be written in italics (e.g., *-l*).

Expressions, if not written on a separate indented line, should be specified in italics. Again, the use of nonbreaking spaces may be appropriate if the expression is inlined with normal text.

When showing example shell sessions, user input should be formatted in bold, for example

```
$ date
Thu Jul  7 13:01:27 CEST 2016
```

Any reference to another man page should be written with the name in bold, *always* followed by the section number, formatted in Roman (normal) font, without any separating spaces (e.g., *intro*(2)). The preferred way to write this in the source file is:

```
.BR intro (2)
```

(Including the section number in cross references lets tools like *man2html*(1) create properly hyperlinked pages.)

Control characters should be written in bold face, with no quotes; for example, **^X**.

Spelling

Starting with release 2.59, *man-pages* follows American spelling conventions (previously, there was a random mix of British and American spellings); please write all new pages and patches according to these conventions.

Aside from the well-known spelling differences, there are a few other subtleties to watch for:

- American English tends to use the forms "backward", "upward", "toward", and so on rather than the British forms "backwards", "upwards", "towards", and so on.
- Opinions are divided on "acknowledgement" vs "acknowledgment". The latter is predominant, but not universal usage in American English. POSIX and the BSD license use the former spelling. In the Linux man-pages project, we use "acknowledgement".

BSD version numbers

The classical scheme for writing BSD version numbers is *x.yBSD*, where *x.y* is the version number (e.g., 4.2BSD). Avoid forms such as *BSD 4.3*.

Capitalization

In subsection ("SS") headings, capitalize the first word in the heading, but otherwise use lowercase, except where English usage (e.g., proper nouns) or programming language requirements (e.g., identifier names) dictate otherwise. For example:

```
.SS Unicode under Linux
```

Indentation of structure definitions, shell session logs, and so on

When structure definitions, shell session logs, and so on are included in running text, indent them by 4 spaces (i.e., a block enclosed by *.in +4n* and *.in*), format them using the *.EX* and *.EE* macros, and surround them with suitable paragraph markers (either *.P* or *.IP*). For example:

```
.P
.in +4n
.EX
int
main(int argc, char *argv[])
{
    return 0;
}
.EE
.in
.P
```

Preferred terms

The following table lists some preferred terms to use in man pages, mainly to ensure consistency across pages.

Term	Avoid using	Notes
built-in	builtin	
Epoch	epoch	For the UNIX Epoch (00:00:00, 1 Jan 1970 UTC)
filename	file name	
filesystem	file system	
hostname	host name	
inode	i-node	
lowercase	lower case, lower-case	
nonzero	non-zero	
pathname	path name	
pseudoterminal	pseudo-terminal	
privileged port	reserved port, system port	
real-time	realtime, real time	
run time	runtime	
saved set-group-ID	saved group ID, saved set-GID	
saved set-user-ID	saved user ID, saved set-UID	
set-group-ID	set-GID, setgid	
set-user-ID	set-UID, setuid	
superuser	super user, super-user	
superblock	super block, super-block	
symbolic link	symlink	
timestamp	time stamp	
timezone	time zone	

uppercase	upper case, upper-case	
usable	useable	
user space	userspace	
username	user name	
x86-64	x86_64	Except if referring to result of "uname −m" or similar
zeros	zeroes	

See also the discussion *Hyphenation of attributive compounds* below.

Terms to avoid

The following table lists some terms to avoid using in man pages, along with some suggested alternatives, mainly to ensure consistency across pages.

Avoid	Use instead	Notes
32bit	32-bit	same for 8-bit, 16-bit, etc.
current process	calling process	A common mistake made by kernel programmers when writing man pages
manpage	man page, manual page	
minus infinity	negative infinity	
non-root	unprivileged user	
non-superuser	unprivileged user	
nonprivileged	unprivileged	
OS	operating system	
plus infinity	positive infinity	
pty	pseudoterminal	
tty	terminal	
Unices	UNIX systems	
Unixes	UNIX systems	

Trademarks

Use the correct spelling and case for trademarks. The following is a list of the correct spellings of various relevant trademarks that are sometimes misspelled:

DG/UX
HP-UX
UNIX
UnixWare

NULL, NUL, null pointer, and null byte

A *null pointer* is a pointer that points to nothing, and is normally indicated by the constant *NULL*. On the other hand, *NUL* is the *null byte*, a byte with the value 0, represented in C via the character constant *'\0'*.

The preferred term for the pointer is "null pointer" or simply "NULL"; avoid writing "NULL pointer".

The preferred term for the byte is "null byte". Avoid writing "NUL", since it is too easily confused with "NULL". Avoid also the terms "zero byte" and "null character". The byte that terminates a C string should be described as "the terminating null byte"; strings may be described as "null-terminated", but avoid the use of "NUL-terminated".

Hyperlinks

For hyperlinks, use the *.UR*/*.UE* macro pair (see *groff_man*(7)). This produces proper hyperlinks that can be used in a web browser, when rendering a page with, say:

```
BROWSER=firefox man -H pagename
```

Use of e.g., i.e., etc., a.k.a., and similar

In general, the use of abbreviations such as "e.g.", "i.e.", "etc.", "cf.", and "a.k.a." should be avoided, in favor of suitable full wordings ("for example", "that is", "and so on", "compare to", "also known as").

The only place where such abbreviations may be acceptable is in *short* parenthetical asides (e.g., like this one).

Always include periods in such abbreviations, as shown here. In addition, "e.g." and "i.e." should

always be followed by a comma.

Em-dashes

The way to write an em-dash—the glyph that appears at either end of this subphrase—in *roff is with the macro "\[em]". (On an ASCII terminal, an em-dash typically renders as two hyphens, but in other typographical contexts it renders as a long dash.) Em-dashes should be written *without* surrounding spaces.

Hyphenation of attributive compounds

Compound terms should be hyphenated when used attributively (i.e., to qualify a following noun). Some examples:

32-bit value
command-line argument
floating-point number
run-time check
user-space function
wide-character string

Hyphenation with multi, non, pre, re, sub, and so on

The general tendency in modern English is not to hyphenate after prefixes such as "multi", "non", "pre", "re", "sub", and so on. Manual pages should generally follow this rule when these prefixes are used in natural English constructions with simple suffixes. The following list gives some examples of the preferred forms:

interprocess
multithreaded
multiprocess
nonblocking
nondefault
nonempty
noninteractive
nonnegative
nonportable
nonzero
preallocated
precreate
prerecorded
reestablished
reinitialize
rearm
reread
subcomponent
subdirectory
subsystem

Hyphens should be retained when the prefixes are used in nonstandard English words, with trademarks, proper nouns, acronyms, or compound terms. Some examples:

non-ASCII
non-English
non-NULL
non-real-time

Finally, note that "re-create" and "recreate" are two different verbs, and the former is probably what you want.

Generating optimal glyphs

Where a real minus character is required (e.g., for numbers such as −1, for man page cross references such as *utf-8*(7), or when writing options that have a leading dash, such as in *ls −l*), use the following form in the man page source:

```
\-
```

This guideline applies also to code examples.

The use of real minus signs serves the following purposes:

- To provide better renderings on various targets other than ASCII terminals, notably in PDF and on Unicode/UTF−8-capable terminals.
- To generate glyphs that when copied from rendered pages will produce real minus signs when pasted into a terminal.

To produce unslanted single quotes that render well in ASCII, UTF-8, and PDF, use "\[aq]" ("apostrophe quote"); for example

```
\[aq]C\[aq]
```

where *C* is the quoted character. This guideline applies also to character constants used in code examples.

Where a proper caret (^) that renders well in both a terminal and PDF is required, use "\[ha]". This is especially necessary in code samples, to get a nicely rendered caret when rendering to PDF.

Using a naked "~" character results in a poor rendering in PDF. Instead use "\[ti]". This is especially necessary in code samples, to get a nicely rendered tilde when rendering to PDF.

Example programs and shell sessions

Manual pages may include example programs demonstrating how to use a system call or library function. However, note the following:

- Example programs should be written in C.
- An example program is necessary and useful only if it demonstrates something beyond what can easily be provided in a textual description of the interface. An example program that does nothing other than call an interface usually serves little purpose.
- Example programs should ideally be short (e.g., a good example can often be provided in less than 100 lines of code), though in some cases longer programs may be necessary to properly illustrate the use of an API.
- Expressive code is appreciated.
- Comments should included where helpful. Complete sentences in free-standing comments should be terminated by a period. Periods should generally be omitted in "tag" comments (i.e., comments that are placed on the same line of code); such comments are in any case typically brief phrases rather than complete sentences.
- Example programs should do error checking after system calls and library function calls.
- Example programs should be complete, and compile without warnings when compiled with *cc −Wall*.
- Where possible and appropriate, example programs should allow experimentation, by varying their behavior based on inputs (ideally from command-line arguments, or alternatively, via input read by the program).
- Example programs should be laid out according to Kernighan and Ritchie style, with 4-space indents. (Avoid the use of TAB characters in source code!) The following command can be used to format your source code to something close to the preferred style:

  ```
  indent −npro −kr −i4 −ts4 −sob −l72 −ss −nut −psl prog.c
  ```

- For consistency, all example programs should terminate using either of:

  ```
  exit(EXIT_SUCCESS);
  exit(EXIT_FAILURE);
  ```

  Avoid using the following forms to terminate a program:

  ```
  exit(0);
  exit(1);
  return n;
  ```

- If there is extensive explanatory text before the program source code, mark off the source code with a subsection heading *Program source*, as in:

```
.SS Program source
```

Always do this if the explanatory text includes a shell session log.

If you include a shell session log demonstrating the use of a program or other system feature:

- Place the session log above the source code listing.
- Indent the session log by four spaces.
- Boldface the user input text, to distinguish it from output produced by the system.

For some examples of what example programs should look like, see *wait*(2) and *pipe*(2).

EXAMPLES

For canonical examples of how man pages in the *man-pages* package should look, see *pipe*(2) and *fcntl*(2).

NAME

math_error − detecting errors from mathematical functions

SYNOPSIS

#include <math.h>
#include <errno.h>
#include <fenv.h>

DESCRIPTION

When an error occurs, most library functions indicate this fact by returning a special value (e.g., −1 or NULL). Because they typically return a floating-point number, the mathematical functions declared in *<math.h>* indicate an error using other mechanisms. There are two error-reporting mechanisms: the older one sets *errno*; the newer one uses the floating-point exception mechanism (the use of *feclearexcept*(3) and *fetestexcept*(3), as outlined below) described in *fenv*(3).

A portable program that needs to check for an error from a mathematical function should set *errno* to zero, and make the following call

```
feclearexcept(FE_ALL_EXCEPT);
```

before calling a mathematical function.

Upon return from the mathematical function, if *errno* is nonzero, or the following call (see *fenv*(3)) returns nonzero

```
fetestexcept(FE_INVALID | FE_DIVBYZERO | FE_OVERFLOW |
             FE_UNDERFLOW);
```

then an error occurred in the mathematical function.

The error conditions that can occur for mathematical functions are described below.

Domain error

A *domain error* occurs when a mathematical function is supplied with an argument whose value falls outside the domain for which the function is defined (e.g., giving a negative argument to *log*(3)). When a domain error occurs, math functions commonly return a NaN (though some functions return a different value in this case); *errno* is set to **EDOM**, and an "invalid" (**FE_INVALID**) floating-point exception is raised.

Pole error

A *pole error* occurs when the mathematical result of a function is an exact infinity (e.g., the logarithm of 0 is negative infinity). When a pole error occurs, the function returns the (signed) value **HUGE_VAL**, **HUGE_VALF**, or **HUGE_VALL**, depending on whether the function result type is *double*, *float*, or *long double*. The sign of the result is that which is mathematically correct for the function. *errno* is set to **ERANGE**, and a "divide-by-zero" (**FE_DIVBYZERO**) floating-point exception is raised.

Range error

A *range error* occurs when the magnitude of the function result means that it cannot be represented in the result type of the function. The return value of the function depends on whether the range error was an overflow or an underflow.

A floating result *overflows* if the result is finite, but is too large to represented in the result type. When an overflow occurs, the function returns the value **HUGE_VAL**, **HUGE_VALF**, or **HUGE_VALL**, depending on whether the function result type is *double*, *float*, or *long double*. *errno* is set to **ERANGE**, and an "overflow" (**FE_OVERFLOW**) floating-point exception is raised.

A floating result *underflows* if the result is too small to be represented in the result type. If an underflow occurs, a mathematical function typically returns 0.0 (C99 says a function shall return "an implementation-defined value whose magnitude is no greater than the smallest normalized positive number in the specified type"). *errno* may be set to **ERANGE**, and an "underflow" (**FE_UNDERFLOW**) floating-point exception may be raised.

Some functions deliver a range error if the supplied argument value, or the correct function result, would be *subnormal*. A subnormal value is one that is nonzero, but with a magnitude that is so small that it can't be presented in normalized form (i.e., with a 1 in the most significant bit of the significand). The representation of a subnormal number will contain one or more leading zeros in the significand.

NOTES

The *math_errhandling* identifier specified by C99 and POSIX.1 is not supported by glibc. This identifier is supposed to indicate which of the two error-notification mechanisms (*errno*, exceptions retrievable via *fetestexcept*(3)) is in use. The standards require that at least one be in use, but permit both to be available. The current (glibc 2.8) situation under glibc is messy. Most (but not all) functions raise exceptions on errors. Some also set *errno*. A few functions set *errno*, but don't raise an exception. A very few functions do neither. See the individual manual pages for details.

To avoid the complexities of using *errno* and *fetestexcept*(3) for error checking, it is often advised that one should instead check for bad argument values before each call. For example, the following code ensures that *log*(3)'s argument is not a NaN and is not zero (a pole error) or less than zero (a domain error):

```
double x, r;

if (isnan(x) || islessequal(x, 0)) {
    /* Deal with NaN / pole error / domain error */
}

r = log(x);
```

The discussion on this page does not apply to the complex mathematical functions (i.e., those declared by <*complex.h*>), which in general are not required to return errors by C99 and POSIX.1.

The *gcc*(1) *−fno−math−errno* option causes the executable to employ implementations of some mathematical functions that are faster than the standard implementations, but do not set *errno* on error. (The *gcc*(1) *−ffast−math* option also enables *−fno−math−errno*.) An error can still be tested for using *fetestexcept*(3).

NAME

mount_namespaces − overview of Linux mount namespaces

DESCRIPTION

For an overview of namespaces, see *namespaces*(7).

Mount namespaces provide isolation of the list of mounts seen by the processes in each namespace instance. Thus, the processes in each of the mount namespace instances will see distinct single-directory hierarchies.

The views provided by the */proc/*pid*/mounts*, */proc/*pid*/mountinfo*, and */proc/*pid*/mountstats* files (all described in *proc*(5)) correspond to the mount namespace in which the process with the PID *pid* resides. (All of the processes that reside in the same mount namespace will see the same view in these files.)

A new mount namespace is created using either *clone*(2) or *unshare*(2) with the **CLONE_NEWNS** flag. When a new mount namespace is created, its mount list is initialized as follows:

- If the namespace is created using *clone*(2), the mount list of the child's namespace is a copy of the mount list in the parent process's mount namespace.
- If the namespace is created using *unshare*(2), the mount list of the new namespace is a copy of the mount list in the caller's previous mount namespace.

Subsequent modifications to the mount list (**mount**(2) and *umount*(2)) in either mount namespace will not (by default) affect the mount list seen in the other namespace (but see the following discussion of shared subtrees).

SHARED SUBTREES

After the implementation of mount namespaces was completed, experience showed that the isolation that they provided was, in some cases, too great. For example, in order to make a newly loaded optical disk available in all mount namespaces, a mount operation was required in each namespace. For this use case, and others, the shared subtree feature was introduced in Linux 2.6.15. This feature allows for automatic, controlled propagation of *mount*(2) and *umount*(2) *events* between namespaces (or, more precisely, between the mounts that are members of a *peer group* that are propagating events to one another).

Each mount is marked (via *mount*(2)) as having one of the following *propagation types*:

MS_SHARED
: This mount shares events with members of a peer group. *mount*(2) and *umount*(2) events immediately under this mount will propagate to the other mounts that are members of the peer group. *Propagation* here means that the same *mount*(2) or *umount*(2) will automatically occur under all of the other mounts in the peer group. Conversely, *mount*(2) and *umount*(2) events that take place under peer mounts will propagate to this mount.

MS_PRIVATE
: This mount is private; it does not have a peer group. *mount*(2) and *umount*(2) events do not propagate into or out of this mount.

MS_SLAVE
: *mount*(2) and *umount*(2) events propagate into this mount from a (master) shared peer group. *mount*(2) and *umount*(2) events under this mount do not propagate to any peer.

  Note that a mount can be the slave of another peer group while at the same time sharing *mount*(2) and *umount*(2) events with a peer group of which it is a member. (More precisely, one peer group can be the slave of another peer group.)

MS_UNBINDABLE
: This is like a private mount, and in addition this mount can't be bind mounted. Attempts to bind mount this mount (**mount**(2) with the **MS_BIND** flag) will fail.

  When a recursive bind mount (**mount**(2) with the **MS_BIND** and **MS_REC** flags) is performed on a directory subtree, any bind mounts within the subtree are automatically pruned (i.e., not replicated) when replicating that subtree to produce the target subtree.

For a discussion of the propagation type assigned to a new mount, see NOTES.

The propagation type is a per-mount-point setting; some mounts may be marked as shared (with each

shared mount being a member of a distinct peer group), while others are private (or slaved or unbindable).

Note that a mount's propagation type determines whether *mount*(2) and *umount*(2) of mounts *immediately under* the mount are propagated. Thus, the propagation type does not affect propagation of events for grandchildren and further removed descendant mounts. What happens if the mount itself is unmounted is determined by the propagation type that is in effect for the *parent* of the mount.

Members are added to a *peer group* when a mount is marked as shared and either:

(a) the mount is replicated during the creation of a new mount namespace; or

(b) a new bind mount is created from the mount.

In both of these cases, the new mount joins the peer group of which the existing mount is a member.

A new peer group is also created when a child mount is created under an existing mount that is marked as shared. In this case, the new child mount is also marked as shared and the resulting peer group consists of all the mounts that are replicated under the peers of parent mounts.

A mount ceases to be a member of a peer group when either the mount is explicitly unmounted, or when the mount is implicitly unmounted because a mount namespace is removed (because it has no more member processes).

The propagation type of the mounts in a mount namespace can be discovered via the "optional fields" exposed in */proc/*pid*/mountinfo*. (See *proc*(5) for details of this file.) The following tags can appear in the optional fields for a record in that file:

shared:X
: This mount is shared in peer group *X*. Each peer group has a unique ID that is automatically generated by the kernel, and all mounts in the same peer group will show the same ID. (These IDs are assigned starting from the value 1, and may be recycled when a peer group ceases to have any members.)

master:X
: This mount is a slave to shared peer group *X*.

propagate_from:X (since Linux 2.6.26)
: This mount is a slave and receives propagation from shared peer group *X*. This tag will always appear in conjunction with a *master:X* tag. Here, *X* is the closest dominant peer group under the process's root directory. If *X* is the immediate master of the mount, or if there is no dominant peer group under the same root, then only the *master:X* field is present and not the *propagate_from:X* field. For further details, see below.

unbindable
: This is an unbindable mount.

If none of the above tags is present, then this is a private mount.

MS_SHARED and MS_PRIVATE example

Suppose that on a terminal in the initial mount namespace, we mark one mount as shared and another as private, and then view the mounts in */proc/self/mountinfo*:

```
sh1# mount --make-shared /mntS
sh1# mount --make-private /mntP
sh1# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
77 61 8:17 / /mntS rw,relatime shared:1
83 61 8:15 / /mntP rw,relatime
```

From the */proc/self/mountinfo* output, we see that */mntS* is a shared mount in peer group 1, and that */mntP* has no optional tags, indicating that it is a private mount. The first two fields in each record in this file are the unique ID for this mount, and the mount ID of the parent mount. We can further inspect this file to see that the parent mount of */mntS* and */mntP* is the root directory, */*, which is mounted as private:

```
sh1# cat /proc/self/mountinfo | awk '$1 == 61' | sed 's/ - .*//'
61 0 8:2 / / rw,relatime
```

On a second terminal, we create a new mount namespace where we run a second shell and inspect the

mounts:

```
$ PS1='sh2# ' sudo unshare -m --propagation unchanged sh
sh2# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
222 145 8:17 / /mntS rw,relatime shared:1
225 145 8:15 / /mntP rw,relatime
```

The new mount namespace received a copy of the initial mount namespace's mounts. These new mounts maintain the same propagation types, but have unique mount IDs. (The *--propagation unchanged* option prevents *unshare*(1) from marking all mounts as private when creating a new mount namespace, which it does by default.)

In the second terminal, we then create submounts under each of */mntS* and */mntP* and inspect the set-up:

```
sh2# mkdir /mntS/a
sh2# mount /dev/sdb6 /mntS/a
sh2# mkdir /mntP/b
sh2# mount /dev/sdb7 /mntP/b
sh2# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
222 145 8:17 / /mntS rw,relatime shared:1
225 145 8:15 / /mntP rw,relatime
178 222 8:22 / /mntS/a rw,relatime shared:2
230 225 8:23 / /mntP/b rw,relatime
```

From the above, it can be seen that */mntS/a* was created as shared (inheriting this setting from its parent mount) and */mntP/b* was created as a private mount.

Returning to the first terminal and inspecting the set-up, we see that the new mount created under the shared mount */mntS* propagated to its peer mount (in the initial mount namespace), but the new mount created under the private mount */mntP* did not propagate:

```
sh1# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
77 61 8:17 / /mntS rw,relatime shared:1
83 61 8:15 / /mntP rw,relatime
179 77 8:22 / /mntS/a rw,relatime shared:2
```

MS_SLAVE example

Making a mount a slave allows it to receive propagated *mount*(2) and *umount*(2) events from a master shared peer group, while preventing it from propagating events to that master. This is useful if we want to (say) receive a mount event when an optical disk is mounted in the master shared peer group (in another mount namespace), but want to prevent *mount*(2) and *umount*(2) events under the slave mount from having side effects in other namespaces.

We can demonstrate the effect of slaving by first marking two mounts as shared in the initial mount namespace:

```
sh1# mount --make-shared /mntX
sh1# mount --make-shared /mntY
sh1# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
132 83 8:23 / /mntX rw,relatime shared:1
133 83 8:22 / /mntY rw,relatime shared:2
```

On a second terminal, we create a new mount namespace and inspect the mounts:

```
sh2# unshare -m --propagation unchanged sh
sh2# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
168 167 8:23 / /mntX rw,relatime shared:1
169 167 8:22 / /mntY rw,relatime shared:2
```

In the new mount namespace, we then mark one of the mounts as a slave:

```
sh2# mount --make-slave /mntY
sh2# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
168 167 8:23 / /mntX rw,relatime shared:1
169 167 8:22 / /mntY rw,relatime master:2
```

From the above output, we see that */mntY* is now a slave mount that is receiving propagation events

from the shared peer group with the ID 2.

Continuing in the new namespace, we create submounts under each of */mntX* and */mntY*:

```
sh2# mkdir /mntX/a
sh2# mount /dev/sda3 /mntX/a
sh2# mkdir /mntY/b
sh2# mount /dev/sda5 /mntY/b
```

When we inspect the state of the mounts in the new mount namespace, we see that */mntX/a* was created as a new shared mount (inheriting the "shared" setting from its parent mount) and */mntY/b* was created as a private mount:

```
sh2# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
168 167 8:23 / /mntX rw,relatime shared:1
169 167 8:22 / /mntY rw,relatime master:2
173 168 8:3 / /mntX/a rw,relatime shared:3
175 169 8:5 / /mntY/b rw,relatime
```

Returning to the first terminal (in the initial mount namespace), we see that the mount */mntX/a* propagated to the peer (the shared */mntX*), but the mount */mntY/b* was not propagated:

```
sh1# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
132 83 8:23 / /mntX rw,relatime shared:1
133 83 8:22 / /mntY rw,relatime shared:2
174 132 8:3 / /mntX/a rw,relatime shared:3
```

Now we create a new mount under */mntY* in the first shell:

```
sh1# mkdir /mntY/c
sh1# mount /dev/sda1 /mntY/c
sh1# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
132 83 8:23 / /mntX rw,relatime shared:1
133 83 8:22 / /mntY rw,relatime shared:2
174 132 8:3 / /mntX/a rw,relatime shared:3
178 133 8:1 / /mntY/c rw,relatime shared:4
```

When we examine the mounts in the second mount namespace, we see that in this case the new mount has been propagated to the slave mount, and that the new mount is itself a slave mount (to peer group 4):

```
sh2# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
168 167 8:23 / /mntX rw,relatime shared:1
169 167 8:22 / /mntY rw,relatime master:2
173 168 8:3 / /mntX/a rw,relatime shared:3
175 169 8:5 / /mntY/b rw,relatime
179 169 8:1 / /mntY/c rw,relatime master:4
```

MS_UNBINDABLE example

One of the primary purposes of unbindable mounts is to avoid the "mount explosion" problem when repeatedly performing bind mounts of a higher-level subtree at a lower-level mount. The problem is illustrated by the following shell session.

Suppose we have a system with the following mounts:

```
# mount | awk '{print $1, $2, $3}'
/dev/sda1 on /
/dev/sdb6 on /mntX
/dev/sdb7 on /mntY
```

Suppose furthermore that we wish to recursively bind mount the root directory under several users' home directories. We do this for the first user, and inspect the mounts:

```
# mount --rbind / /home/cecilia/
# mount | awk '{print $1, $2, $3}'
/dev/sda1 on /
/dev/sdb6 on /mntX
/dev/sdb7 on /mntY
```

```
/dev/sda1 on /home/cecilia
/dev/sdb6 on /home/cecilia/mntX
/dev/sdb7 on /home/cecilia/mntY
```

When we repeat this operation for the second user, we start to see the explosion problem:

```
# mount --rbind / /home/henry
# mount | awk '{print $1, $2, $3}'
/dev/sda1 on /
/dev/sdb6 on /mntX
/dev/sdb7 on /mntY
/dev/sda1 on /home/cecilia
/dev/sdb6 on /home/cecilia/mntX
/dev/sdb7 on /home/cecilia/mntY
/dev/sda1 on /home/henry
/dev/sdb6 on /home/henry/mntX
/dev/sdb7 on /home/henry/mntY
/dev/sda1 on /home/henry/home/cecilia
/dev/sdb6 on /home/henry/home/cecilia/mntX
/dev/sdb7 on /home/henry/home/cecilia/mntY
```

Under */home/henry*, we have not only recursively added the */mntX* and */mntY* mounts, but also the recursive mounts of those directories under */home/cecilia* that were created in the previous step. Upon repeating the step for a third user, it becomes obvious that the explosion is exponential in nature:

```
# mount --rbind / /home/otto
# mount | awk '{print $1, $2, $3}'
/dev/sda1 on /
/dev/sdb6 on /mntX
/dev/sdb7 on /mntY
/dev/sda1 on /home/cecilia
/dev/sdb6 on /home/cecilia/mntX
/dev/sdb7 on /home/cecilia/mntY
/dev/sda1 on /home/henry
/dev/sdb6 on /home/henry/mntX
/dev/sdb7 on /home/henry/mntY
/dev/sda1 on /home/henry/home/cecilia
/dev/sdb6 on /home/henry/home/cecilia/mntX
/dev/sdb7 on /home/henry/home/cecilia/mntY
/dev/sda1 on /home/otto
/dev/sdb6 on /home/otto/mntX
/dev/sdb7 on /home/otto/mntY
/dev/sda1 on /home/otto/home/cecilia
/dev/sdb6 on /home/otto/home/cecilia/mntX
/dev/sdb7 on /home/otto/home/cecilia/mntY
/dev/sda1 on /home/otto/home/henry
/dev/sdb6 on /home/otto/home/henry/mntX
/dev/sdb7 on /home/otto/home/henry/mntY
/dev/sda1 on /home/otto/home/henry/home/cecilia
/dev/sdb6 on /home/otto/home/henry/home/cecilia/mntX
/dev/sdb7 on /home/otto/home/henry/home/cecilia/mntY
```

The mount explosion problem in the above scenario can be avoided by making each of the new mounts unbindable. The effect of doing this is that recursive mounts of the root directory will not replicate the unbindable mounts. We make such a mount for the first user:

```
# mount --rbind --make-unbindable / /home/cecilia
```

Before going further, we show that unbindable mounts are indeed unbindable:

```
# mkdir /mntZ
# mount --bind /home/cecilia /mntZ
mount: wrong fs type, bad option, bad superblock on /home/cecilia,
```

```
       missing codepage or helper program, or other error

       In some cases useful info is found in syslog - try
       dmesg | tail or so.
```

Now we create unbindable recursive bind mounts for the other two users:

```
# mount --rbind --make-unbindable / /home/henry
# mount --rbind --make-unbindable / /home/otto
```

Upon examining the list of mounts, we see there has been no explosion of mounts, because the unbindable mounts were not replicated under each user's directory:

```
# mount | awk '{print $1, $2, $3}'
/dev/sda1 on /
/dev/sdb6 on /mntX
/dev/sdb7 on /mntY
/dev/sda1 on /home/cecilia
/dev/sdb6 on /home/cecilia/mntX
/dev/sdb7 on /home/cecilia/mntY
/dev/sda1 on /home/henry
/dev/sdb6 on /home/henry/mntX
/dev/sdb7 on /home/henry/mntY
/dev/sda1 on /home/otto
/dev/sdb6 on /home/otto/mntX
/dev/sdb7 on /home/otto/mntY
```

Propagation type transitions

The following table shows the effect that applying a new propagation type (i.e., *mount --make-xxxx*) has on the existing propagation type of a mount. The rows correspond to existing propagation types, and the columns are the new propagation settings. For reasons of space, "private" is abbreviated as "priv" and "unbindable" as "unbind".

	make-shared	**make-slave**	**make-priv**	**make-unbind**
shared	shared	slave/priv [1]	priv	unbind
slave	slave+shared	slave [2]	priv	unbind
slave+shared	slave+shared	slave	priv	unbind
private	shared	priv [2]	priv	unbind
unbindable	shared	unbind [2]	priv	unbind

Note the following details to the table:

[1] If a shared mount is the only mount in its peer group, making it a slave automatically makes it private.

[2] Slaving a nonshared mount has no effect on the mount.

Bind (MS_BIND) semantics

Suppose that the following command is performed:

```
mount --bind A/a B/b
```

Here, *A* is the source mount, *B* is the destination mount, *a* is a subdirectory path under the mount point *A*, and *b* is a subdirectory path under the mount point *B*. The propagation type of the resulting mount, *B/b*, depends on the propagation types of the mounts *A* and *B*, and is summarized in the following table.

		source(A)			
		shared	**private**	**slave**	**unbind**
dest(B)	**shared**	shared	shared	slave+shared	invalid
	nonshared	shared	private	slave	invalid

Note that a recursive bind of a subtree follows the same semantics as for a bind operation on each mount in the subtree. (Unbindable mounts are automatically pruned at the target mount point.)

For further details, see *Documentation/filesystems/sharedsubtree.rst* in the kernel source tree.

Move (MS_MOVE) semantics

Suppose that the following command is performed:

```
mount --move A B/b
```

Here, *A* is the source mount, *B* is the destination mount, and *b* is a subdirectory path under the mount point *B*. The propagation type of the resulting mount, *B/b*, depends on the propagation types of the mounts *A* and *B*, and is summarized in the following table.

		source(A)			
		shared	**private**	**slave**	**unbind**
dest(B)	**shared**	shared	shared	slave+shared	invalid
	nonshared	shared	private	slave	unbindable

Note: moving a mount that resides under a shared mount is invalid.

For further details, see *Documentation/filesystems/sharedsubtree.rst* in the kernel source tree.

Mount semantics

Suppose that we use the following command to create a mount:

```
mount device B/b
```

Here, *B* is the destination mount, and *b* is a subdirectory path under the mount point *B*. The propagation type of the resulting mount, *B/b*, follows the same rules as for a bind mount, where the propagation type of the source mount is considered always to be private.

Unmount semantics

Suppose that we use the following command to tear down a mount:

```
umount A
```

Here, *A* is a mount on *B/b*, where *B* is the parent mount and *b* is a subdirectory path under the mount point *B*. If **B** is shared, then all most-recently-mounted mounts at *b* on mounts that receive propagation from mount *B* and do not have submounts under them are unmounted.

The /proc/ pid /mountinfo propagate_from tag

The *propagate_from:X* tag is shown in the optional fields of a */proc/*pid*/mountinfo* record in cases where a process can't see a slave's immediate master (i.e., the pathname of the master is not reachable from the filesystem root directory) and so cannot determine the chain of propagation between the mounts it can see.

In the following example, we first create a two-link master-slave chain between the mounts */mnt*, */tmp/etc*, and */mnt/tmp/etc*. Then the *chroot*(1) command is used to make the */tmp/etc* mount point unreachable from the root directory, creating a situation where the master of */mnt/tmp/etc* is not reachable from the (new) root directory of the process.

First, we bind mount the root directory onto */mnt* and then bind mount */proc* at */mnt/proc* so that after the later *chroot*(1) the *proc*(5) filesystem remains visible at the correct location in the chroot-ed environment.

```
# mkdir -p /mnt/proc
# mount --bind / /mnt
# mount --bind /proc /mnt/proc
```

Next, we ensure that the */mnt* mount is a shared mount in a new peer group (with no peers):

```
# mount --make-private /mnt  # Isolate from any previous peer group
# mount --make-shared /mnt
# cat /proc/self/mountinfo | grep '/mnt' | sed 's/ - .*//'
239 61 8:2 / /mnt ... shared:102
248 239 0:4 / /mnt/proc ... shared:5
```

Next, we bind mount */mnt/etc* onto */tmp/etc*:

```
# mkdir -p /tmp/etc
# mount --bind /mnt/etc /tmp/etc
# cat /proc/self/mountinfo | egrep '/mnt|/tmp/' | sed 's/ - .*//'
239 61 8:2 / /mnt ... shared:102
248 239 0:4 / /mnt/proc ... shared:5
```

```
267 40 8:2 /etc /tmp/etc ... shared:102
```

Initially, these two mounts are in the same peer group, but we then make the */tmp/etc* a slave of */mnt/etc*, and then make */tmp/etc* shared as well, so that it can propagate events to the next slave in the chain:

```
# mount --make-slave /tmp/etc
# mount --make-shared /tmp/etc
# cat /proc/self/mountinfo | egrep '/mnt|/tmp/' | sed 's/ - .*//'
239 61 8:2 / /mnt ... shared:102
248 239 0:4 / /mnt/proc ... shared:5
267 40 8:2 /etc /tmp/etc ... shared:105 master:102
```

Then we bind mount */tmp/etc* onto */mnt/tmp/etc*. Again, the two mounts are initially in the same peer group, but we then make */mnt/tmp/etc* a slave of */tmp/etc*:

```
# mkdir -p /mnt/tmp/etc
# mount --bind /tmp/etc /mnt/tmp/etc
# mount --make-slave /mnt/tmp/etc
# cat /proc/self/mountinfo | egrep '/mnt|/tmp/' | sed 's/ - .*//'
239 61 8:2 / /mnt ... shared:102
248 239 0:4 / /mnt/proc ... shared:5
267 40 8:2 /etc /tmp/etc ... shared:105 master:102
273 239 8:2 /etc /mnt/tmp/etc ... master:105
```

From the above, we see that */mnt* is the master of the slave */tmp/etc*, which in turn is the master of the slave */mnt/tmp/etc*.

We then *chroot*(1) to the */mnt* directory, which renders the mount with ID 267 unreachable from the (new) root directory:

```
# chroot /mnt
```

When we examine the state of the mounts inside the chroot-ed environment, we see the following:

```
# cat /proc/self/mountinfo | sed 's/ - .*//'
239 61 8:2 / / ... shared:102
248 239 0:4 / /proc ... shared:5
273 239 8:2 /etc /tmp/etc ... master:105 propagate_from:102
```

Above, we see that the mount with ID 273 is a slave whose master is the peer group 105. The mount point for that master is unreachable, and so a *propagate_from* tag is displayed, indicating that the closest dominant peer group (i.e., the nearest reachable mount in the slave chain) is the peer group with the ID 102 (corresponding to the */mnt* mount point before the *chroot*(1) was performed).

STANDARDS

Linux.

HISTORY

Linux 2.4.19.

NOTES

The propagation type assigned to a new mount depends on the propagation type of the parent mount. If the mount has a parent (i.e., it is a non-root mount point) and the propagation type of the parent is **MS_SHARED**, then the propagation type of the new mount is also **MS_SHARED**. Otherwise, the propagation type of the new mount is **MS_PRIVATE**.

Notwithstanding the fact that the default propagation type for new mount is in many cases **MS_PRIVATE**, **MS_SHARED** is typically more useful. For this reason, *systemd*(1) automatically remounts all mounts as **MS_SHARED** on system startup. Thus, on most modern systems, the default propagation type is in practice **MS_SHARED**.

Since, when one uses *unshare*(1) to create a mount namespace, the goal is commonly to provide full isolation of the mounts in the new namespace, *unshare*(1) (since *util-linux* 2.27) in turn reverses the step performed by *systemd*(1), by making all mounts private in the new namespace. That is, *unshare*(1) performs the equivalent of the following in the new mount namespace:

```
mount --make-rprivate /
```

To prevent this, one can use the *−−propagation unchanged* option to *unshare*(1)

An application that creates a new mount namespace directly using *clone*(2) or *unshare*(2) may desire to prevent propagation of mount events to other mount namespaces (as is done by *unshare*(1)). This can be done by changing the propagation type of mounts in the new namespace to either **MS_SLAVE** or **MS_PRIVATE**, using a call such as the following:

```
mount(NULL, "/", MS_SLAVE | MS_REC, NULL);
```

For a discussion of propagation types when moving mounts (**MS_MOVE**) and creating bind mounts (**MS_BIND**), see *Documentation/filesystems/sharedsubtree.rst*.

Restrictions on mount namespaces

Note the following points with respect to mount namespaces:

[1] Each mount namespace has an owner user namespace. As explained above, when a new mount namespace is created, its mount list is initialized as a copy of the mount list of another mount namespace. If the new namespace and the namespace from which the mount list was copied are owned by different user namespaces, then the new mount namespace is considered *less privileged*.

[2] When creating a less privileged mount namespace, shared mounts are reduced to slave mounts. This ensures that mappings performed in less privileged mount namespaces will not propagate to more privileged mount namespaces.

[3] Mounts that come as a single unit from a more privileged mount namespace are locked together and may not be separated in a less privileged mount namespace. (The *unshare*(2) **CLONE_NEWNS** operation brings across all of the mounts from the original mount namespace as a single unit, and recursive mounts that propagate between mount namespaces propagate as a single unit.)

In this context, "may not be separated" means that the mounts are locked so that they may not be individually unmounted. Consider the following example:

```
$ sudo sh
# mount --bind /dev/null /etc/shadow
# cat /etc/shadow       # Produces no output
```

The above steps, performed in a more privileged mount namespace, have created a bind mount that obscures the contents of the shadow password file, */etc/shadow*. For security reasons, it should not be possible to *umount*(2) that mount in a less privileged mount namespace, since that would reveal the contents of */etc/shadow*.

Suppose we now create a new mount namespace owned by a new user namespace. The new mount namespace will inherit copies of all of the mounts from the previous mount namespace. However, those mounts will be locked because the new mount namespace is less privileged. Consequently, an attempt to *umount*(2) the mount fails as show in the following step:

```
# unshare --user --map-root-user --mount \
              strace -o /tmp/log \
              umount /mnt/dir
umount: /etc/shadow: not mounted.
# grep '^umount' /tmp/log
umount2("/etc/shadow", 0)     = -1 EINVAL (Invalid argument)
```

The error message from *mount*(8) is a little confusing, but the *strace*(1) output reveals that the underlying *umount2*(2) system call failed with the error **EINVAL**, which is the error that the kernel returns to indicate that the mount is locked.

Note, however, that it is possible to stack (and unstack) a mount on top of one of the inherited locked mounts in a less privileged mount namespace:

```
# echo 'aaaaa' > /tmp/a    # File to mount onto /etc/shadow
# unshare --user --map-root-user --mount \
    sh -c 'mount --bind /tmp/a /etc/shadow; cat /etc/shadow'
aaaaa
# umount /etc/shadow
```

The final *umount*(8) command above, which is performed in the initial mount namespace, makes the original */etc/shadow* file once more visible in that namespace.

[4] Following on from point [3], note that it is possible to *umount*(2) an entire subtree of mounts that propagated as a unit into a less privileged mount namespace, as illustrated in the following example.

First, we create new user and mount namespaces using *unshare*(1)In the new mount namespace, the propagation type of all mounts is set to private. We then create a shared bind mount at */mnt*, and a small hierarchy of mounts underneath that mount.

```
$ PS1='ns1# ' sudo unshare --user --map-root-user \
                    --mount --propagation private bash
ns1# echo $$        # We need the PID of this shell later
778501
ns1# mount --make-shared --bind /mnt /mnt
ns1# mkdir /mnt/x
ns1# mount --make-private -t tmpfs none /mnt/x
ns1# mkdir /mnt/x/y
ns1# mount --make-private -t tmpfs none /mnt/x/y
ns1# grep /mnt /proc/self/mountinfo | sed 's/ - .*//'
986 83 8:5 /mnt /mnt rw,relatime shared:344
989 986 0:56 / /mnt/x rw,relatime
990 989 0:57 / /mnt/x/y rw,relatime
```

Continuing in the same shell session, we then create a second shell in a new user namespace and a new (less privileged) mount namespace and check the state of the propagated mounts rooted at */mnt*.

```
ns1# PS1='ns2# ' unshare --user --map-root-user \
                    --mount --propagation unchanged bash
ns2# grep /mnt /proc/self/mountinfo | sed 's/ - .*//'
1239 1204 8:5 /mnt /mnt rw,relatime master:344
1240 1239 0:56 / /mnt/x rw,relatime
1241 1240 0:57 / /mnt/x/y rw,relatime
```

Of note in the above output is that the propagation type of the mount */mnt* has been reduced to slave, as explained in point [2]. This means that submount events will propagate from the master */mnt* in "ns1", but propagation will not occur in the opposite direction.

From a separate terminal window, we then use *nsenter*(1) to enter the mount and user namespaces corresponding to "ns1". In that terminal window, we then recursively bind mount */mnt/x* at the location */mnt/ppp*.

```
$ PS1='ns3# ' sudo nsenter -t 778501 --user --mount
ns3# mount --rbind --make-private /mnt/x /mnt/ppp
ns3# grep /mnt /proc/self/mountinfo | sed 's/ - .*//'
986 83 8:5 /mnt /mnt rw,relatime shared:344
989 986 0:56 / /mnt/x rw,relatime
990 989 0:57 / /mnt/x/y rw,relatime
1242 986 0:56 / /mnt/ppp rw,relatime
1243 1242 0:57 / /mnt/ppp/y rw,relatime shared:518
```

Because the propagation type of the parent mount, */mnt*, was shared, the recursive bind mount propagated a small subtree of mounts under the slave mount */mnt* into "ns2", as can be verified by executing the following command in that shell session:

```
ns2# grep /mnt /proc/self/mountinfo | sed 's/ - .*//'
1239 1204 8:5 /mnt /mnt rw,relatime master:344
1240 1239 0:56 / /mnt/x rw,relatime
1241 1240 0:57 / /mnt/x/y rw,relatime
1244 1239 0:56 / /mnt/ppp rw,relatime
1245 1244 0:57 / /mnt/ppp/y rw,relatime master:518
```

While it is not possible to *umount*(2) a part of the propagated subtree (*/mnt/ppp/y*) in "ns2", it is possible to *umount*(2) the entire subtree, as shown by the following commands:

```
ns2# umount /mnt/ppp/y
umount: /mnt/ppp/y: not mounted.
ns2# umount -l /mnt/ppp | sed 's/ - .*//'      # Succeeds...
ns2# grep /mnt /proc/self/mountinfo
1239 1204 8:5 /mnt /mnt rw,relatime master:344
1240 1239 0:56 / /mnt/x rw,relatime
1241 1240 0:57 / /mnt/x/y rw,relatime
```

[5] The *mount*(2) flags **MS_RDONLY**, **MS_NOSUID**, **MS_NOEXEC**, and the "atime" flags (**MS_NOATIME**, **MS_NODIRATIME**, **MS_RELATIME**) settings become locked when propagated from a more privileged to a less privileged mount namespace, and may not be changed in the less privileged mount namespace.

This point is illustrated in the following example where, in a more privileged mount namespace, we create a bind mount that is marked as read-only. For security reasons, it should not be possible to make the mount writable in a less privileged mount namespace, and indeed the kernel prevents this:

```
$ sudo mkdir /mnt/dir
$ sudo mount --bind -o ro /some/path /mnt/dir
$ sudo unshare --user --map-root-user --mount \
               mount -o remount,rw /mnt/dir
mount: /mnt/dir: permission denied.
```

[6] A file or directory that is a mount point in one namespace that is not a mount point in another namespace, may be renamed, unlinked, or removed (**rmdir**(2)) in the mount namespace in which it is not a mount point (subject to the usual permission checks). Consequently, the mount point is removed in the mount namespace where it was a mount point.

Previously (before Linux 3.18), attempting to unlink, rename, or remove a file or directory that was a mount point in another mount namespace would result in the error **EBUSY**. That behavior had technical problems of enforcement (e.g., for NFS) and permitted denial-of-service attacks against more privileged users (i.e., preventing individual files from being updated by bind mounting on top of them).

EXAMPLES

See *pivot_root*(2).

NAME

mq_overview − overview of POSIX message queues

DESCRIPTION

POSIX message queues allow processes to exchange data in the form of messages. This API is distinct from that provided by System V message queues (**msgget**(2), *msgsnd*(2), *msgrcv*(2), etc.), but provides similar functionality.

Message queues are created and opened using *mq_open*(3); this function returns a *message queue descriptor* (*mqd_t*), which is used to refer to the open message queue in later calls. Each message queue is identified by a name of the form */somename*; that is, a null-terminated string of up to **NAME_MAX** (i.e., 255) characters consisting of an initial slash, followed by one or more characters, none of which are slashes. Two processes can operate on the same queue by passing the same name to *mq_open*(3).

Messages are transferred to and from a queue using *mq_send*(3) and *mq_receive*(3). When a process has finished using the queue, it closes it using *mq_close*(3), and when the queue is no longer required, it can be deleted using *mq_unlink*(3). Queue attributes can be retrieved and (in some cases) modified using *mq_getattr*(3) and *mq_setattr*(3). A process can request asynchronous notification of the arrival of a message on a previously empty queue using *mq_notify*(3).

A message queue descriptor is a reference to an *open message queue description* (see *open*(2)). After a *fork*(2), a child inherits copies of its parent's message queue descriptors, and these descriptors refer to the same open message queue descriptions as the corresponding message queue descriptors in the parent. Corresponding message queue descriptors in the two processes share the flags (*mq_flags*) that are associated with the open message queue description.

Each message has an associated *priority*, and messages are always delivered to the receiving process highest priority first. Message priorities range from 0 (low) to *sysconf(_SC_MQ_PRIO_MAX) − 1* (high). On Linux, *sysconf(_SC_MQ_PRIO_MAX)* returns 32768, but POSIX.1 requires only that an implementation support at least priorities in the range 0 to 31; some implementations provide only this range.

The remainder of this section describes some specific details of the Linux implementation of POSIX message queues.

Library interfaces and system calls

In most cases the **mq_***() library interfaces listed above are implemented on top of underlying system calls of the same name. Deviations from this scheme are indicated in the following table:

Library interface	System call
mq_close(3)	close(2)
mq_getattr(3)	mq_getsetattr(2)
mq_notify(3)	mq_notify(2)
mq_open(3)	mq_open(2)
mq_receive(3)	mq_timedreceive(2)
mq_send(3)	mq_timedsend(2)
mq_setattr(3)	mq_getsetattr(2)
mq_timedreceive(3)	mq_timedreceive(2)
mq_timedsend(3)	mq_timedsend(2)
mq_unlink(3)	mq_unlink(2)

Versions

POSIX message queues have been supported since Linux 2.6.6. glibc support has been provided since glibc 2.3.4.

Kernel configuration

Support for POSIX message queues is configurable via the **CONFIG_POSIX_MQUEUE** kernel configuration option. This option is enabled by default.

Persistence

POSIX message queues have kernel persistence: if not removed by *mq_unlink*(3), a message queue will exist until the system is shut down.

Linking

Programs using the POSIX message queue API must be compiled with *cc −lrt* to link against the real-time library, *librt*.

/proc interfaces

The following interfaces can be used to limit the amount of kernel memory consumed by POSIX message queues and to set the default attributes for new message queues:

/proc/sys/fs/mqueue/msg_default (since Linux 3.5)

This file defines the value used for a new queue's *mq_maxmsg* setting when the queue is created with a call to *mq_open*(3) where *attr* is specified as NULL. The default value for this file is 10. The minimum and maximum are as for */proc/sys/fs/mqueue/msg_max*. A new queue's default *mq_maxmsg* value will be the smaller of *msg_default* and *msg_max*. Before Linux 2.6.28, the default *mq_maxmsg* was 10; from Linux 2.6.28 to Linux 3.4, the default was the value defined for the *msg_max* limit.

/proc/sys/fs/mqueue/msg_max

This file can be used to view and change the ceiling value for the maximum number of messages in a queue. This value acts as a ceiling on the *attr->mq_maxmsg* argument given to *mq_open*(3). The default value for *msg_max* is 10. The minimum value is 1 (10 before Linux 2.6.28). The upper limit is **HARD_MSGMAX**. The *msg_max* limit is ignored for privileged processes (**CAP_SYS_RESOURCE**), but the **HARD_MSGMAX** ceiling is nevertheless imposed.

The definition of **HARD_MSGMAX** has changed across kernel versions:

- Up to Linux 2.6.32: *131072 / sizeof(void *)*
- Linux 2.6.33 to Linux 3.4: *(32768 * sizeof(void *) / 4)*
- Since Linux 3.5: 65,536

/proc/sys/fs/mqueue/msgsize_default (since Linux 3.5)

This file defines the value used for a new queue's *mq_msgsize* setting when the queue is created with a call to *mq_open*(3) where *attr* is specified as NULL. The default value for this file is 8192 (bytes). The minimum and maximum are as for */proc/sys/fs/mqueue/msgsize_max*. If *msgsize_default* exceeds *msgsize_max*, a new queue's default *mq_msgsize* value is capped to the *msgsize_max* limit. Before Linux 2.6.28, the default *mq_msgsize* was 8192; from Linux 2.6.28 to Linux 3.4, the default was the value defined for the *msgsize_max* limit.

/proc/sys/fs/mqueue/msgsize_max

This file can be used to view and change the ceiling on the maximum message size. This value acts as a ceiling on the *attr->mq_msgsize* argument given to *mq_open*(3). The default value for *msgsize_max* is 8192 bytes. The minimum value is 128 (8192 before Linux 2.6.28). The upper limit for *msgsize_max* has varied across kernel versions:

- Before Linux 2.6.28, the upper limit is **INT_MAX**.
- From Linux 2.6.28 to Linux 3.4, the limit is 1,048,576.
- Since Linux 3.5, the limit is 16,777,216 (**HARD_MSGSIZEMAX**).

The *msgsize_max* limit is ignored for privileged process (**CAP_SYS_RESOURCE**), but, since Linux 3.5, the **HARD_MSGSIZEMAX** ceiling is enforced for privileged processes.

/proc/sys/fs/mqueue/queues_max

This file can be used to view and change the system-wide limit on the number of message queues that can be created. The default value for *queues_max* is 256. No ceiling is imposed on the *queues_max* limit; privileged processes (**CAP_SYS_RESOURCE**) can exceed the limit (but see BUGS).

Resource limit

The **RLIMIT_MSGQUEUE** resource limit, which places a limit on the amount of space that can be consumed by all of the message queues belonging to a process's real user ID, is described in *getrlimit*(2).

Mounting the message queue filesystem

On Linux, message queues are created in a virtual filesystem. (Other implementations may also provide such a feature, but the details are likely to differ.) This filesystem can be mounted (by the superuser) using the following commands:

```
# mkdir /dev/mqueue
```

```
# mount -t mqueue none /dev/mqueue
```

The sticky bit is automatically enabled on the mount directory.

After the filesystem has been mounted, the message queues on the system can be viewed and manipulated using the commands usually used for files (e.g., *ls*(1) and *rm*(1)).

The contents of each file in the directory consist of a single line containing information about the queue:

```
$ cat /dev/mqueue/mymq
QSIZE:129     NOTIFY:2    SIGNO:0    NOTIFY_PID:8260
```

These fields are as follows:

QSIZE Number of bytes of data in all messages in the queue (but see BUGS).

NOTIFY_PID
If this is nonzero, then the process with this PID has used *mq_notify*(3) to register for asynchronous message notification, and the remaining fields describe how notification occurs.

NOTIFY
Notification method: 0 is **SIGEV_SIGNAL**; 1 is **SIGEV_NONE**; and 2 is **SIGEV_THREAD**.

SIGNO
Signal number to be used for **SIGEV_SIGNAL**.

Linux implementation of message queue descriptors

On Linux, a message queue descriptor is actually a file descriptor. (POSIX does not require such an implementation.) This means that a message queue descriptor can be monitored using *select*(2), *poll*(2), or *epoll*(7). This is not portable.

The close-on-exec flag (see *open*(2)) is automatically set on the file descriptor returned by *mq_open*(2).

IPC namespaces

For a discussion of the interaction of POSIX message queue objects and IPC namespaces, see *ipc_namespaces*(7).

NOTES

System V message queues (**msgget**(2), *msgsnd*(2), *msgrcv*(2), etc.) are an older API for exchanging messages between processes. POSIX message queues provide a better designed interface than System V message queues; on the other hand POSIX message queues are less widely available (especially on older systems) than System V message queues.

Linux does not currently (Linux 2.6.26) support the use of access control lists (ACLs) for POSIX message queues.

BUGS

Since Linux 3.5 to Linux 3.14, the kernel imposed a ceiling of 1024 (**HARD_QUEUESMAX**) on the value to which the *queues_max* limit could be raised, and the ceiling was enforced even for privileged processes. This ceiling value was removed in Linux 3.14, and patches to stable Linux 3.5.x to Linux 3.13.x also removed the ceiling.

As originally implemented (and documented), the QSIZE field displayed the total number of (user-supplied) bytes in all messages in the message queue. Some changes in Linux 3.5 inadvertently changed the behavior, so that this field also included a count of kernel overhead bytes used to store the messages in the queue. This behavioral regression was rectified in Linux 4.2 (and earlier stable kernel series), so that the count once more included just the bytes of user data in messages in the queue.

EXAMPLES

An example of the use of various message queue functions is shown in *mq_notify*(3).

NAME

namespaces − overview of Linux namespaces

DESCRIPTION

A namespace wraps a global system resource in an abstraction that makes it appear to the processes within the namespace that they have their own isolated instance of the global resource. Changes to the global resource are visible to other processes that are members of the namespace, but are invisible to other processes. One use of namespaces is to implement containers.

This page provides pointers to information on the various namespace types, describes the associated */proc* files, and summarizes the APIs for working with namespaces.

Namespace types

The following table shows the namespace types available on Linux. The second column of the table shows the flag value that is used to specify the namespace type in various APIs. The third column identifies the manual page that provides details on the namespace type. The last column is a summary of the resources that are isolated by the namespace type.

Namespace	Flag	Page	Isolates
Cgroup	**CLONE_NEWCGROUP**	*cgroup_namespaces*(7)	Cgroup root directory
IPC	**CLONE_NEWIPC**	*ipc_namespaces*(7)	System V IPC, POSIX message queues
Network	**CLONE_NEWNET**	*network_namespaces*(7)	Network devices, stacks, ports, etc.
Mount	**CLONE_NEWNS**	*mount_namespaces*(7)	Mount points
PID	**CLONE_NEWPID**	*pid_namespaces*(7)	Process IDs
Time	**CLONE_NEWTIME**	*time_namespaces*(7)	Boot and monotonic clocks
User	**CLONE_NEWUSER**	*user_namespaces*(7)	User and group IDs
UTS	**CLONE_NEWUTS**	*uts_namespaces*(7)	Hostname and NIS domain name

The namespaces API

As well as various */proc* files described below, the namespaces API includes the following system calls:

clone(2)
: The *clone*(2) system call creates a new process. If the *flags* argument of the call specifies one or more of the **CLONE_NEW*** flags listed above, then new namespaces are created for each flag, and the child process is made a member of those namespaces. (This system call also implements a number of features unrelated to namespaces.)

setns(2)
: The *setns*(2) system call allows the calling process to join an existing namespace. The namespace to join is specified via a file descriptor that refers to one of the */proc/*pid*/ns* files described below.

unshare(2)
: The *unshare*(2) system call moves the calling process to a new namespace. If the *flags* argument of the call specifies one or more of the **CLONE_NEW*** flags listed above, then new namespaces are created for each flag, and the calling process is made a member of those namespaces. (This system call also implements a number of features unrelated to namespaces.)

ioctl(2) Various *ioctl*(2) operations can be used to discover information about namespaces. These operations are described in *ioctl_ns*(2).

Creation of new namespaces using *clone*(2) and *unshare*(2) in most cases requires the **CAP_SYS_ADMIN** capability, since, in the new namespace, the creator will have the power to change global resources that are visible to other processes that are subsequently created in, or join the namespace. User namespaces are the exception: since Linux 3.8, no privilege is required to create a user namespace.

The */proc/*pid*/ns/* directory

Each process has a */proc/*pid*/ns/* subdirectory containing one entry for each namespace that supports being manipulated by *setns*(2):

```
$ ls -l /proc/$$/ns | awk '{print $1, $9, $10, $11}'
total 0
lrwxrwxrwx. cgroup -> cgroup:[4026531835]
lrwxrwxrwx. ipc -> ipc:[4026531839]
lrwxrwxrwx. mnt -> mnt:[4026531840]
lrwxrwxrwx. net -> net:[4026531969]
lrwxrwxrwx. pid -> pid:[4026531836]
lrwxrwxrwx. pid_for_children -> pid:[4026531834]
lrwxrwxrwx. time -> time:[4026531834]
lrwxrwxrwx. time_for_children -> time:[4026531834]
lrwxrwxrwx. user -> user:[4026531837]
lrwxrwxrwx. uts -> uts:[4026531838]
```

Bind mounting (see *mount*(2)) one of the files in this directory to somewhere else in the filesystem keeps the corresponding namespace of the process specified by *pid* alive even if all processes currently in the namespace terminate.

Opening one of the files in this directory (or a file that is bind mounted to one of these files) returns a file handle for the corresponding namespace of the process specified by *pid*. As long as this file descriptor remains open, the namespace will remain alive, even if all processes in the namespace terminate. The file descriptor can be passed to *setns*(2).

In Linux 3.7 and earlier, these files were visible as hard links. Since Linux 3.8, they appear as symbolic links. If two processes are in the same namespace, then the device IDs and inode numbers of their */proc/*pid*/ns/*xxx symbolic links will be the same; an application can check this using the *stat.st_dev* and *stat.st_ino* fields returned by *stat*(2). The content of this symbolic link is a string containing the namespace type and inode number as in the following example:

```
$ readlink /proc/$$/ns/uts
uts:[4026531838]
```

The symbolic links in this subdirectory are as follows:

*/proc/*pid*/ns/cgroup* (since Linux 4.6)
: This file is a handle for the cgroup namespace of the process.

*/proc/*pid*/ns/ipc* (since Linux 3.0)
: This file is a handle for the IPC namespace of the process.

*/proc/*pid*/ns/mnt* (since Linux 3.8)
: This file is a handle for the mount namespace of the process.

*/proc/*pid*/ns/net* (since Linux 3.0)
: This file is a handle for the network namespace of the process.

*/proc/*pid*/ns/pid* (since Linux 3.8)
: This file is a handle for the PID namespace of the process. This handle is permanent for the lifetime of the process (i.e., a process's PID namespace membership never changes).

*/proc/*pid*/ns/pid_for_children* (since Linux 4.12)
: This file is a handle for the PID namespace of child processes created by this process. This can change as a consequence of calls to *unshare*(2) and *setns*(2) (see *pid_namespaces*(7)), so the file may differ from */proc/*pid*/ns/pid*. The symbolic link gains a value only after the first child process is created in the namespace. (Beforehand, *readlink*(2) of the symbolic link will return an empty buffer.)

*/proc/*pid*/ns/time* (since Linux 5.6)
: This file is a handle for the time namespace of the process.

*/proc/*pid*/ns/time_for_children* (since Linux 5.6)
: This file is a handle for the time namespace of child processes created by this process. This can change as a consequence of calls to *unshare*(2) and *setns*(2) (see *time_namespaces*(7)), so the file may differ from */proc/*pid*/ns/time*.

*/proc/*pid*/ns/user* (since Linux 3.8)
This file is a handle for the user namespace of the process.

*/proc/*pid*/ns/uts* (since Linux 3.0)
This file is a handle for the UTS namespace of the process.

Permission to dereference or read (**readlink**(2)) these symbolic links is governed by a ptrace access mode **PTRACE_MODE_READ_FSCREDS** check; see *ptrace*(2).

The */proc/sys/user* directory

The files in the */proc/sys/user* directory (which is present since Linux 4.9) expose limits on the number of namespaces of various types that can be created. The files are as follows:

max_cgroup_namespaces
The value in this file defines a per-user limit on the number of cgroup namespaces that may be created in the user namespace.

max_ipc_namespaces
The value in this file defines a per-user limit on the number of ipc namespaces that may be created in the user namespace.

max_mnt_namespaces
The value in this file defines a per-user limit on the number of mount namespaces that may be created in the user namespace.

max_net_namespaces
The value in this file defines a per-user limit on the number of network namespaces that may be created in the user namespace.

max_pid_namespaces
The value in this file defines a per-user limit on the number of PID namespaces that may be created in the user namespace.

max_time_namespaces (since Linux 5.7)
The value in this file defines a per-user limit on the number of time namespaces that may be created in the user namespace.

max_user_namespaces
The value in this file defines a per-user limit on the number of user namespaces that may be created in the user namespace.

max_uts_namespaces
The value in this file defines a per-user limit on the number of uts namespaces that may be created in the user namespace.

Note the following details about these files:

- The values in these files are modifiable by privileged processes.
- The values exposed by these files are the limits for the user namespace in which the opening process resides.
- The limits are per-user. Each user in the same user namespace can create namespaces up to the defined limit.
- The limits apply to all users, including UID 0.
- These limits apply in addition to any other per-namespace limits (such as those for PID and user namespaces) that may be enforced.
- Upon encountering these limits, *clone*(2) and *unshare*(2) fail with the error **ENOSPC**.
- For the initial user namespace, the default value in each of these files is half the limit on the number of threads that may be created (*/proc/sys/kernel/threads-max*). In all descendant user namespaces, the default value in each file is **MAXINT**.
- When a namespace is created, the object is also accounted against ancestor namespaces. More precisely:

- Each user namespace has a creator UID.
- When a namespace is created, it is accounted against the creator UIDs in each of the ancestor user namespaces, and the kernel ensures that the corresponding namespace limit for the creator UID in the ancestor namespace is not exceeded.
- The aforementioned point ensures that creating a new user namespace cannot be used as a means to escape the limits in force in the current user namespace.

Namespace lifetime

Absent any other factors, a namespace is automatically torn down when the last process in the namespace terminates or leaves the namespace. However, there are a number of other factors that may pin a namespace into existence even though it has no member processes. These factors include the following:

- An open file descriptor or a bind mount exists for the corresponding */proc/*pid*/ns/** file.
- The namespace is hierarchical (i.e., a PID or user namespace), and has a child namespace.
- It is a user namespace that owns one or more nonuser namespaces.
- It is a PID namespace, and there is a process that refers to the namespace via a */proc/*pid*/ns/pid_for_children* symbolic link.
- It is a time namespace, and there is a process that refers to the namespace via a */proc/*pid*/ns/time_for_children* symbolic link.
- It is an IPC namespace, and a corresponding mount of an *mqueue* filesystem (see *mq_overview*(7)) refers to this namespace.
- It is a PID namespace, and a corresponding mount of a *proc*(5) filesystem refers to this namespace.

EXAMPLES

See *clone*(2) and *user_namespaces*(7).

NAME

netdevice − low-level access to Linux network devices

SYNOPSIS

#include <sys/ioctl.h>
#include <net/if.h>

DESCRIPTION

This man page describes the sockets interface which is used to configure network devices.

Linux supports some standard ioctls to configure network devices. They can be used on any socket's file descriptor regardless of the family or type. Most of them pass an *ifreq* structure:

```
struct ifreq {
    char ifr_name[IFNAMSIZ]; /* Interface name */
    union {
        struct sockaddr ifr_addr;
        struct sockaddr ifr_dstaddr;
        struct sockaddr ifr_broadaddr;
        struct sockaddr ifr_netmask;
        struct sockaddr ifr_hwaddr;
        short           ifr_flags;
        int             ifr_ifindex;
        int             ifr_metric;
        int             ifr_mtu;
        struct ifmap    ifr_map;
        char            ifr_slave[IFNAMSIZ];
        char            ifr_newname[IFNAMSIZ];
        char           *ifr_data;
    };
};
```

AF_INET6 is an exception. It passes an *in6_ifreq* structure:

```
struct in6_ifreq {
    struct in6_addr     ifr6_addr;
    u32                 ifr6_prefixlen;
    int                 ifr6_ifindex; /* Interface index */
};
```

Normally, the user specifies which device to affect by setting *ifr_name* to the name of the interface or *ifr6_ifindex* to the index of the interface. All other members of the structure may share memory.

Ioctls

If an ioctl is marked as privileged, then using it requires an effective user ID of 0 or the **CAP_NET_ADMIN** capability. If this is not the case, **EPERM** will be returned.

SIOCGIFNAME
Given the *ifr_ifindex*, return the name of the interface in *ifr_name*. This is the only ioctl which returns its result in *ifr_name*.

SIOCGIFINDEX
Retrieve the interface index of the interface into *ifr_ifindex*.

SIOCGIFFLAGS
SIOCSIFFLAGS
Get or set the active flag word of the device. *ifr_flags* contains a bit mask of the following values:

Device flags	
IFF_UP	Interface is running.
IFF_BROADCAST	Valid broadcast address set.
IFF_DEBUG	Internal debugging flag.
IFF_LOOPBACK	Interface is a loopback interface.
IFF_POINTOPOINT	Interface is a point-to-point link.

IFF_RUNNING	Resources allocated.
IFF_NOARP	No arp protocol, L2 destination address not set.
IFF_PROMISC	Interface is in promiscuous mode.
IFF_NOTRAILERS	Avoid use of trailers.
IFF_ALLMULTI	Receive all multicast packets.
IFF_MASTER	Master of a load balancing bundle.
IFF_SLAVE	Slave of a load balancing bundle.
IFF_MULTICAST	Supports multicast
IFF_PORTSEL	Is able to select media type via ifmap.
IFF_AUTOMEDIA	Auto media selection active.
IFF_DYNAMIC	The addresses are lost when the interface goes down.
IFF_LOWER_UP	Driver signals L1 up (since Linux 2.6.17)
IFF_DORMANT	Driver signals dormant (since Linux 2.6.17)
IFF_ECHO	Echo sent packets (since Linux 2.6.25)

Setting the active flag word is a privileged operation, but any process may read it.

SIOCGIFPFLAGS
SIOCSIFPFLAGS

Get or set extended (private) flags for the device. *ifr_flags* contains a bit mask of the following values:

	Private flags
IFF_802_1Q_VLAN	Interface is 802.1Q VLAN device.
IFF_EBRIDGE	Interface is Ethernet bridging device.
IFF_SLAVE_INACTIVE	Interface is inactive bonding slave.
IFF_MASTER_8023AD	Interface is 802.3ad bonding master.
IFF_MASTER_ALB	Interface is balanced-alb bonding master.
IFF_BONDING	Interface is a bonding master or slave.
IFF_SLAVE_NEEDARP	Interface needs ARPs for validation.
IFF_ISATAP	Interface is RFC4214 ISATAP interface.

Setting the extended (private) interface flags is a privileged operation.

SIOCGIFADDR
SIOCSIFADDR
SIOCDIFADDR

Get, set, or delete the address of the device using *ifr_addr*, or *ifr6_addr* with *ifr6_prefixlen*. Setting or deleting the interface address is a privileged operation. For compatibility, **SIOCGIFADDR** returns only **AF_INET** addresses, **SIOCSIFADDR** accepts **AF_INET** and **AF_INET6** addresses, and **SIOCDIFADDR** deletes only **AF_INET6** addresses. A **AF_INET** address can be deleted by setting it to zero via **SIOCSIFADDR**.

SIOCGIFDSTADDR
SIOCSIFDSTADDR

Get or set the destination address of a point-to-point device using *ifr_dstaddr*. For compatibility, only **AF_INET** addresses are accepted or returned. Setting the destination address is a privileged operation.

SIOCGIFBRDADDR
SIOCSIFBRDADDR

Get or set the broadcast address for a device using *ifr_brdaddr*. For compatibility, only **AF_INET** addresses are accepted or returned. Setting the broadcast address is a privileged operation.

SIOCGIFNETMASK
SIOCSIFNETMASK

Get or set the network mask for a device using *ifr_netmask*. For compatibility, only **AF_INET** addresses are accepted or returned. Setting the network mask is a privileged operation.

SIOCGIFMETRIC
SIOCSIFMETRIC
Get or set the metric of the device using *ifr_metric*. This is currently not implemented; it sets *ifr_metric* to 0 if you attempt to read it and returns **EOPNOTSUPP** if you attempt to set it.

SIOCGIFMTU
SIOCSIFMTU
Get or set the MTU (Maximum Transfer Unit) of a device using *ifr_mtu*. Setting the MTU is a privileged operation. Setting the MTU to too small values may cause kernel crashes.

SIOCGIFHWADDR
SIOCSIFHWADDR
Get or set the hardware address of a device using *ifr_hwaddr*. The hardware address is specified in a struct *sockaddr*. *sa_family* contains the ARPHRD_* device type, *sa_data* the L2 hardware address starting from byte 0. Setting the hardware address is a privileged operation.

SIOCSIFHWBROADCAST
Set the hardware broadcast address of a device from *ifr_hwaddr*. This is a privileged operation.

SIOCGIFMAP
SIOCSIFMAP
Get or set the interface's hardware parameters using *ifr_map*. Setting the parameters is a privileged operation.

```
struct ifmap {
    unsigned long   mem_start;
    unsigned long   mem_end;
    unsigned short  base_addr;
    unsigned char   irq;
    unsigned char   dma;
    unsigned char   port;
};
```

The interpretation of the ifmap structure depends on the device driver and the architecture.

SIOCADDMULTI
SIOCDELMULTI
Add an address to or delete an address from the device's link layer multicast filters using *ifr_hwaddr*. These are privileged operations. See also *packet*(7) for an alternative.

SIOCGIFTXQLEN
SIOCSIFTXQLEN
Get or set the transmit queue length of a device using *ifr_qlen*. Setting the transmit queue length is a privileged operation.

SIOCSIFNAME
Changes the name of the interface specified in *ifr_name* to *ifr_newname*. This is a privileged operation. It is allowed only when the interface is not up.

SIOCGIFCONF
Return a list of interface (network layer) addresses. This currently means only addresses of the **AF_INET** (IPv4) family for compatibility. Unlike the others, this ioctl passes an *ifconf* structure:

```
struct ifconf {
    int                ifc_len; /* size of buffer */
    union {
        char          *ifc_buf; /* buffer address */
        struct ifreq *ifc_req; /* array of structures */
    };
};
```

If *ifc_req* is NULL, **SIOCGIFCONF** returns the necessary buffer size in bytes for receiving all available addresses in *ifc_len*. Otherwise, *ifc_req* contains a pointer to an array of *ifreq* structures to be filled with all currently active L3 interface addresses. *ifc_len* contains the size

of the array in bytes. Within each *ifreq* structure, *ifr_name* will receive the interface name, and *ifr_addr* the address. The actual number of bytes transferred is returned in *ifc_len*.

If the size specified by *ifc_len* is insufficient to store all the addresses, the kernel will skip the exceeding ones and return success. There is no reliable way of detecting this condition once it has occurred. It is therefore recommended to either determine the necessary buffer size beforehand by calling **SIOCGIFCONF** with *ifc_req* set to NULL, or to retry the call with a bigger buffer whenever *ifc_len* upon return differs by less than *sizeof(struct ifreq)* from its original value.

If an error occurs accessing the *ifconf* or *ifreq* structures, **EFAULT** will be returned.

Most protocols support their own ioctls to configure protocol-specific interface options. See the protocol man pages for a description. For configuring IP addresses, see *ip*(7).

In addition, some devices support private ioctls. These are not described here.

NOTES

SIOCGIFCONF and the other ioctls that accept or return only **AF_INET** socket addresses are IP-specific and perhaps should rather be documented in *ip*(7).

The names of interfaces with no addresses or that don't have the **IFF_RUNNING** flag set can be found via */proc/net/dev*.

AF_INET6 IPv6 addresses can be read from */proc/net/if_inet6* or via *rtnetlink*(7). Adding a new IPv6 address and deleting an existing IPv6 address can be done via **SIOCSIFADDR** and **SIOCDIFADDR** or via *rtnetlink*(7). Retrieving or changing destination IPv6 addresses of a point-to-point interface is possible only via *rtnetlink*(7).

BUGS

glibc 2.1 is missing the *ifr_newname* macro in <*net/if.h*>. Add the following to your program as a workaround:

```
#ifndef ifr_newname
#define ifr_newname     ifr_ifru.ifru_slave
#endif
```

NAME

netlink − communication between kernel and user space (AF_NETLINK)

SYNOPSIS

#include <asm/types.h>
#include <sys/socket.h>
#include <linux/netlink.h>

netlink_socket = socket(AF_NETLINK, *socket_type***,** *netlink_family***);**

DESCRIPTION

Netlink is used to transfer information between the kernel and user-space processes. It consists of a standard sockets-based interface for user space processes and an internal kernel API for kernel modules. The internal kernel interface is not documented in this manual page. There is also an obsolete netlink interface via netlink character devices; this interface is not documented here and is provided only for backward compatibility.

Netlink is a datagram-oriented service. Both **SOCK_RAW** and **SOCK_DGRAM** are valid values for *socket_type*. However, the netlink protocol does not distinguish between datagram and raw sockets.

netlink_family selects the kernel module or netlink group to communicate with. The currently assigned netlink families are:

NETLINK_ROUTE
Receives routing and link updates and may be used to modify the routing tables (both IPv4 and IPv6), IP addresses, link parameters, neighbor setups, queueing disciplines, traffic classes, and packet classifiers (see *rtnetlink*(7)).

NETLINK_W1 (Linux 2.6.13 to Linux 2.16.17)
Messages from 1-wire subsystem.

NETLINK_USERSOCK
Reserved for user-mode socket protocols.

NETLINK_FIREWALL (up to and including Linux 3.4)
Transport IPv4 packets from netfilter to user space. Used by *ip_queue* kernel module. After a long period of being declared obsolete (in favor of the more advanced *nfnetlink_queue* feature), **NETLINK_FIREWALL** was removed in Linux 3.5.

NETLINK_SOCK_DIAG (since Linux 3.3)
Query information about sockets of various protocol families from the kernel (see *sock_diag*(7)).

NETLINK_INET_DIAG (since Linux 2.6.14)
An obsolete synonym for **NETLINK_SOCK_DIAG**.

NETLINK_NFLOG (up to and including Linux 3.16)
Netfilter/iptables ULOG.

NETLINK_XFRM
IPsec.

NETLINK_SELINUX (since Linux 2.6.4)
SELinux event notifications.

NETLINK_ISCSI (since Linux 2.6.15)
Open-iSCSI.

NETLINK_AUDIT (since Linux 2.6.6)
Auditing.

NETLINK_FIB_LOOKUP (since Linux 2.6.13)
Access to FIB lookup from user space.

NETLINK_CONNECTOR (since Linux 2.6.14)
Kernel connector. See *Documentation/driver−api/connector.rst* (or */Documentation/connector/connector.** in Linux 5.2 and earlier) in the Linux kernel source tree for further information.

NETLINK_NETFILTER (since Linux 2.6.14)
Netfilter subsystem.

NETLINK_SCSITRANSPORT (since Linux 2.6.19)
SCSI Transports.

NETLINK_RDMA (since Linux 3.0)
Infiniband RDMA.

NETLINK_IP6_FW (up to and including Linux 3.4)
Transport IPv6 packets from netfilter to user space. Used by *ip6_queue* kernel module.

NETLINK_DNRTMSG
DECnet routing messages.

NETLINK_KOBJECT_UEVENT (since Linux 2.6.10)
Kernel messages to user space.

NETLINK_GENERIC (since Linux 2.6.15)
Generic netlink family for simplified netlink usage.

NETLINK_CRYPTO (since Linux 3.2)
Netlink interface to request information about ciphers registered with the kernel crypto API as well as allow configuration of the kernel crypto API.

Netlink messages consist of a byte stream with one or multiple *nlmsghdr* headers and associated payload. The byte stream should be accessed only with the standard **NLMSG_*** macros. See *netlink*(3) for further information.

In multipart messages (multiple *nlmsghdr* headers with associated payload in one byte stream) the first and all following headers have the **NLM_F_MULTI** flag set, except for the last header which has the type **NLMSG_DONE**.

After each *nlmsghdr* the payload follows.

```
struct nlmsghdr {
    __u32 nlmsg_len;    /* Length of message including header */
    __u16 nlmsg_type;   /* Type of message content */
    __u16 nlmsg_flags;  /* Additional flags */
    __u32 nlmsg_seq;    /* Sequence number */
    __u32 nlmsg_pid;    /* Sender port ID */
};
```

nlmsg_type can be one of the standard message types: **NLMSG_NOOP** message is to be ignored, **NLMSG_ERROR** message signals an error and the payload contains an *nlmsgerr* structure, **NLMSG_DONE** message terminates a multipart message. Error messages get the original request appended, unless the user requests to cap the error message, and get extra error data if requested.

```
struct nlmsgerr {
    int error;        /* Negative errno or 0 for acknowledgements */
    struct nlmsghdr msg;  /* Message header that caused the error */
    /*
     * followed by the message contents
     * unless NETLINK_CAP_ACK was set
     * or the ACK indicates success (error == 0).
     * For example Generic Netlink message with attributes.
     * message length is aligned with NLMSG_ALIGN()
     */
    /*
     * followed by TLVs defined in enum nlmsgerr_attrs
     * if NETLINK_EXT_ACK was set
     */
};
```

A netlink family usually specifies more message types, see the appropriate manual pages for that, for example, *rtnetlink*(7) for **NETLINK_ROUTE**.

Standard flag bits in *nlmsg_flags*	
NLM_F_REQUEST	Must be set on all request messages.
NLM_F_MULTI	The message is part of a multipart message terminated by **NLMSG_DONE**.
NLM_F_ACK	Request for an acknowledgement on success.
NLM_F_ECHO	Echo this request.

Additional flag bits for GET requests	
NLM_F_ROOT	Return the complete table instead of a single entry.
NLM_F_MATCH	Return all entries matching criteria passed in message content. Not implemented yet.
NLM_F_ATOMIC	Return an atomic snapshot of the table.
NLM_F_DUMP	Convenience macro; equivalent to (NLM_F_ROOT|NLM_F_MATCH).

Note that **NLM_F_ATOMIC** requires the **CAP_NET_ADMIN** capability or an effective UID of 0.

Additional flag bits for NEW requests	
NLM_F_REPLACE	Replace existing matching object.
NLM_F_EXCL	Don't replace if the object already exists.
NLM_F_CREATE	Create object if it doesn't already exist.
NLM_F_APPEND	Add to the end of the object list.

nlmsg_seq and *nlmsg_pid* are used to track messages. *nlmsg_pid* shows the origin of the message. Note that there isn't a 1:1 relationship between *nlmsg_pid* and the PID of the process if the message originated from a netlink socket. See the **ADDRESS FORMATS** section for further information.

Both *nlmsg_seq* and *nlmsg_pid* are opaque to netlink core.

Netlink is not a reliable protocol. It tries its best to deliver a message to its destination(s), but may drop messages when an out-of-memory condition or other error occurs. For reliable transfer the sender can request an acknowledgement from the receiver by setting the **NLM_F_ACK** flag. An acknowledgement is an **NLMSG_ERROR** packet with the error field set to 0. The application must generate acknowledgements for received messages itself. The kernel tries to send an **NLMSG_ERROR** message for every failed packet. A user process should follow this convention too.

However, reliable transmissions from kernel to user are impossible in any case. The kernel can't send a netlink message if the socket buffer is full: the message will be dropped and the kernel and the user-space process will no longer have the same view of kernel state. It is up to the application to detect when this happens (via the **ENOBUFS** error returned by *recvmsg*(2)) and resynchronize.

Address formats

The *sockaddr_nl* structure describes a netlink client in user space or in the kernel. A *sockaddr_nl* can be either unicast (only sent to one peer) or sent to netlink multicast groups (*nl_groups* not equal 0).

```
struct sockaddr_nl {
    sa_family_t     nl_family;  /* AF_NETLINK */
    unsigned short  nl_pad;     /* Zero */
    pid_t           nl_pid;     /* Port ID */
    __u32           nl_groups;  /* Multicast groups mask */
};
```

nl_pid is the unicast address of netlink socket. It's always 0 if the destination is in the kernel. For a user-space process, *nl_pid* is usually the PID of the process owning the destination socket. However, *nl_pid* identifies a netlink socket, not a process. If a process owns several netlink sockets, then *nl_pid* can be equal to the process ID only for at most one socket. There are two ways to assign *nl_pid* to a netlink socket. If the application sets *nl_pid* before calling *bind*(2), then it is up to the application to make sure that *nl_pid* is unique. If the application sets it to 0, the kernel takes care of assigning it. The kernel assigns the process ID to the first netlink socket the process opens and assigns a unique *nl_pid* to every netlink socket that the process subsequently creates.

nl_groups is a bit mask with every bit representing a netlink group number. Each netlink family has a set of 32 multicast groups. When *bind*(2) is called on the socket, the *nl_groups* field in the *sockaddr_nl* should be set to a bit mask of the groups which it wishes to listen to. The default value for this field is zero which means that no multicasts will be received. A socket may multicast messages to any of the multicast groups by setting *nl_groups* to a bit mask of the groups it wishes to send to when it calls *sendmsg*(2) or does a *connect*(2). Only processes with an effective UID of 0 or the

CAP_NET_ADMIN capability may send or listen to a netlink multicast group. Since Linux 2.6.13, messages can't be broadcast to multiple groups. Any replies to a message received for a multicast group should be sent back to the sending PID and the multicast group. Some Linux kernel subsystems may additionally allow other users to send and/or receive messages. As at Linux 3.0, the **NETLINK_KOBJECT_UEVENT**, **NETLINK_GENERIC**, **NETLINK_ROUTE**, and **NETLINK_SELINUX** groups allow other users to receive messages. No groups allow other users to send messages.

Socket options

To set or get a netlink socket option, call *getsockopt*(2) to read or *setsockopt*(2) to write the option with the option level argument set to **SOL_NETLINK**. Unless otherwise noted, *optval* is a pointer to an *int*.

NETLINK_PKTINFO (since Linux 2.6.14)
: Enable **nl_pktinfo** control messages for received packets to get the extended destination group number.

NETLINK_ADD_MEMBERSHIP
NETLINK_DROP_MEMBERSHIP (since Linux 2.6.14)
: Join/leave a group specified by *optval*.

NETLINK_LIST_MEMBERSHIPS (since Linux 4.2)
: Retrieve all groups a socket is a member of. *optval* is a pointer to **__u32** and *optlen* is the size of the array. The array is filled with the full membership set of the socket, and the required array size is returned in *optlen*.

NETLINK_BROADCAST_ERROR (since Linux 2.6.30)
: When not set, **netlink_broadcast()** only reports **ESRCH** errors and silently ignore **ENOBUFS** errors.

NETLINK_NO_ENOBUFS (since Linux 2.6.30)
: This flag can be used by unicast and broadcast listeners to avoid receiving **ENOBUFS** errors.

NETLINK_LISTEN_ALL_NSID (since Linux 4.2)
: When set, this socket will receive netlink notifications from all network namespaces that have an *nsid* assigned into the network namespace where the socket has been opened. The *nsid* is sent to user space via an ancillary data.

NETLINK_CAP_ACK (since Linux 4.3)
: The kernel may fail to allocate the necessary room for the acknowledgement message back to user space. This option trims off the payload of the original netlink message. The netlink message header is still included, so the user can guess from the sequence number which message triggered the acknowledgement.

VERSIONS

The socket interface to netlink first appeared Linux 2.2.

Linux 2.0 supported a more primitive device-based netlink interface (which is still available as a compatibility option). This obsolete interface is not described here.

NOTES

It is often better to use netlink via *libnetlink* or *libnl* than via the low-level kernel interface.

BUGS

This manual page is not complete.

EXAMPLES

The following example creates a **NETLINK_ROUTE** netlink socket which will listen to the **RTMGRP_LINK** (network interface create/delete/up/down events) and **RTMGRP_IPV4_IFADDR** (IPv4 addresses add/delete events) multicast groups.

```
struct sockaddr_nl sa;

memset(&sa, 0, sizeof(sa));
sa.nl_family = AF_NETLINK;
sa.nl_groups = RTMGRP_LINK | RTMGRP_IPV4_IFADDR;
```

```
fd = socket(AF_NETLINK, SOCK_RAW, NETLINK_ROUTE);
bind(fd, (struct sockaddr *) &sa, sizeof(sa));
```

The next example demonstrates how to send a netlink message to the kernel (pid 0). Note that the application must take care of message sequence numbers in order to reliably track acknowledgements.

```
struct nlmsghdr *nh;    /* The nlmsghdr with payload to send */
struct sockaddr_nl sa;
struct iovec iov = { nh, nh->nlmsg_len };
struct msghdr msg;

msg = { &sa, sizeof(sa), &iov, 1, NULL, 0, 0 };
memset(&sa, 0, sizeof(sa));
sa.nl_family = AF_NETLINK;
nh->nlmsg_pid = 0;
nh->nlmsg_seq = ++sequence_number;
/* Request an ack from kernel by setting NLM_F_ACK */
nh->nlmsg_flags |= NLM_F_ACK;

sendmsg(fd, &msg, 0);
```

And the last example is about reading netlink message.

```
int len;
/* 8192 to avoid message truncation on platforms with
   page size > 4096 */
struct nlmsghdr buf[8192/sizeof(struct nlmsghdr)];
struct iovec iov = { buf, sizeof(buf) };
struct sockaddr_nl sa;
struct msghdr msg;
struct nlmsghdr *nh;

msg = { &sa, sizeof(sa), &iov, 1, NULL, 0, 0 };
len = recvmsg(fd, &msg, 0);

for (nh = (struct nlmsghdr *) buf; NLMSG_OK (nh, len);
     nh = NLMSG_NEXT (nh, len)) {
    /* The end of multipart message */
    if (nh->nlmsg_type == NLMSG_DONE)
        return;

    if (nh->nlmsg_type == NLMSG_ERROR)
        /* Do some error handling */
    ...

    /* Continue with parsing payload */
    ...
}
```

RFC 3549 "Linux Netlink as an IP Services Protocol"

NAME

network_namespaces − overview of Linux network namespaces

DESCRIPTION

Network namespaces provide isolation of the system resources associated with networking: network devices, IPv4 and IPv6 protocol stacks, IP routing tables, firewall rules, the */proc/net* directory (which is a symbolic link to */proc/*pid*/net*), the */sys/class/net* directory, various files under */proc/sys/net*, port numbers (sockets), and so on. In addition, network namespaces isolate the UNIX domain abstract socket namespace (see *unix*(7)).

A physical network device can live in exactly one network namespace. When a network namespace is freed (i.e., when the last process in the namespace terminates), its physical network devices are moved back to the initial network namespace (not to the namespace of the parent of the process).

A virtual network (**veth**(4)) device pair provides a pipe-like abstraction that can be used to create tunnels between network namespaces, and can be used to create a bridge to a physical network device in another namespace. When a namespace is freed, the *veth*(4) devices that it contains are destroyed.

Use of network namespaces requires a kernel that is configured with the **CONFIG_NET_NS** option.

NAME

nptl − Native POSIX Threads Library

DESCRIPTION

NPTL (Native POSIX Threads Library) is the GNU C library POSIX threads implementation that is used on modern Linux systems.

NPTL and signals

NPTL makes internal use of the first two real-time signals (signal numbers 32 and 33). One of these signals is used to support thread cancelation and POSIX timers (see *timer_create*(2)); the other is used as part of a mechanism that ensures all threads in a process always have the same UIDs and GIDs, as required by POSIX. These signals cannot be used in applications.

To prevent accidental use of these signals in applications, which might interfere with the operation of the NPTL implementation, various glibc library functions and system call wrapper functions attempt to hide these signals from applications, as follows:

- **SIGRTMIN** is defined with the value 34 (rather than 32).
- The *sigwaitinfo*(2), *sigtimedwait*(2), and *sigwait*(3) interfaces silently ignore requests to wait for these two signals if they are specified in the signal set argument of these calls.
- The *sigprocmask*(2) and *pthread_sigmask*(3) interfaces silently ignore attempts to block these two signals.
- The *sigaction*(2), *pthread_kill*(3), and *pthread_sigqueue*(3) interfaces fail with the error **EINVAL** (indicating an invalid signal number) if these signals are specified.
- *sigfillset*(3) does not include these two signals when it creates a full signal set.

NPTL and process credential changes

At the Linux kernel level, credentials (user and group IDs) are a per-thread attribute. However, POSIX requires that all of the POSIX threads in a process have the same credentials. To accommodate this requirement, the NPTL implementation wraps all of the system calls that change process credentials with functions that, in addition to invoking the underlying system call, arrange for all other threads in the process to also change their credentials.

The implementation of each of these system calls involves the use of a real-time signal that is sent (using *tgkill*(2)) to each of the other threads that must change its credentials. Before sending these signals, the thread that is changing credentials saves the new credential(s) and records the system call being employed in a global buffer. A signal handler in the receiving thread(s) fetches this information and then uses the same system call to change its credentials.

Wrapper functions employing this technique are provided for *setgid*(2), *setuid*(2), *setegid*(2), *seteuid*(2), *setregid*(2), *setreuid*(2), *setresgid*(2), *setresuid*(2), and *setgroups*(2).

STANDARDS

For details of the conformance of NPTL to the POSIX standard, see *pthreads*(7).

NOTES

POSIX says that any thread in any process with access to the memory containing a process-shared (**PTHREAD_PROCESS_SHARED**) mutex can operate on that mutex. However, on 64-bit x86 systems, the mutex definition for x86-64 is incompatible with the mutex definition for i386, meaning that 32-bit and 64-bit binaries can’t share mutexes on x86-64 systems.

credentials(7), *pthreads*(7), *signal*(7), *standards*(7)

NAME

numa − overview of Non-Uniform Memory Architecture

DESCRIPTION

Non-Uniform Memory Access (NUMA) refers to multiprocessor systems whose memory is divided into multiple memory nodes. The access time of a memory node depends on the relative locations of the accessing CPU and the accessed node. (This contrasts with a symmetric multiprocessor system, where the access time for all of the memory is the same for all CPUs.) Normally, each CPU on a NUMA system has a local memory node whose contents can be accessed faster than the memory in the node local to another CPU or the memory on a bus shared by all CPUs.

NUMA system calls

The Linux kernel implements the following NUMA-related system calls: *get_mempolicy*(2), *mbind*(2), *migrate_pages*(2), *move_pages*(2), and *set_mempolicy*(2). However, applications should normally use the interface provided by *libnuma*; see "Library Support" below.

*/proc/*pid*/numa_maps* (since Linux 2.6.14)

This file displays information about a process's NUMA memory policy and allocation.

Each line contains information about a memory range used by the process, displaying—among other information—the effective memory policy for that memory range and on which nodes the pages have been allocated.

numa_maps is a read-only file. When */proc/*pid*/numa_maps* is read, the kernel will scan the virtual address space of the process and report how memory is used. One line is displayed for each unique memory range of the process.

The first field of each line shows the starting address of the memory range. This field allows a correlation with the contents of the */proc/*pid*/maps* file, which contains the end address of the range and other information, such as the access permissions and sharing.

The second field shows the memory policy currently in effect for the memory range. Note that the effective policy is not necessarily the policy installed by the process for that memory range. Specifically, if the process installed a "default" policy for that range, the effective policy for that range will be the process policy, which may or may not be "default".

The rest of the line contains information about the pages allocated in the memory range, as follows:

N<*node*>=<*nr_pages*>
: The number of pages allocated on <*node*>. <*nr_pages*> includes only pages currently mapped by the process. Page migration and memory reclaim may have temporarily unmapped pages associated with this memory range. These pages may show up again only after the process has attempted to reference them. If the memory range represents a shared memory area or file mapping, other processes may currently have additional pages mapped in a corresponding memory range.

file=<*filename*>
: The file backing the memory range. If the file is mapped as private, write accesses may have generated COW (Copy-On-Write) pages in this memory range. These pages are displayed as anonymous pages.

heap
: Memory range is used for the heap.

stack
: Memory range is used for the stack.

huge
: Huge memory range. The page counts shown are huge pages and not regular sized pages.

anon=<*pages*>
: The number of anonymous page in the range.

dirty=<*pages*>
: Number of dirty pages.

mapped=<*pages*>
: Total number of mapped pages, if different from *dirty* and *anon* pages.

mapmax=<*count*>
: Maximum mapcount (number of processes mapping a single page) encountered during the scan. This may be used as an indicator of the degree of sharing occurring in a given memory

range.

swapcache=<count>
Number of pages that have an associated entry on a swap device.

active=<pages>
The number of pages on the active list. This field is shown only if different from the number of pages in this range. This means that some inactive pages exist in the memory range that may be removed from memory by the swapper soon.

writeback=<pages>
Number of pages that are currently being written out to disk.

STANDARDS

None.

NOTES

The Linux NUMA system calls and */proc* interface are available only if the kernel was configured and built with the **CONFIG_NUMA** option.

Library support

Link with *−lnuma* to get the system call definitions. *libnuma* and the required *<numaif.h>* header are available in the *numactl* package.

However, applications should not use these system calls directly. Instead, the higher level interface provided by the *numa*(3) functions in the *numactl* package is recommended. The *numactl* package is available at . The package is also included in some Linux distributions. Some distributions include the development library and header in the separate *numactl−devel* package.

SEE ALSO

get_mempolicy(2), *mbind*(2), *move_pages*(2), *set_mempolicy*(2), *numa*(3), *cpuset*(7), *numactl*(8)

NAME

operator − C operator precedence and order of evaluation

DESCRIPTION

This manual page lists C operators and their precedence in evaluation.

Operator	**Associativity**	**Notes**
[] () . −> ++ −−	left to right	[1]
++ −− & * + − ~ ! sizeof	right to left	[2]
(type)	right to left	
* / %	left to right	
+ −	left to right	
<< >>	left to right	
< > <= >=	left to right	
== !=	left to right	
&	left to right	
^	left to right	
|	left to right	
&&	left to right	
||	left to right	
?:	right to left	
= *= /= %= += −= <<= >>= &= ^= |=	right to left	
,	left to right	

The following notes provide further information to the above table:

[1] The ++ and −− operators at this precedence level are the postfix flavors of the operators.

[2] The ++ and −− operators at this precedence level are the prefix flavors of the operators.

NAME

packet − packet interface on device level

SYNOPSIS

#include <sys/socket.h>
#include <linux/if_packet.h>
#include <net/ethernet.h> /* the L2 protocols */

packet_socket = socket(AF_PACKET, int *socket_type***, int** *protocol***);**

DESCRIPTION

Packet sockets are used to receive or send raw packets at the device driver (OSI Layer 2) level. They allow the user to implement protocol modules in user space on top of the physical layer.

The *socket_type* is either **SOCK_RAW** for raw packets including the link-level header or **SOCK_DGRAM** for cooked packets with the link-level header removed. The link-level header information is available in a common format in a *sockaddr_ll* structure. *protocol* is the IEEE 802.3 protocol number in network byte order. See the <*linux/if_ether.h*> include file for a list of allowed protocols. When protocol is set to **htons(ETH_P_ALL)**, then all protocols are received. All incoming packets of that protocol type will be passed to the packet socket before they are passed to the protocols implemented in the kernel. If *protocol* is set to zero, no packets are received. *bind*(2) can optionally be called with a nonzero *sll_protocol* to start receiving packets for the protocols specified.

In order to create a packet socket, a process must have the **CAP_NET_RAW** capability in the user namespace that governs its network namespace.

SOCK_RAW packets are passed to and from the device driver without any changes in the packet data. When receiving a packet, the address is still parsed and passed in a standard *sockaddr_ll* address structure. When transmitting a packet, the user-supplied buffer should contain the physical-layer header. That packet is then queued unmodified to the network driver of the interface defined by the destination address. Some device drivers always add other headers. **SOCK_RAW** is similar to but not compatible with the obsolete **AF_INET/SOCK_PACKET** of Linux 2.0.

SOCK_DGRAM operates on a slightly higher level. The physical header is removed before the packet is passed to the user. Packets sent through a **SOCK_DGRAM** packet socket get a suitable physical-layer header based on the information in the *sockaddr_ll* destination address before they are queued.

By default, all packets of the specified protocol type are passed to a packet socket. To get packets only from a specific interface use *bind*(2) specifying an address in a *struct sockaddr_ll* to bind the packet socket to an interface. Fields used for binding are *sll_family* (should be **AF_PACKET**), *sll_protocol*, and *sll_ifindex*.

The *connect*(2) operation is not supported on packet sockets.

When the **MSG_TRUNC** flag is passed to *recvmsg*(2), *recv*(2), or *recvfrom*(2), the real length of the packet on the wire is always returned, even when it is longer than the buffer.

Address types

The *sockaddr_ll* structure is a device-independent physical-layer address.

```
struct sockaddr_ll {
    unsigned short sll_family;   /* Always AF_PACKET */
    unsigned short sll_protocol; /* Physical-layer protocol */
    int            sll_ifindex;  /* Interface number */
    unsigned short sll_hatype;   /* ARP hardware type */
    unsigned char  sll_pkttype;  /* Packet type */
    unsigned char  sll_halen;    /* Length of address */
    unsigned char  sll_addr[8];  /* Physical-layer address */
};
```

The fields of this structure are as follows:

sll_protocol
: is the standard ethernet protocol type in network byte order as defined in the <*linux/if_ether.h*> include file. It defaults to the socket's protocol.

sll_ifindex
: is the interface index of the interface (see *netdevice*(7)); 0 matches any interface (only permitted for binding). *sll_hatype* is an ARP type as defined in the <*linux/if_arp.h*> include file.

sll_pkttype
: contains the packet type. Valid types are **PACKET_HOST** for a packet addressed to the local host, **PACKET_BROADCAST** for a physical-layer broadcast packet, **PACKET_MULTICAST** for a packet sent to a physical-layer multicast address, **PACKET_OTHERHOST** for a packet to some other host that has been caught by a device driver in promiscuous mode, and **PACKET_OUTGOING** for a packet originating from the local host that is looped back to a packet socket. These types make sense only for receiving.

sll_addr
sll_halen
: contain the physical-layer (e.g., IEEE 802.3) address and its length. The exact interpretation depends on the device.

When you send packets, it is enough to specify *sll_family*, *sll_addr*, *sll_halen*, *sll_ifindex*, and *sll_protocol*. The other fields should be 0. *sll_hatype* and *sll_pkttype* are set on received packets for your information.

Socket options

Packet socket options are configured by calling *setsockopt*(2) with level **SOL_PACKET**.

PACKET_ADD_MEMBERSHIP
PACKET_DROP_MEMBERSHIP
: Packet sockets can be used to configure physical-layer multicasting and promiscuous mode. **PACKET_ADD_MEMBERSHIP** adds a binding and **PACKET_DROP_MEMBERSHIP** drops it. They both expect a *packet_mreq* structure as argument:

```
struct packet_mreq {
    int            mr_ifindex;    /* interface index */
    unsigned short mr_type;       /* action */
    unsigned short mr_alen;       /* address length */
    unsigned char  mr_address[8]; /* physical-layer address */
};
```

mr_ifindex contains the interface index for the interface whose status should be changed. The *mr_type* field specifies which action to perform. **PACKET_MR_PROMISC** enables receiving all packets on a shared medium (often known as "promiscuous mode"), **PACKET_MR_MULTICAST** binds the socket to the physical-layer multicast group specified in *mr_address* and *mr_alen*, and **PACKET_MR_ALLMULTI** sets the socket up to receive all multicast packets arriving at the interface.

In addition, the traditional ioctls **SIOCSIFFLAGS**, **SIOCADDMULTI**, **SIOCDELMULTI** can be used for the same purpose.

PACKET_AUXDATA (since Linux 2.6.21)
: If this binary option is enabled, the packet socket passes a metadata structure along with each packet in the *recvmsg*(2) control field. The structure can be read with *cmsg*(3). It is defined as

```
struct tpacket_auxdata {
    __u32 tp_status;
    __u32 tp_len;      /* packet length */
    __u32 tp_snaplen;  /* captured length */
    __u16 tp_mac;
    __u16 tp_net;
    __u16 tp_vlan_tci;
    __u16 tp_vlan_tpid; /* Since Linux 3.14; earlier, these
                           were unused padding bytes */
};
```

PACKET_FANOUT (since Linux 3.1)
: To scale processing across threads, packet sockets can form a fanout group. In this mode, each matching packet is enqueued onto only one socket in the group. A socket joins a fanout

group by calling *setsockopt*(2) with level **SOL_PACKET** and option **PACKET_FANOUT**. Each network namespace can have up to 65536 independent groups. A socket selects a group by encoding the ID in the first 16 bits of the integer option value. The first packet socket to join a group implicitly creates it. To successfully join an existing group, subsequent packet sockets must have the same protocol, device settings, fanout mode, and flags (see below). Packet sockets can leave a fanout group only by closing the socket. The group is deleted when the last socket is closed.

Fanout supports multiple algorithms to spread traffic between sockets, as follows:

- The default mode, **PACKET_FANOUT_HASH**, sends packets from the same flow to the same socket to maintain per-flow ordering. For each packet, it chooses a socket by taking the packet flow hash modulo the number of sockets in the group, where a flow hash is a hash over network-layer address and optional transport-layer port fields.
- The load-balance mode **PACKET_FANOUT_LB** implements a round-robin algorithm.
- **PACKET_FANOUT_CPU** selects the socket based on the CPU that the packet arrived on.
- **PACKET_FANOUT_ROLLOVER** processes all data on a single socket, moving to the next when one becomes backlogged.
- **PACKET_FANOUT_RND** selects the socket using a pseudo-random number generator.
- **PACKET_FANOUT_QM** (available since Linux 3.14) selects the socket using the recorded queue_mapping of the received skb.

Fanout modes can take additional options. IP fragmentation causes packets from the same flow to have different flow hashes. The flag **PACKET_FANOUT_FLAG_DEFRAG**, if set, causes packets to be defragmented before fanout is applied, to preserve order even in this case. Fanout mode and options are communicated in the second 16 bits of the integer option value. The flag **PACKET_FANOUT_FLAG_ROLLOVER** enables the roll over mechanism as a backup strategy: if the original fanout algorithm selects a backlogged socket, the packet rolls over to the next available one.

PACKET_LOSS (with **PACKET_TX_RING**)
When a malformed packet is encountered on a transmit ring, the default is to reset its *tp_status* to **TP_STATUS_WRONG_FORMAT** and abort the transmission immediately. The malformed packet blocks itself and subsequently enqueued packets from being sent. The format error must be fixed, the associated *tp_status* reset to **TP_STATUS_SEND_REQUEST**, and the transmission process restarted via *send*(2). However, if **PACKET_LOSS** is set, any malformed packet will be skipped, its *tp_status* reset to **TP_STATUS_AVAILABLE**, and the transmission process continued.

PACKET_RESERVE (with **PACKET_RX_RING**)
By default, a packet receive ring writes packets immediately following the metadata structure and alignment padding. This integer option reserves additional headroom.

PACKET_RX_RING
Create a memory-mapped ring buffer for asynchronous packet reception. The packet socket reserves a contiguous region of application address space, lays it out into an array of packet slots and copies packets (up to *tp_snaplen*) into subsequent slots. Each packet is preceded by a metadata structure similar to *tpacket_auxdata*. The protocol fields encode the offset to the data from the start of the metadata header. *tp_net* stores the offset to the network layer. If the packet socket is of type **SOCK_DGRAM**, then *tp_mac* is the same. If it is of type **SOCK_RAW**, then that field stores the offset to the link-layer frame. Packet socket and application communicate the head and tail of the ring through the *tp_status* field. The packet socket owns all slots with *tp_status* equal to **TP_STATUS_KERNEL**. After filling a slot, it changes the status of the slot to transfer ownership to the application. During normal operation, the new *tp_status* value has at least the **TP_STATUS_USER** bit set to signal that a received packet has been stored. When the application has finished processing a packet, it transfers ownership of the slot back to the socket by setting *tp_status* equal to **TP_STATUS_KERNEL**.

Packet sockets implement multiple variants of the packet ring. The implementation details are described in *Documentation/networking/packet_mmap.rst* in the Linux kernel source tree.

PACKET_STATISTICS
Retrieve packet socket statistics in the form of a structure

```
struct tpacket_stats {
    unsigned int tp_packets;  /* Total packet count */
    unsigned int tp_drops;    /* Dropped packet count */
};
```

Receiving statistics resets the internal counters. The statistics structure differs when using a ring of variant **TPACKET_V3**.

PACKET_TIMESTAMP (with **PACKET_RX_RING**; since Linux 2.6.36)
The packet receive ring always stores a timestamp in the metadata header. By default, this is a software generated timestamp generated when the packet is copied into the ring. This integer option selects the type of timestamp. Besides the default, it support the two hardware formats described in *Documentation/networking/timestamping.rst* in the Linux kernel source tree.

PACKET_TX_RING (since Linux 2.6.31)
Create a memory-mapped ring buffer for packet transmission. This option is similar to **PACKET_RX_RING** and takes the same arguments. The application writes packets into slots with *tp_status* equal to **TP_STATUS_AVAILABLE** and schedules them for transmission by changing *tp_status* to **TP_STATUS_SEND_REQUEST**. When packets are ready to be transmitted, the application calls *send*(2) or a variant thereof. The *buf* and *len* fields of this call are ignored. If an address is passed using *sendto*(2) or *sendmsg*(2), then that overrides the socket default. On successful transmission, the socket resets *tp_status* to **TP_STATUS_AVAILABLE**. It immediately aborts the transmission on error unless **PACKET_LOSS** is set.

PACKET_VERSION (with **PACKET_RX_RING**; since Linux 2.6.27)
By default, **PACKET_RX_RING** creates a packet receive ring of variant **TPACKET_V1**. To create another variant, configure the desired variant by setting this integer option before creating the ring.

PACKET_QDISC_BYPASS (since Linux 3.14)
By default, packets sent through packet sockets pass through the kernel's qdisc (traffic control) layer, which is fine for the vast majority of use cases. For traffic generator appliances using packet sockets that intend to brute-force flood the network—for example, to test devices under load in a similar fashion to pktgen—this layer can be bypassed by setting this integer option to 1. A side effect is that packet buffering in the qdisc layer is avoided, which will lead to increased drops when network device transmit queues are busy; therefore, use at your own risk.

Ioctls

SIOCGSTAMP can be used to receive the timestamp of the last received packet. Argument is a *struct timeval* variable.

In addition, all standard ioctls defined in *netdevice*(7) and *socket*(7) are valid on packet sockets.

Error handling

Packet sockets do no error handling other than errors occurred while passing the packet to the device driver. They don't have the concept of a pending error.

ERRORS

EADDRNOTAVAIL
Unknown multicast group address passed.

EFAULT
User passed invalid memory address.

EINVAL
Invalid argument.

EMSGSIZE
Packet is bigger than interface MTU.

ENETDOWN
Interface is not up.

ENOBUFS
Not enough memory to allocate the packet.

ENODEV
Unknown device name or interface index specified in interface address.

ENOENT
No packet received.

ENOTCONN
No interface address passed.

ENXIO
Interface address contained an invalid interface index.

EPERM
User has insufficient privileges to carry out this operation.

In addition, other errors may be generated by the low-level driver.

VERSIONS

AF_PACKET is a new feature in Linux 2.2. Earlier Linux versions supported only **SOCK_PACKET**.

NOTES

For portable programs it is suggested to use **AF_PACKET** via *pcap*(3); although this covers only a subset of the **AF_PACKET** features.

The **SOCK_DGRAM** packet sockets make no attempt to create or parse the IEEE 802.2 LLC header for a IEEE 802.3 frame. When **ETH_P_802_3** is specified as protocol for sending the kernel creates the 802.3 frame and fills out the length field; the user has to supply the LLC header to get a fully conforming packet. Incoming 802.3 packets are not multiplexed on the DSAP/SSAP protocol fields; instead they are supplied to the user as protocol **ETH_P_802_2** with the LLC header prefixed. It is thus not possible to bind to **ETH_P_802_3**; bind to **ETH_P_802_2** instead and do the protocol multiplex yourself. The default for sending is the standard Ethernet DIX encapsulation with the protocol filled in.

Packet sockets are not subject to the input or output firewall chains.

Compatibility

In Linux 2.0, the only way to get a packet socket was with the call:

```
socket(AF_INET, SOCK_PACKET, protocol)
```

This is still supported, but deprecated and strongly discouraged. The main difference between the two methods is that **SOCK_PACKET** uses the old *struct sockaddr_pkt* to specify an interface, which doesn't provide physical-layer independence.

```
struct sockaddr_pkt {
    unsigned short spkt_family;
    unsigned char  spkt_device[14];
    unsigned short spkt_protocol;
};
```

spkt_family contains the device type, *spkt_protocol* is the IEEE 802.3 protocol type as defined in <*sys/if_ether.h*> and *spkt_device* is the device name as a null-terminated string, for example, eth0.

This structure is obsolete and should not be used in new code.

BUGS

LLC header handling

The IEEE 802.2/803.3 LLC handling could be considered as a bug.

MSG_TRUNC issues

The **MSG_TRUNC** *recvmsg*(2) extension is an ugly hack and should be replaced by a control message. There is currently no way to get the original destination address of packets via **SOCK_DGRAM**.

spkt_device device name truncation

The *spkt_device* field of *sockaddr_pkt* has a size of 14 bytes, which is less than the constant **IFNAMSIZ** defined in <*net/if.h*> which is 16 bytes and describes the system limit for a network interface

name. This means the names of network devices longer than 14 bytes will be truncated to fit into *spkt_device*. All these lengths include the terminating null byte ('\0').

Issues from this with old code typically show up with very long interface names used by the **Predictable Network Interface Names** feature enabled by default in many modern Linux distributions.

The preferred solution is to rewrite code to avoid **SOCK_PACKET**. Possible user solutions are to disable **Predictable Network Interface Names** or to rename the interface to a name of at most 13 bytes, for example using the *ip*(8) tool.

Documentation issues

Socket filters are not documented.

NAME

path_resolution − how a pathname is resolved to a file

DESCRIPTION

Some UNIX/Linux system calls have as parameter one or more filenames. A filename (or pathname) is resolved as follows.

Step 1: start of the resolution process

If the pathname starts with the '/' character, the starting lookup directory is the root directory of the calling process. A process inherits its root directory from its parent. Usually this will be the root directory of the file hierarchy. A process may get a different root directory by use of the *chroot*(2) system call, or may temporarily use a different root directory by using *openat2*(2) with the **RESOLVE_IN_ROOT** flag set.

A process may get an entirely private mount namespace in case it—or one of its ancestors—was started by an invocation of the *clone*(2) system call that had the **CLONE_NEWNS** flag set. This handles the '/' part of the pathname.

If the pathname does not start with the '/' character, the starting lookup directory of the resolution process is the current working directory of the process — or in the case of *openat*(2)-style system calls, the *dfd* argument (or the current working directory if **AT_FDCWD** is passed as the *dfd* argument). The current working directory is inherited from the parent, and can be changed by use of the *chdir*(2) system call.

Pathnames starting with a '/' character are called absolute pathnames. Pathnames not starting with a '/' are called relative pathnames.

Step 2: walk along the path

Set the current lookup directory to the starting lookup directory. Now, for each nonfinal component of the pathname, where a component is a substring delimited by '/' characters, this component is looked up in the current lookup directory.

If the process does not have search permission on the current lookup directory, an **EACCES** error is returned ("Permission denied").

If the component is not found, an **ENOENT** error is returned ("No such file or directory").

If the component is found, but is neither a directory nor a symbolic link, an **ENOTDIR** error is returned ("Not a directory").

If the component is found and is a directory, we set the current lookup directory to that directory, and go to the next component.

If the component is found and is a symbolic link, we first resolve this symbolic link (with the current lookup directory as starting lookup directory). Upon error, that error is returned. If the result is not a directory, an **ENOTDIR** error is returned. If the resolution of the symbolic link is successful and returns a directory, we set the current lookup directory to that directory, and go to the next component. Note that the resolution process here can involve recursion if the prefix (’dirname’) component of a pathname contains a filename that is a symbolic link that resolves to a directory (where the prefix component of that directory may contain a symbolic link, and so on). In order to protect the kernel against stack overflow, and also to protect against denial of service, there are limits on the maximum recursion depth, and on the maximum number of symbolic links followed. An **ELOOP** error is returned when the maximum is exceeded ("Too many levels of symbolic links").

As currently implemented on Linux, the maximum number of symbolic links that will be followed while resolving a pathname is 40. Before Linux 2.6.18, the limit on the recursion depth was 5. Starting with Linux 2.6.18, this limit was raised to 8. In Linux 4.2, the kernel’s pathname-resolution code was reworked to eliminate the use of recursion, so that the only limit that remains is the maximum of 40 resolutions for the entire pathname.

The resolution of symbolic links during this stage can be blocked by using *openat2*(2), with the **RESOLVE_NO_SYMLINKS** flag set.

Step 3: find the final entry

The lookup of the final component of the pathname goes just like that of all other components, as described in the previous step, with two differences: (i) the final component need not be a directory (at least as far as the path resolution process is concerned—it may have to be a directory, or a nondirectory,

because of the requirements of the specific system call), and (ii) it is not necessarily an error if the component is not found—maybe we are just creating it. The details on the treatment of the final entry are described in the manual pages of the specific system calls.

. and ..

By convention, every directory has the entries "." and "..", which refer to the directory itself and to its parent directory, respectively.

The path resolution process will assume that these entries have their conventional meanings, regardless of whether they are actually present in the physical filesystem.

One cannot walk up past the root: "/.." is the same as "/".

Mount points

After a *mount dev path* command, the pathname "path" refers to the root of the filesystem hierarchy on the device "dev", and no longer to whatever it referred to earlier.

One can walk out of a mounted filesystem: "path/.." refers to the parent directory of "path", outside of the filesystem hierarchy on "dev".

Traversal of mount points can be blocked by using *openat2*(2), with the **RESOLVE_NO_XDEV** flag set (though note that this also restricts bind mount traversal).

Trailing slashes

If a pathname ends in a '/', that forces resolution of the preceding component as in Step 2: the component preceding the slash either exists and resolves to a directory or it names a directory that is to be created immediately after the pathname is resolved. Otherwise, a trailing '/' is ignored.

Final symbolic link

If the last component of a pathname is a symbolic link, then it depends on the system call whether the file referred to will be the symbolic link or the result of path resolution on its contents. For example, the system call *lstat*(2) will operate on the symbolic link, while *stat*(2) operates on the file pointed to by the symbolic link.

Length limit

There is a maximum length for pathnames. If the pathname (or some intermediate pathname obtained while resolving symbolic links) is too long, an **ENAMETOOLONG** error is returned ("Filename too long").

Empty pathname

In the original UNIX, the empty pathname referred to the current directory. Nowadays POSIX decrees that an empty pathname must not be resolved successfully. Linux returns **ENOENT** in this case.

Permissions

The permission bits of a file consist of three groups of three bits; see *chmod*(1) and *stat*(2). The first group of three is used when the effective user ID of the calling process equals the owner ID of the file. The second group of three is used when the group ID of the file either equals the effective group ID of the calling process, or is one of the supplementary group IDs of the calling process (as set by *setgroups*(2)). When neither holds, the third group is used.

Of the three bits used, the first bit determines read permission, the second write permission, and the last execute permission in case of ordinary files, or search permission in case of directories.

Linux uses the fsuid instead of the effective user ID in permission checks. Ordinarily the fsuid will equal the effective user ID, but the fsuid can be changed by the system call *setfsuid*(2).

(Here "fsuid" stands for something like "filesystem user ID". The concept was required for the implementation of a user space NFS server at a time when processes could send a signal to a process with the same effective user ID. It is obsolete now. Nobody should use *setfsuid*(2).)

Similarly, Linux uses the fsgid ("filesystem group ID") instead of the effective group ID. See *setfsgid*(2).

Bypassing permission checks: superuser and capabilities

On a traditional UNIX system, the superuser (*root*, user ID 0) is all-powerful, and bypasses all permissions restrictions when accessing files.

On Linux, superuser privileges are divided into capabilities (see *capabilities*(7)). Two capabilities are relevant for file permissions checks: **CAP_DAC_OVERRIDE** and **CAP_DAC_READ_SEARCH**. (A

process has these capabilities if its fsuid is 0.)

The **CAP_DAC_OVERRIDE** capability overrides all permission checking, but grants execute permission only when at least one of the file's three execute permission bits is set.

The **CAP_DAC_READ_SEARCH** capability grants read and search permission on directories, and read permission on ordinary files.

NAME

persistent-keyring − per-user persistent keyring

DESCRIPTION

The persistent keyring is a keyring used to anchor keys on behalf of a user. Each UID the kernel deals with has its own persistent keyring that is shared between all threads owned by that UID. The persistent keyring has a name (description) of the form *_persistent.<UID>* where *<UID>* is the user ID of the corresponding user.

The persistent keyring may not be accessed directly, even by processes with the appropriate UID. Instead, it must first be linked to one of a process's keyrings, before that keyring can access the persistent keyring by virtue of its possessor permits. This linking is done with the *keyctl_get_persistent*(3) function.

If a persistent keyring does not exist when it is accessed by the *keyctl_get_persistent*(3) operation, it will be automatically created.

Each time the *keyctl_get_persistent*(3) operation is performed, the persistent keyring's expiration timer is reset to the value in:

```
/proc/sys/kernel/keys/persistent_keyring_expiry
```

Should the timeout be reached, the persistent keyring will be removed and everything it pins can then be garbage collected. The keyring will then be re-created on a subsequent call to *keyctl_get_persistent*(3)

The persistent keyring is not directly searched by *request_key*(2); it is searched only if it is linked into one of the keyrings that is searched by *request_key*(2).

The persistent keyring is independent of *clone*(2), *fork*(2), *vfork*(2), *execve*(2), and *_exit*(2). It persists until its expiration timer triggers, at which point it is garbage collected. This allows the persistent keyring to carry keys beyond the life of the kernel's record of the corresponding UID (the destruction of which results in the destruction of the *user-keyring*(7) and the *user-session-keyring*(7)). The persistent keyring can thus be used to hold authentication tokens for processes that run without user interaction, such as programs started by *cron*(8)

The persistent keyring is used to store UID-specific objects that themselves have limited lifetimes (e.g., kerberos tokens). If those tokens cease to be used (i.e., the persistent keyring is not accessed), then the timeout of the persistent keyring ensures that the corresponding objects are automatically discarded.

Special operations

The *keyutils* library provides the *keyctl_get_persistent*(3) function for manipulating persistent keyrings. (This function is an interface to the *keyctl*(2) **KEYCTL_GET_PERSISTENT** operation.) This operation allows the calling thread to get the persistent keyring corresponding to its own UID or, if the thread has the **CAP_SETUID** capability, the persistent keyring corresponding to some other UID in the same user namespace.

NOTES

Each user namespace owns a keyring called *.persistent_register* that contains links to all of the persistent keys in that namespace. (The *.persistent_register* keyring can be seen when reading the contents of the */proc/keys* file for the UID 0 in the namespace.) The *keyctl_get_persistent*(3) operation looks for a key with a name of the form *_persistent.*UID in that keyring, creates the key if it does not exist, and links it into the keyring.

NAME

pid_namespaces − overview of Linux PID namespaces

DESCRIPTION

For an overview of namespaces, see *namespaces*(7).

PID namespaces isolate the process ID number space, meaning that processes in different PID namespaces can have the same PID. PID namespaces allow containers to provide functionality such as suspending/resuming the set of processes in the container and migrating the container to a new host while the processes inside the container maintain the same PIDs.

PIDs in a new PID namespace start at 1, somewhat like a standalone system, and calls to *fork*(2), *vfork*(2), or *clone*(2) will produce processes with PIDs that are unique within the namespace.

Use of PID namespaces requires a kernel that is configured with the **CONFIG_PID_NS** option.

The namespace init process

The first process created in a new namespace (i.e., the process created using *clone*(2) with the **CLONE_NEWPID** flag, or the first child created by a process after a call to *unshare*(2) using the **CLONE_NEWPID** flag) has the PID 1, and is the "init" process for the namespace (see *init*(1)). This process becomes the parent of any child processes that are orphaned because a process that resides in this PID namespace terminated (see below for further details).

If the "init" process of a PID namespace terminates, the kernel terminates all of the processes in the namespace via a **SIGKILL** signal. This behavior reflects the fact that the "init" process is essential for the correct operation of a PID namespace. In this case, a subsequent *fork*(2) into this PID namespace fail with the error **ENOMEM**; it is not possible to create a new process in a PID namespace whose "init" process has terminated. Such scenarios can occur when, for example, a process uses an open file descriptor for a */proc/*pid*/ns/pid* file corresponding to a process that was in a namespace to *setns*(2) into that namespace after the "init" process has terminated. Another possible scenario can occur after a call to *unshare*(2): if the first child subsequently created by a *fork*(2) terminates, then subsequent calls to *fork*(2) fail with **ENOMEM**.

Only signals for which the "init" process has established a signal handler can be sent to the "init" process by other members of the PID namespace. This restriction applies even to privileged processes, and prevents other members of the PID namespace from accidentally killing the "init" process.

Likewise, a process in an ancestor namespace can—subject to the usual permission checks described in *kill*(2)—send signals to the "init" process of a child PID namespace only if the "init" process has established a handler for that signal. (Within the handler, the *siginfo_t si_pid* field described in *sigaction*(2) will be zero.) **SIGKILL** or **SIGSTOP** are treated exceptionally: these signals are forcibly delivered when sent from an ancestor PID namespace. Neither of these signals can be caught by the "init" process, and so will result in the usual actions associated with those signals (respectively, terminating and stopping the process).

Starting with Linux 3.4, the *reboot*(2) system call causes a signal to be sent to the namespace "init" process. See *reboot*(2) for more details.

Nesting PID namespaces

PID namespaces can be nested: each PID namespace has a parent, except for the initial ("root") PID namespace. The parent of a PID namespace is the PID namespace of the process that created the namespace using *clone*(2) or *unshare*(2). PID namespaces thus form a tree, with all namespaces ultimately tracing their ancestry to the root namespace. Since Linux 3.7, the kernel limits the maximum nesting depth for PID namespaces to 32.

A process is visible to other processes in its PID namespace, and to the processes in each direct ancestor PID namespace going back to the root PID namespace. In this context, "visible" means that one process can be the target of operations by another process using system calls that specify a process ID. Conversely, the processes in a child PID namespace can’t see processes in the parent and further removed ancestor namespaces. More succinctly: a process can see (e.g., send signals with *kill*(2), set nice values with *setpriority*(2), etc.) only processes contained in its own PID namespace and in descendants of that namespace.

A process has one process ID in each of the layers of the PID namespace hierarchy in which is visible, and walking back though each direct ancestor namespace through to the root PID namespace. System calls that operate on process IDs always operate using the process ID that is visible in the PID

namespace of the caller. A call to *getpid*(2) always returns the PID associated with the namespace in which the process was created.

Some processes in a PID namespace may have parents that are outside of the namespace. For example, the parent of the initial process in the namespace (i.e., the *init*(1) process with PID 1) is necessarily in another namespace. Likewise, the direct children of a process that uses *setns*(2) to cause its children to join a PID namespace are in a different PID namespace from the caller of *setns*(2). Calls to *getppid*(2) for such processes return 0.

While processes may freely descend into child PID namespaces (e.g., using *setns*(2) with a PID namespace file descriptor), they may not move in the other direction. That is to say, processes may not enter any ancestor namespaces (parent, grandparent, etc.). Changing PID namespaces is a one-way operation.

The **NS_GET_PARENT** *ioctl*(2) operation can be used to discover the parental relationship between PID namespaces; see *ioctl_ns*(2).

setns(2) and unshare(2) semantics

Calls to *setns*(2) that specify a PID namespace file descriptor and calls to *unshare*(2) with the **CLONE_NEWPID** flag cause children subsequently created by the caller to be placed in a different PID namespace from the caller. (Since Linux 4.12, that PID namespace is shown via the */proc/*pid*/ns/pid_for_children* file, as described in *namespaces*(7).) These calls do not, however, change the PID namespace of the calling process, because doing so would change the caller's idea of its own PID (as reported by *getpid*()), which would break many applications and libraries.

To put things another way: a process's PID namespace membership is determined when the process is created and cannot be changed thereafter. Among other things, this means that the parental relationship between processes mirrors the parental relationship between PID namespaces: the parent of a process is either in the same namespace or resides in the immediate parent PID namespace.

A process may call *unshare*(2) with the **CLONE_NEWPID** flag only once. After it has performed this operation, its */proc/*pid*/ns/pid_for_children* symbolic link will be empty until the first child is created in the namespace.

Adoption of orphaned children

When a child process becomes orphaned, it is reparented to the "init" process in the PID namespace of its parent (unless one of the nearer ancestors of the parent employed the *prctl*(2) **PR_SET_CHILD_SUBREAPER** command to mark itself as the reaper of orphaned descendant processes). Note that because of the *setns*(2) and *unshare*(2) semantics described above, this may be the "init" process in the PID namespace that is the *parent* of the child's PID namespace, rather than the "init" process in the child's own PID namespace.

Compatibility of CLONE_NEWPID with other CLONE_* flags

In current versions of Linux, **CLONE_NEWPID** can't be combined with **CLONE_THREAD**. Threads are required to be in the same PID namespace such that the threads in a process can send signals to each other. Similarly, it must be possible to see all of the threads of a process in the *proc*(5) filesystem. Additionally, if two threads were in different PID namespaces, the process ID of the process sending a signal could not be meaningfully encoded when a signal is sent (see the description of the *siginfo_t* type in *sigaction*(2)). Since this is computed when a signal is enqueued, a signal queue shared by processes in multiple PID namespaces would defeat that.

In earlier versions of Linux, **CLONE_NEWPID** was additionally disallowed (failing with the error **EINVAL**) in combination with **CLONE_SIGHAND** (before Linux 4.3) as well as **CLONE_VM** (before Linux 3.12). The changes that lifted these restrictions have also been ported to earlier stable kernels.

/proc and PID namespaces

A */proc* filesystem shows (in the */proc/*pid directories) only processes visible in the PID namespace of the process that performed the mount, even if the */proc* filesystem is viewed from processes in other namespaces.

After creating a new PID namespace, it is useful for the child to change its root directory and mount a new procfs instance at */proc* so that tools such as *ps*(1) work correctly. If a new mount namespace is simultaneously created by including **CLONE_NEWNS** in the *flags* argument of *clone*(2) or *unshare*(2), then it isn't necessary to change the root directory: a new procfs instance can be mounted

directly over */proc*.

From a shell, the command to mount */proc* is:

```
$ mount -t proc proc /proc
```

Calling *readlink*(2) on the path */proc/self* yields the process ID of the caller in the PID namespace of the procfs mount (i.e., the PID namespace of the process that mounted the procfs). This can be useful for introspection purposes, when a process wants to discover its PID in other namespaces.

/proc files

/proc/sys/kernel/ns_last_pid (since Linux 3.3)

This file (which is virtualized per PID namespace) displays the last PID that was allocated in this PID namespace. When the next PID is allocated, the kernel will search for the lowest unallocated PID that is greater than this value, and when this file is subsequently read it will show that PID.

This file is writable by a process that has the **CAP_SYS_ADMIN** or (since Linux 5.9) **CAP_CHECKPOINT_RESTORE** capability inside the user namespace that owns the PID namespace. This makes it possible to determine the PID that is allocated to the next process that is created inside this PID namespace.

Miscellaneous

When a process ID is passed over a UNIX domain socket to a process in a different PID namespace (see the description of **SCM_CREDENTIALS** in *unix*(7)), it is translated into the corresponding PID value in the receiving process's PID namespace.

STANDARDS

Linux.

EXAMPLES

See *user_namespaces*(7).

NAME

pipe − overview of pipes and FIFOs

DESCRIPTION

Pipes and FIFOs (also known as named pipes) provide a unidirectional interprocess communication channel. A pipe has a *read end* and a *write end*. Data written to the write end of a pipe can be read from the read end of the pipe.

A pipe is created using *pipe*(2), which creates a new pipe and returns two file descriptors, one referring to the read end of the pipe, the other referring to the write end. Pipes can be used to create a communication channel between related processes; see *pipe*(2) for an example.

A FIFO (short for First In First Out) has a name within the filesystem (created using *mkfifo*(3)), and is opened using *open*(2). Any process may open a FIFO, assuming the file permissions allow it. The read end is opened using the **O_RDONLY** flag; the write end is opened using the **O_WRONLY** flag. See *fifo*(7) for further details. *Note*: although FIFOs have a pathname in the filesystem, I/O on FIFOs does not involve operations on the underlying device (if there is one).

I/O on pipes and FIFOs

The only difference between pipes and FIFOs is the manner in which they are created and opened. Once these tasks have been accomplished, I/O on pipes and FIFOs has exactly the same semantics.

If a process attempts to read from an empty pipe, then *read*(2) will block until data is available. If a process attempts to write to a full pipe (see below), then *write*(2) blocks until sufficient data has been read from the pipe to allow the write to complete.

Nonblocking I/O is possible by using the *fcntl*(2) **F_SETFL** operation to enable the **O_NONBLOCK** open file status flag or by opening a *fifo*(7) with **O_NONBLOCK**. If any process has the pipe open for writing, reads fail with **EAGAIN**; otherwise—with no potential writers—reads succeed and return empty.

The communication channel provided by a pipe is a *byte stream*: there is no concept of message boundaries.

If all file descriptors referring to the write end of a pipe have been closed, then an attempt to *read*(2) from the pipe will see end-of-file (**read**(2) will return 0). If all file descriptors referring to the read end of a pipe have been closed, then a *write*(2) will cause a **SIGPIPE** signal to be generated for the calling process. If the calling process is ignoring this signal, then *write*(2) fails with the error **EPIPE**. An application that uses *pipe*(2) and *fork*(2) should use suitable *close*(2) calls to close unnecessary duplicate file descriptors; this ensures that end-of-file and **SIGPIPE**/**EPIPE** are delivered when appropriate.

It is not possible to apply *lseek*(2) to a pipe.

Pipe capacity

A pipe has a limited capacity. If the pipe is full, then a *write*(2) will block or fail, depending on whether the **O_NONBLOCK** flag is set (see below). Different implementations have different limits for the pipe capacity. Applications should not rely on a particular capacity: an application should be designed so that a reading process consumes data as soon as it is available, so that a writing process does not remain blocked.

Before Linux 2.6.11, the capacity of a pipe was the same as the system page size (e.g., 4096 bytes on i386). Since Linux 2.6.11, the pipe capacity is 16 pages (i.e., 65,536 bytes in a system with a page size of 4096 bytes). Since Linux 2.6.35, the default pipe capacity is 16 pages, but the capacity can be queried and set using the *fcntl*(2) **F_GETPIPE_SZ** and **F_SETPIPE_SZ** operations. See *fcntl*(2) for more information.

The following *ioctl*(2) operation, which can be applied to a file descriptor that refers to either end of a pipe, places a count of the number of unread bytes in the pipe in the *int* buffer pointed to by the final argument of the call:

```
ioctl(fd, FIONREAD, &nbytes);
```

The **FIONREAD** operation is not specified in any standard, but is provided on many implementations.

/proc files

On Linux, the following files control how much memory can be used for pipes:

/proc/sys/fs/pipe-max-pages (only in Linux 2.6.34)
An upper limit, in pages, on the capacity that an unprivileged user (one without the **CAP_SYS_RESOURCE** capability) can set for a pipe.

The default value for this limit is 16 times the default pipe capacity (see above); the lower limit is two pages.

This interface was removed in Linux 2.6.35, in favor of */proc/sys/fs/pipe-max-size*.

/proc/sys/fs/pipe-max-size (since Linux 2.6.35)
The maximum size (in bytes) of individual pipes that can be set by users without the **CAP_SYS_RESOURCE** capability. The value assigned to this file may be rounded upward, to reflect the value actually employed for a convenient implementation. To determine the rounded-up value, display the contents of this file after assigning a value to it.

The default value for this file is 1048576 (1 MiB). The minimum value that can be assigned to this file is the system page size. Attempts to set a limit less than the page size cause *write*(2) to fail with the error **EINVAL**.

Since Linux 4.9, the value on this file also acts as a ceiling on the default capacity of a new pipe or newly opened FIFO.

/proc/sys/fs/pipe-user-pages-hard (since Linux 4.5)
The hard limit on the total size (in pages) of all pipes created or set by a single unprivileged user (i.e., one with neither the **CAP_SYS_RESOURCE** nor the **CAP_SYS_ADMIN** capability). So long as the total number of pages allocated to pipe buffers for this user is at this limit, attempts to create new pipes will be denied, and attempts to increase a pipe's capacity will be denied.

When the value of this limit is zero (which is the default), no hard limit is applied.

/proc/sys/fs/pipe-user-pages-soft (since Linux 4.5)
The soft limit on the total size (in pages) of all pipes created or set by a single unprivileged user (i.e., one with neither the **CAP_SYS_RESOURCE** nor the **CAP_SYS_ADMIN** capability). So long as the total number of pages allocated to pipe buffers for this user is at this limit, individual pipes created by a user will be limited to one page, and attempts to increase a pipe's capacity will be denied.

When the value of this limit is zero, no soft limit is applied. The default value for this file is 16384, which permits creating up to 1024 pipes with the default capacity.

Before Linux 4.9, some bugs affected the handling of the *pipe-user-pages-soft* and *pipe-user-pages-hard* limits; see BUGS.

PIPE_BUF
POSIX.1 says that writes of less than **PIPE_BUF** bytes must be atomic: the output data is written to the pipe as a contiguous sequence. Writes of more than **PIPE_BUF** bytes may be nonatomic: the kernel may interleave the data with data written by other processes. POSIX.1 requires **PIPE_BUF** to be at least 512 bytes. (On Linux, **PIPE_BUF** is 4096 bytes.) The precise semantics depend on whether the file descriptor is nonblocking (**O_NONBLOCK**), whether there are multiple writers to the pipe, and on *n*, the number of bytes to be written:

O_NONBLOCK disabled, *n* <= **PIPE_BUF**
All *n* bytes are written atomically; *write*(2) may block if there is not room for *n* bytes to be written immediately

O_NONBLOCK enabled, *n* <= **PIPE_BUF**
If there is room to write *n* bytes to the pipe, then *write*(2) succeeds immediately, writing all *n* bytes; otherwise *write*(2) fails, with *errno* set to **EAGAIN**.

O_NONBLOCK disabled, *n* > **PIPE_BUF**
The write is nonatomic: the data given to *write*(2) may be interleaved with *write*(2)s by other process; the *write*(2) blocks until *n* bytes have been written.

O_NONBLOCK enabled, *n* > **PIPE_BUF**
If the pipe is full, then *write*(2) fails, with *errno* set to **EAGAIN**. Otherwise, from 1 to *n* bytes may be written (i.e., a "partial write" may occur; the caller should check the return value from *write*(2) to see how many bytes were actually written), and these bytes may be

interleaved with writes by other processes.

Open file status flags

The only open file status flags that can be meaningfully applied to a pipe or FIFO are **O_NONBLOCK** and **O_ASYNC**.

Setting the **O_ASYNC** flag for the read end of a pipe causes a signal (**SIGIO** by default) to be generated when new input becomes available on the pipe. The target for delivery of signals must be set using the *fcntl*(2) **F_SETOWN** command. On Linux, **O_ASYNC** is supported for pipes and FIFOs only since Linux 2.6.

Portability notes

On some systems (but not Linux), pipes are bidirectional: data can be transmitted in both directions between the pipe ends. POSIX.1 requires only unidirectional pipes. Portable applications should avoid reliance on bidirectional pipe semantics.

BUGS

Before Linux 4.9, some bugs affected the handling of the *pipe-user-pages-soft* and *pipe-user-pages-hard* limits when using the *fcntl*(2) **F_SETPIPE_SZ** operation to change a pipe's capacity:

(a) When increasing the pipe capacity, the checks against the soft and hard limits were made against existing consumption, and excluded the memory required for the increased pipe capacity. The new increase in pipe capacity could then push the total memory used by the user for pipes (possibly far) over a limit. (This could also trigger the problem described next.)

Starting with Linux 4.9, the limit checking includes the memory required for the new pipe capacity.

(b) The limit checks were performed even when the new pipe capacity was less than the existing pipe capacity. This could lead to problems if a user set a large pipe capacity, and then the limits were lowered, with the result that the user could no longer decrease the pipe capacity.

Starting with Linux 4.9, checks against the limits are performed only when increasing a pipe's capacity; an unprivileged user can always decrease a pipe's capacity.

(c) The accounting and checking against the limits were done as follows:

(1) Test whether the user has exceeded the limit.
(2) Make the new pipe buffer allocation.
(3) Account new allocation against the limits.

This was racey. Multiple processes could pass point (1) simultaneously, and then allocate pipe buffers that were accounted for only in step (3), with the result that the user's pipe buffer allocation could be pushed over the limit.

Starting with Linux 4.9, the accounting step is performed before doing the allocation, and the operation fails if the limit would be exceeded.

Before Linux 4.9, bugs similar to points (a) and (c) could also occur when the kernel allocated memory for a new pipe buffer; that is, when calling *pipe*(2) and when opening a previously unopened FIFO.

NAME

pkeys − overview of Memory Protection Keys

DESCRIPTION

Memory Protection Keys (pkeys) are an extension to existing page-based memory permissions. Normal page permissions using page tables require expensive system calls and TLB invalidations when changing permissions. Memory Protection Keys provide a mechanism for changing protections without requiring modification of the page tables on every permission change.

To use pkeys, software must first "tag" a page in the page tables with a pkey. After this tag is in place, an application only has to change the contents of a register in order to remove write access, or all access to a tagged page.

Protection keys work in conjunction with the existing **PROT_READ**, **PROT_WRITE**, and **PROT_EXEC** permissions passed to system calls such as *mprotect*(2) and *mmap*(2), but always act to further restrict these traditional permission mechanisms.

If a process performs an access that violates pkey restrictions, it receives a **SIGSEGV** signal. See *sigaction*(2) for details of the information available with that signal.

To use the pkeys feature, the processor must support it, and the kernel must contain support for the feature on a given processor. As of early 2016 only future Intel x86 processors are supported, and this hardware supports 16 protection keys in each process. However, pkey 0 is used as the default key, so a maximum of 15 are available for actual application use. The default key is assigned to any memory region for which a pkey has not been explicitly assigned via *pkey_mprotect*(2).

Protection keys have the potential to add a layer of security and reliability to applications. But they have not been primarily designed as a security feature. For instance, WRPKRU is a completely unprivileged instruction, so pkeys are useless in any case that an attacker controls the PKRU register or can execute arbitrary instructions.

Applications should be very careful to ensure that they do not "leak" protection keys. For instance, before calling *pkey_free*(2), the application should be sure that no memory has that pkey assigned. If the application left the freed pkey assigned, a future user of that pkey might inadvertently change the permissions of an unrelated data structure, which could impact security or stability. The kernel currently allows in-use pkeys to have *pkey_free*(2) called on them because it would have processor or memory performance implications to perform the additional checks needed to disallow it. Implementation of the necessary checks is left up to applications. Applications may implement these checks by searching the */proc/*pid*/smaps* file for memory regions with the pkey assigned. Further details can be found in *proc*(5).

Any application wanting to use protection keys needs to be able to function without them. They might be unavailable because the hardware that the application runs on does not support them, the kernel code does not contain support, the kernel support has been disabled, or because the keys have all been allocated, perhaps by a library the application is using. It is recommended that applications wanting to use protection keys should simply call *pkey_alloc*(2) and test whether the call succeeds, instead of attempting to detect support for the feature in any other way.

Although unnecessary, hardware support for protection keys may be enumerated with the *cpuid* instruction. Details of how to do this can be found in the Intel Software Developers Manual. The kernel performs this enumeration and exposes the information in */proc/cpuinfo* under the "flags" field. The string "pku" in this field indicates hardware support for protection keys and the string "ospke" indicates that the kernel contains and has enabled protection keys support.

Applications using threads and protection keys should be especially careful. Threads inherit the protection key rights of the parent at the time of the *clone*(2), system call. Applications should either ensure that their own permissions are appropriate for child threads at the time when *clone*(2) is called, or ensure that each child thread can perform its own initialization of protection key rights.

Signal Handler Behavior

Each time a signal handler is invoked (including nested signals), the thread is temporarily given a new, default set of protection key rights that override the rights from the interrupted context. This means that applications must re-establish their desired protection key rights upon entering a signal handler if the desired rights differ from the defaults. The rights of any interrupted context are restored when the signal handler returns.

This signal behavior is unusual and is due to the fact that the x86 PKRU register (which stores protection key access rights) is managed with the same hardware mechanism (XSAVE) that manages floating-point registers. The signal behavior is the same as that of floating-point registers.

Protection Keys system calls

The Linux kernel implements the following pkey-related system calls: *pkey_mprotect*(2), *pkey_alloc*(2), and *pkey_free*(2).

The Linux pkey system calls are available only if the kernel was configured and built with the **CONFIG_X86_INTEL_MEMORY_PROTECTION_KEYS** option.

EXAMPLES

The program below allocates a page of memory with read and write permissions. It then writes some data to the memory and successfully reads it back. After that, it attempts to allocate a protection key and disallows access to the page by using the WRPKRU instruction. It then tries to access the page, which we now expect to cause a fatal signal to the application.

```
$ ./a.out
buffer contains: 73
about to read buffer again...
Segmentation fault (core dumped)
```

Program source

```
#define _GNU_SOURCE
#include <err.h>

            err(EXIT_FAILURE, "pkey_mprotect");

        printf("about to read buffer again...\n");

        /*
         * This will crash, because we have disallowed access.
         */
        printf("buffer contains: %d\n", *buffer);

        status = pkey_free(pkey);
        if (status == -1)
            err(EXIT_FAILURE, "pkey_free");

        exit(EXIT_SUCCESS);
    }
```

NAME

posixoptions − optional parts of the POSIX standard

DESCRIPTION

The POSIX standard (the information below is from POSIX.1-2001) describes a set of behaviors and interfaces for a compliant system. However, many interfaces are optional and there are feature test macros to test the availability of interfaces at compile time, and functions *sysconf*(3), *fpathconf*(3), *pathconf*(3), *confstr*(3) to do this at run time. From shell scripts one can use *getconf* (1)For more detail, see *sysconf*(3).

We give the name of the POSIX abbreviation, the option, the name of the *sysconf*(3) parameter used to inquire about the option, and possibly a very short description. Much more precise detail can be found in the POSIX standard itself, versions of which can nowadays be accessed freely on the web.

ADV - _POSIX_ADVISORY_INFO - _SC_ADVISORY_INFO

The following advisory functions are present:

posix_fadvise()
posix_fallocate()
posix_memalign()
posix_madvise()

AIO - _POSIX_ASYNCHRONOUS_IO - _SC_ASYNCHRONOUS_IO

The header <*aio.h*> is present. The following functions are present:

aio_cancel()
aio_error()
aio_fsync()
aio_read()
aio_return()
aio_suspend()
aio_write()
lio_listio()

BAR - _POSIX_BARRIERS - _SC_BARRIERS

This option implies the **_POSIX_THREADS** and **_POSIX_THREAD_SAFE_FUNCTIONS** options. The following functions are present:

pthread_barrier_destroy()
pthread_barrier_init()
pthread_barrier_wait()
pthread_barrierattr_destroy()
pthread_barrierattr_init()

--- - POSIX_CHOWN_RESTRICTED

If this option is in effect (as it always is under POSIX.1-2001), then only root may change the owner of a file, and nonroot can set the group of a file only to one of the groups it belongs to. This affects the following functions:

chown()
fchown()

CS - _POSIX_CLOCK_SELECTION - _SC_CLOCK_SELECTION

This option implies the **_POSIX_TIMERS** option. The following functions are present:

pthread_condattr_getclock()
pthread_condattr_setclock()
clock_nanosleep()

If **CLOCK_REALTIME** is changed by the function *clock_settime*(), then this affects all timers set for an absolute time.

CPT - _POSIX_CPUTIME - _SC_CPUTIME

The **CLOCK_PROCESS_CPUTIME_ID** clock ID is supported. The initial value of this clock is 0 for each process. This option implies the **_POSIX_TIMERS** option. The function *clock_getcpuclockid*() is present.

--- - _POSIX_FILE_LOCKING - _SC_FILE_LOCKING
This option has been deleted. Not in final XPG6.

FSC - _POSIX_FSYNC - _SC_FSYNC
The function *fsync*() is present.

IP6 - _POSIX_IPV6 - _SC_IPV6
Internet Protocol Version 6 is supported.

--- - _POSIX_JOB_CONTROL - _SC_JOB_CONTROL
If this option is in effect (as it always is under POSIX.1-2001), then the system implements POSIX-style job control, and the following functions are present:

setpgid()
tcdrain()
tcflush()
tcgetpgrp()
tcsendbreak()
tcsetattr()
tcsetpgrp()

MF - _POSIX_MAPPED_FILES - _SC_MAPPED_FILES
Shared memory is supported. The include file <*sys/mman.h*> is present. The following functions are present:

mmap()
msync()
munmap()

ML - _POSIX_MEMLOCK - _SC_MEMLOCK
Shared memory can be locked into core. The following functions are present:

mlockall()
munlockall()

MR/MLR - _POSIX_MEMLOCK_RANGE - _SC_MEMLOCK_RANGE
More precisely, ranges can be locked into core. The following functions are present:

mlock()
munlock()

MPR - _POSIX_MEMORY_PROTECTION - _SC_MEMORY_PROTECTION
The function *mprotect*() is present.

MSG - _POSIX_MESSAGE_PASSING - _SC_MESSAGE_PASSING
The include file <*mqueue.h*> is present. The following functions are present:

mq_close()
mq_getattr()
mq_notify()
mq_open()
mq_receive()
mq_send()
mq_setattr()
mq_unlink()

MON - _POSIX_MONOTONIC_CLOCK - _SC_MONOTONIC_CLOCK
CLOCK_MONOTONIC is supported. This option implies the **_POSIX_TIMERS** option. The following functions are affected:

aio_suspend()
clock_getres()
clock_gettime()
clock_settime()
timer_create()

--- - _POSIX_MULTI_PROCESS - _SC_MULTI_PROCESS
This option has been deleted. Not in final XPG6.

--- - _POSIX_NO_TRUNC
If this option is in effect (as it always is under POSIX.1-2001), then pathname components longer than **NAME_MAX** are not truncated, but give an error. This property may be dependent on the path prefix of the component.

PIO - _POSIX_PRIORITIZED_IO - _SC_PRIORITIZED_IO
This option says that one can specify priorities for asynchronous I/O. This affects the functions

aio_read()
aio_write()

PS - _POSIX_PRIORITY_SCHEDULING - _SC_PRIORITY_SCHEDULING
The include file <*sched.h*> is present. The following functions are present:

sched_get_priority_max()
sched_get_priority_min()
sched_getparam()
sched_getscheduler()
sched_rr_get_interval()
sched_setparam()
sched_setscheduler()
sched_yield()

If also **_POSIX_SPAWN** is in effect, then the following functions are present:

posix_spawnattr_getschedparam()
posix_spawnattr_getschedpolicy()
posix_spawnattr_setschedparam()
posix_spawnattr_setschedpolicy()

RS - _POSIX_RAW_SOCKETS
Raw sockets are supported. The following functions are affected:

getsockopt()
setsockopt()

--- - _POSIX_READER_WRITER_LOCKS - _SC_READER_WRITER_LOCKS
This option implies the **_POSIX_THREADS** option. Conversely, under POSIX.1-2001 the **_POSIX_THREADS** option implies this option.

The following functions are present:

pthread_rwlock_destroy()
pthread_rwlock_init()
pthread_rwlock_rdlock()
pthread_rwlock_tryrdlock()
pthread_rwlock_trywrlock()
pthread_rwlock_unlock()
pthread_rwlock_wrlock()
pthread_rwlockattr_destroy()
pthread_rwlockattr_init()

RTS - _POSIX_REALTIME_SIGNALS - _SC_REALTIME_SIGNALS
Realtime signals are supported. The following functions are present:

sigqueue()
sigtimedwait()
sigwaitinfo()

--- - _POSIX_REGEXP - _SC_REGEXP
If this option is in effect (as it always is under POSIX.1-2001), then POSIX regular expressions are supported and the following functions are present:

regcomp()
regerror()

regexec()
regfree()

--- - _POSIX_SAVED_IDS - _SC_SAVED_IDS
If this option is in effect (as it always is under POSIX.1-2001), then a process has a saved set-user-ID and a saved set-group-ID. The following functions are affected:

exec()
kill()
seteuid()
setegid()
setgid()
setuid()

SEM - _POSIX_SEMAPHORES - _SC_SEMAPHORES
The include file <*semaphore.h*> is present. The following functions are present:

sem_close()
sem_destroy()
sem_getvalue()
sem_init()
sem_open()
sem_post()
sem_trywait()
sem_unlink()
sem_wait()

SHM - _POSIX_SHARED_MEMORY_OBJECTS - _SC_SHARED_MEMORY_OBJECTS
The following functions are present:

mmap()
munmap()
shm_open()
shm_unlink()

--- - _POSIX_SHELL - _SC_SHELL
If this option is in effect (as it always is under POSIX.1-2001), the function *system*() is present.

SPN - _POSIX_SPAWN - _SC_SPAWN
This option describes support for process creation in a context where it is difficult or impossible to use *fork*(), for example, because no MMU is present.

If **_POSIX_SPAWN** is in effect, then the include file <*spawn.h*> and the following functions are present:

posix_spawn()
posix_spawn_file_actions_addclose()
posix_spawn_file_actions_adddup2()
posix_spawn_file_actions_addopen()
posix_spawn_file_actions_destroy()
posix_spawn_file_actions_init()
posix_spawnattr_destroy()
posix_spawnattr_getsigdefault()
posix_spawnattr_getflags()
posix_spawnattr_getpgroup()
posix_spawnattr_getsigmask()
posix_spawnattr_init()
posix_spawnattr_setsigdefault()
posix_spawnattr_setflags()
posix_spawnattr_setpgroup()
posix_spawnattr_setsigmask()
posix_spawnp()

If also **_POSIX_PRIORITY_SCHEDULING** is in effect, then the following functions are present:

posix_spawnattr_getschedparam()

posix_spawnattr_getschedpolicy()
posix_spawnattr_setschedparam()
posix_spawnattr_setschedpolicy()

SPI - _POSIX_SPIN_LOCKS - _SC_SPIN_LOCKS
This option implies the **_POSIX_THREADS** and **_POSIX_THREAD_SAFE_FUNCTIONS** options. The following functions are present:

pthread_spin_destroy()
pthread_spin_init()
pthread_spin_lock()
pthread_spin_trylock()
pthread_spin_unlock()

SS - _POSIX_SPORADIC_SERVER - _SC_SPORADIC_SERVER
The scheduling policy **SCHED_SPORADIC** is supported. This option implies the **_POSIX_PRIORITY_SCHEDULING** option. The following functions are affected:

sched_setparam()
sched_setscheduler()

SIO - _POSIX_SYNCHRONIZED_IO - _SC_SYNCHRONIZED_IO
The following functions are affected:

open()
msync()
fsync()
fdatasync()

TSA - _POSIX_THREAD_ATTR_STACKADDR - _SC_THREAD_ATTR_STACKADDR
The following functions are affected:

pthread_attr_getstack()
pthread_attr_getstackaddr()
pthread_attr_setstack()
pthread_attr_setstackaddr()

TSS - _POSIX_THREAD_ATTR_STACKSIZE - _SC_THREAD_ATTR_STACKSIZE
The following functions are affected:

pthread_attr_getstack()
pthread_attr_getstacksize()
pthread_attr_setstack()
pthread_attr_setstacksize()

TCT - _POSIX_THREAD_CPUTIME - _SC_THREAD_CPUTIME
The clockID CLOCK_THREAD_CPUTIME_ID is supported. This option implies the **_POSIX_TIMERS** option. The following functions are affected:

pthread_getcpuclockid()
clock_getres()
clock_gettime()
clock_settime()
timer_create()

TPI - _POSIX_THREAD_PRIO_INHERIT - _SC_THREAD_PRIO_INHERIT
The following functions are affected:

pthread_mutexattr_getprotocol()
pthread_mutexattr_setprotocol()

TPP - _POSIX_THREAD_PRIO_PROTECT - _SC_THREAD_PRIO_PROTECT
The following functions are affected:

pthread_mutex_getprioceiling()
pthread_mutex_setprioceiling()
pthread_mutexattr_getprioceiling()
pthread_mutexattr_getprotocol()

pthread_mutexattr_setprioceiling()
pthread_mutexattr_setprotocol()

TPS - _POSIX_THREAD_PRIORITY_SCHEDULING - _SC_THREAD_PRIORITY_SCHEDULING
If this option is in effect, the different threads inside a process can run with different priorities and/or different schedulers. The following functions are affected:

pthread_attr_getinheritsched()
pthread_attr_getschedpolicy()
pthread_attr_getscope()
pthread_attr_setinheritsched()
pthread_attr_setschedpolicy()
pthread_attr_setscope()
pthread_getschedparam()
pthread_setschedparam()
pthread_setschedprio()

TSH - _POSIX_THREAD_PROCESS_SHARED - _SC_THREAD_PROCESS_SHARED
The following functions are affected:

pthread_barrierattr_getpshared()
pthread_barrierattr_setpshared()
pthread_condattr_getpshared()
pthread_condattr_setpshared()
pthread_mutexattr_getpshared()
pthread_mutexattr_setpshared()
pthread_rwlockattr_getpshared()
pthread_rwlockattr_setpshared()

TSF - _POSIX_THREAD_SAFE_FUNCTIONS - _SC_THREAD_SAFE_FUNCTIONS
The following functions are affected:

readdir_r()
getgrgid_r()
getgrnam_r()
getpwnam_r()
getpwuid_r()
flockfile()
ftrylockfile()
funlockfile()
getc_unlocked()
getchar_unlocked()
putc_unlocked()
putchar_unlocked()
rand_r()
strerror_r()
strtok_r()
asctime_r()
ctime_r()
gmtime_r()
localtime_r()

TSP - _POSIX_THREAD_SPORADIC_SERVER - _SC_THREAD_SPORADIC_SERVER
This option implies the **_POSIX_THREAD_PRIORITY_SCHEDULING** option. The following functions are affected:

sched_getparam()
sched_setparam()
sched_setscheduler()

THR - _POSIX_THREADS - _SC_THREADS
Basic support for POSIX threads is available. The following functions are present:

pthread_atfork()

pthread_attr_destroy()
pthread_attr_getdetachstate()
pthread_attr_getschedparam()
pthread_attr_init()
pthread_attr_setdetachstate()
pthread_attr_setschedparam()
pthread_cancel()
pthread_cleanup_push()
pthread_cleanup_pop()
pthread_cond_broadcast()
pthread_cond_destroy()
pthread_cond_init()
pthread_cond_signal()
pthread_cond_timedwait()
pthread_cond_wait()
pthread_condattr_destroy()
pthread_condattr_init()
pthread_create()
pthread_detach()
pthread_equal()
pthread_exit()
pthread_getspecific()
pthread_join()
pthread_key_create()
pthread_key_delete()
pthread_mutex_destroy()
pthread_mutex_init()
pthread_mutex_lock()
pthread_mutex_trylock()
pthread_mutex_unlock()
pthread_mutexattr_destroy()
pthread_mutexattr_init()
pthread_once()
pthread_rwlock_destroy()
pthread_rwlock_init()
pthread_rwlock_rdlock()
pthread_rwlock_tryrdlock()
pthread_rwlock_trywrlock()
pthread_rwlock_unlock()
pthread_rwlock_wrlock()
pthread_rwlockattr_destroy()
pthread_rwlockattr_init()
pthread_self ()
pthread_setcancelstate()
pthread_setcanceltype()
pthread_setspecific()
pthread_testcancel()

TMO - _POSIX_TIMEOUTS - _SC_TIMEOUTS

The following functions are present:

mq_timedreceive()
mq_timedsend()
pthread_mutex_timedlock()
pthread_rwlock_timedrdlock()
pthread_rwlock_timedwrlock()
sem_timedwait()
posix_trace_timedgetnext_event()

TMR - _POSIX_TIMERS - _SC_TIMERS
The following functions are present:

clock_getres()
clock_gettime()
clock_settime()
nanosleep()
timer_create()
timer_delete()
timer_gettime()
timer_getoverrun()
timer_settime()

TRC - _POSIX_TRACE - _SC_TRACE
POSIX tracing is available. The following functions are present:

posix_trace_attr_destroy()
posix_trace_attr_getclockres()
posix_trace_attr_getcreatetime()
posix_trace_attr_getgenversion()
posix_trace_attr_getmaxdatasize()
posix_trace_attr_getmaxsystemeventsize()
posix_trace_attr_getmaxusereventsize()
posix_trace_attr_getname()
posix_trace_attr_getstreamfullpolicy()
posix_trace_attr_getstreamsize()
posix_trace_attr_init()
posix_trace_attr_setmaxdatasize()
posix_trace_attr_setname()
posix_trace_attr_setstreamsize()
posix_trace_attr_setstreamfullpolicy()
posix_trace_clear()
posix_trace_create()
posix_trace_event()
posix_trace_eventid_equal()
posix_trace_eventid_get_name()
posix_trace_eventid_open()
posix_trace_eventtypelist_getnext_id()
posix_trace_eventtypelist_rewind()
posix_trace_flush()
posix_trace_get_attr()
posix_trace_get_status()
posix_trace_getnext_event()
posix_trace_shutdown()
posix_trace_start()
posix_trace_stop()
posix_trace_trygetnext_event()

TEF - _POSIX_TRACE_EVENT_FILTER - _SC_TRACE_EVENT_FILTER
This option implies the **_POSIX_TRACE** option. The following functions are present:

posix_trace_eventset_add()
posix_trace_eventset_del()
posix_trace_eventset_empty()
posix_trace_eventset_fill()
posix_trace_eventset_ismember()
posix_trace_get_filter()
posix_trace_set_filter()
posix_trace_trid_eventid_open()

TRI - _POSIX_TRACE_INHERIT - _SC_TRACE_INHERIT
Tracing children of the traced process is supported. This option implies the **_POSIX_TRACE** option. The following functions are present:

posix_trace_attr_getinherited()
posix_trace_attr_setinherited()

TRL - _POSIX_TRACE_LOG - _SC_TRACE_LOG
This option implies the **_POSIX_TRACE** option. The following functions are present:

posix_trace_attr_getlogfullpolicy()
posix_trace_attr_getlogsize()
posix_trace_attr_setlogfullpolicy()
posix_trace_attr_setlogsize()
posix_trace_close()
posix_trace_create_withlog()
posix_trace_open()
posix_trace_rewind()

TYM - _POSIX_TYPED_MEMORY_OBJECTS - _SC_TYPED_MEMORY_OBJECT
The following functions are present:

posix_mem_offset()
posix_typed_mem_get_info()
posix_typed_mem_open()

--- - _POSIX_VDISABLE
Always present (probably 0). Value to set a changeable special control character to indicate that it is disabled.

X/OPEN SYSTEM INTERFACE EXTENSIONS

XSI - _XOPEN_CRYPT - _SC_XOPEN_CRYPT
The following functions are present:

crypt()
encrypt()
setkey()

XSI - _XOPEN_REALTIME - _SC_XOPEN_REALTIME
This option implies the following options:

_POSIX_ASYNCHRONOUS_IO==200112L
_POSIX_FSYNC
_POSIX_MAPPED_FILES
_POSIX_MEMLOCK==200112L
_POSIX_MEMLOCK_RANGE==200112L
_POSIX_MEMORY_PROTECTION
_POSIX_MESSAGE_PASSING==200112L
_POSIX_PRIORITIZED_IO
_POSIX_PRIORITY_SCHEDULING==200112L
_POSIX_REALTIME_SIGNALS==200112L
_POSIX_SEMAPHORES==200112L
_POSIX_SHARED_MEMORY_OBJECTS==200112L
_POSIX_SYNCHRONIZED_IO==200112L
_POSIX_TIMERS==200112L

ADV - --- - ---
The Advanced Realtime option group implies that the following options are all defined to 200112L:

_POSIX_ADVISORY_INFO
_POSIX_CLOCK_SELECTION
(implies **_POSIX_TIMERS**)
_POSIX_CPUTIME
(implies **_POSIX_TIMERS**)

_POSIX_MONOTONIC_CLOCK
(implies **_POSIX_TIMERS**)
_POSIX_SPAWN
_POSIX_SPORADIC_SERVER
(implies **_POSIX_PRIORITY_SCHEDULING**)
_POSIX_TIMEOUTS
_POSIX_TYPED_MEMORY_OBJECTS

XSI - _XOPEN_REALTIME_THREADS - _SC_XOPEN_REALTIME_THREADS
This option implies that the following options are all defined to 200112L:

_POSIX_THREAD_PRIO_INHERIT
_POSIX_THREAD_PRIO_PROTECT
_POSIX_THREAD_PRIORITY_SCHEDULING

ADVANCED REALTIME THREADS - --- - ---
This option implies that the following options are all defined to 200112L:

_POSIX_BARRIERS
(implies **_POSIX_THREADS**, **_POSIX_THREAD_SAFE_FUNCTIONS**)
_POSIX_SPIN_LOCKS
(implies **_POSIX_THREADS**, **_POSIX_THREAD_SAFE_FUNCTIONS**)
_POSIX_THREAD_CPUTIME
(implies **_POSIX_TIMERS**)
_POSIX_THREAD_SPORADIC_SERVER
(implies **_POSIX_THREAD_PRIORITY_SCHEDULING**)

TRACING - --- - ---
This option implies that the following options are all defined to 200112L:

_POSIX_TRACE
_POSIX_TRACE_EVENT_FILTER
_POSIX_TRACE_LOG
_POSIX_TRACE_INHERIT

STREAMS - _XOPEN_STREAMS - _SC_XOPEN_STREAMS
The following functions are present:

fattach()
fdetach()
getmsg()
getpmsg()
ioctl()
isastream()
putmsg()
putpmsg()

XSI - _XOPEN_LEGACY - _SC_XOPEN_LEGACY
Functions included in the legacy option group were previously mandatory, but are now optional in this version. The following functions are present:

bcmp()
bcopy()
bzero()
ecvt()
fcvt()
ftime()
gcvt()
getwd()
index()
mktemp()
rindex()
utimes()
wcswcs()

XSI - _XOPEN_UNIX - _SC_XOPEN_UNIX
The following functions are present:

mmap()
munmap()
msync()

This option implies the following options:

_POSIX_FSYNC
_POSIX_MAPPED_FILES
_POSIX_MEMORY_PROTECTION
_POSIX_THREAD_ATTR_STACKADDR
_POSIX_THREAD_ATTR_STACKSIZE
_POSIX_THREAD_PROCESS_SHARED
_POSIX_THREAD_SAFE_FUNCTIONS
_POSIX_THREADS

This option may imply the following options from the XSI option groups:

Encryption (**_XOPEN_CRYPT**)
Realtime (**_XOPEN_REALTIME**)
Advanced Realtime (**ADB**)
Realtime Threads (**_XOPEN_REALTIME_THREADS**)
Advanced Realtime Threads (**ADVANCED REALTIME THREADS**)
Tracing (**TRACING**)
XSI Streams (**STREAMS**)
Legacy (**_XOPEN_LEGACY**)

NAME

process-keyring − per-process shared keyring

DESCRIPTION

The process keyring is a keyring used to anchor keys on behalf of a process. It is created only when a process requests it. The process keyring has the name (description) *_pid*.

A special serial number value, **KEY_SPEC_PROCESS_KEYRING**, is defined that can be used in lieu of the actual serial number of the calling process's process keyring.

From the *keyctl*(1) utility, '**@p**' can be used instead of a numeric key ID in much the same way, but since *keyctl*(1) is a program run after forking, this is of no utility.

A thread created using the *clone*(2) **CLONE_THREAD** flag has the same process keyring as the caller of *clone*(2). When a new process is created using **fork**() it initially has no process keyring. A process's process keyring is cleared on *execve*(2). The process keyring is destroyed when the last thread that refers to it terminates.

If a process doesn't have a process keyring when it is accessed, then the process keyring will be created if the keyring is to be modified; otherwise, the error **ENOKEY** results.

NAME

pthreads − POSIX threads

DESCRIPTION

POSIX.1 specifies a set of interfaces (functions, header files) for threaded programming commonly known as POSIX threads, or Pthreads. A single process can contain multiple threads, all of which are executing the same program. These threads share the same global memory (data and heap segments), but each thread has its own stack (automatic variables).

POSIX.1 also requires that threads share a range of other attributes (i.e., these attributes are process-wide rather than per-thread):

- process ID
- parent process ID
- process group ID and session ID
- controlling terminal
- user and group IDs
- open file descriptors
- record locks (see *fcntl*(2))
- signal dispositions
- file mode creation mask (**umask**(2))
- current directory (**chdir**(2)) and root directory (**chroot**(2))
- interval timers (**setitimer**(2)) and POSIX timers (**timer_create**(2))
- nice value (**setpriority**(2))
- resource limits (**setrlimit**(2))
- measurements of the consumption of CPU time (**times**(2)) and resources (**getrusage**(2))

As well as the stack, POSIX.1 specifies that various other attributes are distinct for each thread, including:

- thread ID (the *pthread_t* data type)
- signal mask (**pthread_sigmask**(3))
- the *errno* variable
- alternate signal stack (**sigaltstack**(2))
- real-time scheduling policy and priority (**sched**(7))

The following Linux-specific features are also per-thread:

- capabilities (see *capabilities*(7))
- CPU affinity (**sched_setaffinity**(2))

Pthreads function return values

Most pthreads functions return 0 on success, and an error number on failure. The error numbers that can be returned have the same meaning as the error numbers returned in *errno* by conventional system calls and C library functions. Note that the pthreads functions do not set *errno*. For each of the pthreads functions that can return an error, POSIX.1-2001 specifies that the function can never fail with the error **EINTR**.

Thread IDs

Each of the threads in a process has a unique thread identifier (stored in the type *pthread_t*). This identifier is returned to the caller of *pthread_create*(3), and a thread can obtain its own thread identifier using *pthread_self*(3).

Thread IDs are guaranteed to be unique only within a process. (In all pthreads functions that accept a thread ID as an argument, that ID by definition refers to a thread in the same process as the caller.)

The system may reuse a thread ID after a terminated thread has been joined, or a detached thread has terminated. POSIX says: "If an application attempts to use a thread ID whose lifetime has ended, the

behavior is undefined."

Thread-safe functions

A thread-safe function is one that can be safely (i.e., it will deliver the same results regardless of whether it is) called from multiple threads at the same time.

POSIX.1-2001 and POSIX.1-2008 require that all functions specified in the standard shall be thread-safe, except for the following functions:

```
asctime()
basename()
catgets()
crypt()
ctermid() if passed a non-NULL argument
ctime()
dbm_clearerr()
dbm_close()
dbm_delete()
dbm_error()
dbm_fetch()
dbm_firstkey()
dbm_nextkey()
dbm_open()
dbm_store()
dirname()
dlerror()
drand48()
ecvt() [POSIX.1-2001 only (function removed in POSIX.1-2008)]
encrypt()
endgrent()
endpwent()
endutxent()
fcvt() [POSIX.1-2001 only (function removed in POSIX.1-2008)]
ftw()
gcvt() [POSIX.1-2001 only (function removed in POSIX.1-2008)]
getc_unlocked()
getchar_unlocked()
getdate()
getenv()
getgrent()
getgrgid()
getgrnam()
gethostbyaddr() [POSIX.1-2001 only (function removed in
                 POSIX.1-2008)]
gethostbyname() [POSIX.1-2001 only (function removed in
                 POSIX.1-2008)]
gethostent()
getlogin()
getnetbyaddr()
getnetbyname()
getnetent()
getopt()
getprotobyname()
getprotobynumber()
getprotoent()
getpwent()
getpwnam()
getpwuid()
getservbyname()
getservbyport()
```

```
getservent()
getutxent()
getutxid()
getutxline()
gmtime()
hcreate()
hdestroy()
hsearch()
inet_ntoa()
l64a()
lgamma()
lgammaf()
lgammal()
localeconv()
localtime()
lrand48()
mrand48()
nftw()
nl_langinfo()
ptsname()
putc_unlocked()
putchar_unlocked()
putenv()
pututxline()
rand()

wcrtomb() if its final argument is NULL
wcsrtombs() if its final argument is NULL
wcstombs()
wctomb()
```

Async-cancel-safe functions

An async-cancel-safe function is one that can be safely called in an application where asynchronous cancelability is enabled (see *pthread_setcancelstate*(3)).

Only the following functions are required to be async-cancel-safe by POSIX.1-2001 and POSIX.1-2008:

```
pthread_cancel()
pthread_setcancelstate()
pthread_setcanceltype()
```

Cancelation points

POSIX.1 specifies that certain functions must, and certain other functions may, be cancelation points. If a thread is cancelable, its cancelability type is deferred, and a cancelation request is pending for the thread, then the thread is canceled when it calls a function that is a cancelation point.

The following functions are required to be cancelation points by POSIX.1-2001 and/or POSIX.1-2008:

```
accept()
```

```
aio_suspend()
clock_nanosleep()
close()
connect()
creat()
fcntl() F_SETLKW
fdatasync()
fsync()
getmsg()
getpmsg()
lockf() F_LOCK
mq_receive()
mq_send()
mq_timedreceive()
mq_timedsend()
msgrcv()
msgsnd()
msync()
nanosleep()
open()
openat() [Added in POSIX.1-2008]
pause()
poll()
pread()
pselect()
pthread_cond_timedwait()
pthread_cond_wait()
pthread_join()
pthread_testcancel()
putmsg()
putpmsg()
pwrite()
read()
readv()
recv()
recvfrom()
recvmsg()
select()
sem_timedwait()
sem_wait()
send()
sendmsg()
sendto()
sigpause() [POSIX.1-2001 only (moves to "may" list in POSIX.1-2008)]
sigsuspend()
sigtimedwait()
sigwait()
sigwaitinfo()
sleep()
system()
tcdrain()
usleep() [POSIX.1-2001 only (function removed in POSIX.1-2008)]
wait()
waitid()
waitpid()
write()
writev()
```

The following functions may be cancelation points according to POSIX.1-2001 and/or POSIX.1-2008:

```
access()
asctime()
asctime_r()
catclose()
catgets()
catopen()
chmod() [Added in POSIX.1-2008]
chown() [Added in POSIX.1-2008]
closedir()
closelog()
ctermid()
ctime()
ctime_r()
dbm_close()
dbm_delete()
dbm_fetch()
dbm_nextkey()
dbm_open()
dbm_store()
dlclose()
dlopen()
dprintf() [Added in POSIX.1-2008]
endgrent()
endhostent()
endnetent()
endprotoent()
endpwent()
endservent()
endutxent()
faccessat() [Added in POSIX.1-2008]

```

An implementation may also mark other functions not specified in the standard as cancelation points. In particular, an implementation is likely to mark any nonstandard function that may block as a cancelation point. (This includes most functions that can touch files.)

It should be noted that even if an application is not using asynchronous cancelation, that calling a function from the above list from an asynchronous signal handler may cause the equivalent of asynchronous cancelation. The underlying user code may not expect asynchronous cancelation and the state of the user data may become inconsistent. Therefore signals should be used with caution when entering a region of deferred cancelation.

Compiling on Linux

On Linux, programs that use the Pthreads API should be compiled using *cc −pthread*.

Linux implementations of POSIX threads

Over time, two threading implementations have been provided by the GNU C library on Linux:

LinuxThreads

This is the original Pthreads implementation. Since glibc 2.4, this implementation is no longer supported.

NPTL (Native POSIX Threads Library)

This is the modern Pthreads implementation. By comparison with LinuxThreads, NPTL provides closer conformance to the requirements of the POSIX.1 specification and better performance when creating large numbers of threads. NPTL is available since glibc 2.3.2, and requires features that are present in the Linux 2.6 kernel.

Both of these are so-called 1:1 implementations, meaning that each thread maps to a kernel scheduling entity. Both threading implementations employ the Linux *clone*(2) system call. In NPTL, thread synchronization primitives (mutexes, thread joining, and so on) are implemented using the Linux *futex*(2) system call.

LinuxThreads

The notable features of this implementation are the following:

- In addition to the main (initial) thread, and the threads that the program creates using *pthread_create*(3), the implementation creates a "manager" thread. This thread handles thread creation and termination. (Problems can result if this thread is inadvertently killed.)
- Signals are used internally by the implementation. On Linux 2.2 and later, the first three real-time signals are used (see also *signal*(7)). On older Linux kernels, **SIGUSR1** and **SIGUSR2** are used. Applications must avoid the use of whichever set of signals is employed by the implementation.
- Threads do not share process IDs. (In effect, LinuxThreads threads are implemented as processes which share more information than usual, but which do not share a common process ID.) LinuxThreads threads (including the manager thread) are visible as separate processes using *ps*(1)

The LinuxThreads implementation deviates from the POSIX.1 specification in a number of ways, including the following:

- Calls to *getpid*(2) return a different value in each thread.
- Calls to *getppid*(2) in threads other than the main thread return the process ID of the manager thread; instead *getppid*(2) in these threads should return the same value as *getppid*(2) in the main thread.
- When one thread creates a new child process using *fork*(2), any thread should be able to *wait*(2) on the child. However, the implementation allows only the thread that created the child to *wait*(2) on it.
- When a thread calls *execve*(2), all other threads are terminated (as required by POSIX.1). However, the resulting process has the same PID as the thread that called *execve*(2): it should have the same PID as the main thread.
- Threads do not share user and group IDs. This can cause complications with set-user-ID programs and can cause failures in Pthreads functions if an application changes its credentials using *seteuid*(2) or similar.
- Threads do not share a common session ID and process group ID.
- Threads do not share record locks created using *fcntl*(2).
- The information returned by *times*(2) and *getrusage*(2) is per-thread rather than process-wide.
- Threads do not share semaphore undo values (see *semop*(2)).
- Threads do not share interval timers.
- Threads do not share a common nice value.

- POSIX.1 distinguishes the notions of signals that are directed to the process as a whole and signals that are directed to individual threads. According to POSIX.1, a process-directed signal (sent using *kill*(2), for example) should be handled by a single, arbitrarily selected thread within the process. LinuxThreads does not support the notion of process-directed signals: signals may be sent only to specific threads.
- Threads have distinct alternate signal stack settings. However, a new thread's alternate signal stack settings are copied from the thread that created it, so that the threads initially share an alternate signal stack. (A new thread should start with no alternate signal stack defined. If two threads handle signals on their shared alternate signal stack at the same time, unpredictable program failures are likely to occur.)

NPTL

With NPTL, all of the threads in a process are placed in the same thread group; all members of a thread group share the same PID. NPTL does not employ a manager thread.

NPTL makes internal use of the first two real-time signals; these signals cannot be used in applications. See *nptl*(7) for further details.

NPTL still has at least one nonconformance with POSIX.1:

- Threads do not share a common nice value.

Some NPTL nonconformances occur only with older kernels:

- The information returned by *times*(2) and *getrusage*(2) is per-thread rather than process-wide (fixed in Linux 2.6.9).
- Threads do not share resource limits (fixed in Linux 2.6.10).
- Threads do not share interval timers (fixed in Linux 2.6.12).
- Only the main thread is permitted to start a new session using *setsid*(2) (fixed in Linux 2.6.16).
- Only the main thread is permitted to make the process into a process group leader using *setpgid*(2) (fixed in Linux 2.6.16).
- Threads have distinct alternate signal stack settings. However, a new thread's alternate signal stack settings are copied from the thread that created it, so that the threads initially share an alternate signal stack (fixed in Linux 2.6.16).

Note the following further points about the NPTL implementation:

- If the stack size soft resource limit (see the description of **RLIMIT_STACK** in *setrlimit*(2)) is set to a value other than *unlimited*, then this value defines the default stack size for new threads. To be effective, this limit must be set before the program is executed, perhaps using the *ulimit −s* shell built-in command (*limit stacksize* in the C shell).

Determining the threading implementation

Since glibc 2.3.2, the *getconf* (1) command can be used to determine the system's threading implementation, for example:

```
bash$ getconf GNU_LIBPTHREAD_VERSION
NPTL 2.3.4
```

With older glibc versions, a command such as the following should be sufficient to determine the default threading implementation:

```
bash$ $( ldd /bin/ls | grep libc.so | awk '{print $3}' ) | \
                egrep -i 'threads|nptl'
        Native POSIX Threads Library by Ulrich Drepper et al
```

Selecting the threading implementation: LD_ASSUME_KERNEL

On systems with a glibc that supports both LinuxThreads and NPTL (i.e., glibc 2.3.*x*), the **LD_ASSUME_KERNEL** environment variable can be used to override the dynamic linker's default choice of threading implementation. This variable tells the dynamic linker to assume that it is running on top of a particular kernel version. By specifying a kernel version that does not provide the support required by NPTL, we can force the use of LinuxThreads. (The most likely reason for doing this is to run a (broken) application that depends on some nonconformant behavior in LinuxThreads.) For example:

```
bash$ $( LD_ASSUME_KERNEL=2.2.5 ldd /bin/ls | grep libc.so | \
```

```
        awk '{print $3}' ) | egrep -i 'threads|nptl'
linuxthreads-0.10 by Xavier Leroy
```

NAME

pty − pseudoterminal interfaces

DESCRIPTION

A pseudoterminal (sometimes abbreviated "pty") is a pair of virtual character devices that provide a bidirectional communication channel. One end of the channel is called the *master*; the other end is called the *slave*.

The slave end of the pseudoterminal provides an interface that behaves exactly like a classical terminal. A process that expects to be connected to a terminal, can open the slave end of a pseudoterminal and then be driven by a program that has opened the master end. Anything that is written on the master end is provided to the process on the slave end as though it was input typed on a terminal. For example, writing the interrupt character (usually control-C) to the master device would cause an interrupt signal (**SIGINT**) to be generated for the foreground process group that is connected to the slave. Conversely, anything that is written to the slave end of the pseudoterminal can be read by the process that is connected to the master end.

Data flow between master and slave is handled asynchronously, much like data flow with a physical terminal. Data written to the slave will be available at the master promptly, but may not be available immediately. Similarly, there may be a small processing delay between a write to the master, and the effect being visible at the slave.

Historically, two pseudoterminal APIs have evolved: BSD and System V. SUSv1 standardized a pseudoterminal API based on the System V API, and this API should be employed in all new programs that use pseudoterminals.

Linux provides both BSD-style and (standardized) System V-style pseudoterminals. System V-style terminals are commonly called UNIX 98 pseudoterminals on Linux systems.

Since Linux 2.6.4, BSD-style pseudoterminals are considered deprecated: support can be disabled when building the kernel by disabling the **CONFIG_LEGACY_PTYS** option. (Starting with Linux 2.6.30, that option is disabled by default in the mainline kernel.) UNIX 98 pseudoterminals should be used in new applications.

UNIX 98 pseudoterminals

An unused UNIX 98 pseudoterminal master is opened by calling *posix_openpt*(3). (This function opens the master clone device, */dev/ptmx*; see *pts*(4).) After performing any program-specific initializations, changing the ownership and permissions of the slave device using *grantpt*(3), and unlocking the slave using *unlockpt*(3)), the corresponding slave device can be opened by passing the name returned by *ptsname*(3) in a call to *open*(2).

The Linux kernel imposes a limit on the number of available UNIX 98 pseudoterminals. Up to and including Linux 2.6.3, this limit is configured at kernel compilation time (**CONFIG_UNIX98_PTYS**), and the permitted number of pseudoterminals can be up to 2048, with a default setting of 256. Since Linux 2.6.4, the limit is dynamically adjustable via */proc/sys/kernel/pty/max*, and a corresponding file, */proc/sys/kernel/pty/nr*, indicates how many pseudoterminals are currently in use. For further details on these two files, see *proc*(5).

BSD pseudoterminals

BSD-style pseudoterminals are provided as precreated pairs, with names of the form */dev/ptyXY* (master) and */dev/ttyXY* (slave), where X is a letter from the 16-character set [p−za−e], and Y is a letter from the 16-character set [0−9a−f]. (The precise range of letters in these two sets varies across UNIX implementations.) For example, */dev/ptyp1* and */dev/ttyp1* constitute a BSD pseudoterminal pair. A process finds an unused pseudoterminal pair by trying to *open*(2) each pseudoterminal master until an open succeeds. The corresponding pseudoterminal slave (substitute "tty" for "pty" in the name of the master) can then be opened.

FILES

/dev/ptmx
: UNIX 98 master clone device

*/dev/pts/**
: UNIX 98 slave devices

/dev/pty[p−za−e][0−9a−f]
: BSD master devices

/dev/tty[p−za−e][0−9a−f]
: BSD slave devices

NOTES

Pseudoterminals are used by applications such as network login services (*ssh*(1), *rlogin*(1), *telnet*(1)), terminal emulators such as *xterm*(1), *script*(1), *screen*(1), *tmux*(1), *unbuffer*(1), and *expect*(1)

A description of the **TIOCPKT** *ioctl*(2), which controls packet mode operation, can be found in *ioctl_tty*(2).

The BSD *ioctl*(2) operations **TIOCSTOP**, **TIOCSTART**, **TIOCUCNTL**, and **TIOCREMOTE** have not been implemented under Linux.

NAME

queue − implementations of linked lists and queues

DESCRIPTION

The <*sys/queue.h*> header file provides a set of macros that define and operate on the following data structures:

SLIST singly linked lists

LIST doubly linked lists

STAILQ
: singly linked tail queues

TAILQ doubly linked tail queues

CIRCLEQ
: doubly linked circular queues

All structures support the following functionality:

- Insertion of a new entry at the head of the list.
- Insertion of a new entry after any element in the list.
- O(1) removal of an entry from the head of the list.
- Forward traversal through the list.

Code size and execution time depend on the complexity of the data structure being used, so programmers should take care to choose the appropriate one.

Singly linked lists (SLIST)

Singly linked lists are the simplest and support only the above functionality. Singly linked lists are ideal for applications with large datasets and few or no removals, or for implementing a LIFO queue. Singly linked lists add the following functionality:

- O(n) removal of any entry in the list.

Singly linked tail queues (STAILQ)

Singly linked tail queues add the following functionality:

- Entries can be added at the end of a list.
- O(n) removal of any entry in the list.
- They may be concatenated.

However:

- All list insertions must specify the head of the list.
- Each head entry requires two pointers rather than one.

Singly linked tail queues are ideal for applications with large datasets and few or no removals, or for implementing a FIFO queue.

Doubly linked data structures

All doubly linked types of data structures (lists and tail queues) additionally allow:

- Insertion of a new entry before any element in the list.
- O(1) removal of any entry in the list.

However:

- Each element requires two pointers rather than one.

Doubly linked lists (LIST)

Linked lists are the simplest of the doubly linked data structures. They add the following functionality over the above:

- They may be traversed backwards.

However:

- To traverse backwards, an entry to begin the traversal and the list in which it is contained must be specified.

Doubly linked tail queues (TAILQ)

Tail queues add the following functionality:

- Entries can be added at the end of a list.
- They may be traversed backwards, from tail to head.
- They may be concatenated.

However:

- All list insertions and removals must specify the head of the list.
- Each head entry requires two pointers rather than one.

Doubly linked circular queues (CIRCLEQ)

Circular queues add the following functionality over the above:

- The first and last entries are connected.

However:

- The termination condition for traversal is more complex.

STANDARDS

BSD.

HISTORY

<*sys/queue.h*> macros first appeared in 4.4BSD.

NOTES

Some BSDs provide SIMPLEQ instead of STAILQ. They are identical, but for historical reasons they were named differently on different BSDs. STAILQ originated on FreeBSD, and SIMPLEQ originated on NetBSD. For compatibility reasons, some systems provide both sets of macros. glibc provides both STAILQ and SIMPLEQ, which are identical except for a missing SIMPLEQ equivalent to **STAILQ_CONCAT**().

NAME

random − overview of interfaces for obtaining randomness

DESCRIPTION

The kernel random-number generator relies on entropy gathered from device drivers and other sources of environmental noise to seed a cryptographically secure pseudorandom number generator (CSPRNG). It is designed for security, rather than speed.

The following interfaces provide access to output from the kernel CSPRNG:

- The */dev/urandom* and */dev/random* devices, both described in *random*(4). These devices have been present on Linux since early times, and are also available on many other systems.
- The Linux-specific *getrandom*(2) system call, available since Linux 3.17. This system call provides access either to the same source as */dev/urandom* (called the *urandom* source in this page) or to the same source as */dev/random* (called the *random* source in this page). The default is the *urandom* source; the *random* source is selected by specifying the **GRND_RANDOM** flag to the system call. (The *getentropy*(3) function provides a slightly more portable interface on top of *getrandom*(2).)

Initialization of the entropy pool

The kernel collects bits of entropy from the environment. When a sufficient number of random bits has been collected, the entropy pool is considered to be initialized.

Choice of random source

Unless you are doing long-term key generation (and most likely not even then), you probably shouldn't be reading from the */dev/random* device or employing *getrandom*(2) with the **GRND_RANDOM** flag. Instead, either read from the */dev/urandom* device or employ *getrandom*(2) without the **GRND_RANDOM** flag. The cryptographic algorithms used for the *urandom* source are quite conservative, and so should be sufficient for all purposes.

The disadvantage of **GRND_RANDOM** and reads from */dev/random* is that the operation can block for an indefinite period of time. Furthermore, dealing with the partially fulfilled requests that can occur when using **GRND_RANDOM** or when reading from */dev/random* increases code complexity.

Monte Carlo and other probabilistic sampling applications

Using these interfaces to provide large quantities of data for Monte Carlo simulations or other programs/algorithms which are doing probabilistic sampling will be slow. Furthermore, it is unnecessary, because such applications do not need cryptographically secure random numbers. Instead, use the interfaces described in this page to obtain a small amount of data to seed a user-space pseudorandom number generator for use by such applications.

Comparison between getrandom, /dev/urandom, and /dev/random

The following table summarizes the behavior of the various interfaces that can be used to obtain randomness. **GRND_NONBLOCK** is a flag that can be used to control the blocking behavior of *getrandom*(2). The final column of the table considers the case that can occur in early boot time when the entropy pool is not yet initialized.

Interface	**Pool**	**Blocking behavior**	**Behavior when pool is not yet ready**
/dev/random	Blocking pool	If entropy too low, blocks until there is enough entropy again	Blocks until enough entropy gathered
/dev/urandom	CSPRNG output	Never blocks	Returns output from uninitialized CSPRNG (may be low entropy and unsuitable for cryptography)
getrandom()	Same as */dev/urandom*	Does not block once is pool ready	Blocks until pool ready
getrandom() **GRND_RANDOM**	Same as */dev/random*	If entropy too low, blocks until there is enough entropy again	Blocks until pool ready
getrandom() **GRND_NONBLOCK**	Same as */dev/urandom*	Does not block once is pool ready	**EAGAIN**
getrandom() **GRND_RANDOM** + **GRND_NONBLOCK**	Same as */dev/random*	**EAGAIN** if not enough entropy available	**EAGAIN**

Generating cryptographic keys

The amount of seed material required to generate a cryptographic key equals the effective key size of the key. For example, a 3072-bit RSA or Diffie-Hellman private key has an effective key size of 128 bits (it requires about 2^128 operations to break) so a key generator needs only 128 bits (16 bytes) of seed material from */dev/random*.

While some safety margin above that minimum is reasonable, as a guard against flaws in the CSPRNG algorithm, no cryptographic primitive available today can hope to promise more than 256 bits of security, so if any program reads more than 256 bits (32 bytes) from the kernel random pool per invocation, or per reasonable reseed interval (not less than one minute), that should be taken as a sign that its cryptography is *not* skillfully implemented.

NAME

raw − Linux IPv4 raw sockets

SYNOPSIS

#include <sys/socket.h>
#include <netinet/in.h>
raw_socket = socket(AF_INET, SOCK_RAW, int *protocol***);**

DESCRIPTION

Raw sockets allow new IPv4 protocols to be implemented in user space. A raw socket receives or sends the raw datagram not including link level headers.

The IPv4 layer generates an IP header when sending a packet unless the **IP_HDRINCL** socket option is enabled on the socket. When it is enabled, the packet must contain an IP header. For receiving, the IP header is always included in the packet.

In order to create a raw socket, a process must have the **CAP_NET_RAW** capability in the user namespace that governs its network namespace.

All packets or errors matching the *protocol* number specified for the raw socket are passed to this socket. For a list of the allowed protocols, see the IANA list of assigned protocol numbers at and *getprotobyname*(3).

A protocol of **IPPROTO_RAW** implies enabled **IP_HDRINCL** and is able to send any IP protocol that is specified in the passed header. Receiving of all IP protocols via **IPPROTO_RAW** is not possible using raw sockets.

IP Header fields modified on sending by **IP_HDRINCL**	
IP Checksum	Always filled in
Source Address	Filled in when zero
Packet ID	Filled in when zero
Total Length	Always filled in

If **IP_HDRINCL** is specified and the IP header has a nonzero destination address, then the destination address of the socket is used to route the packet. When **MSG_DONTROUTE** is specified, the destination address should refer to a local interface, otherwise a routing table lookup is done anyway but gatewayed routes are ignored.

If **IP_HDRINCL** isn't set, then IP header options can be set on raw sockets with *setsockopt*(2); see *ip*(7) for more information.

Starting with Linux 2.2, all IP header fields and options can be set using IP socket options. This means raw sockets are usually needed only for new protocols or protocols with no user interface (like ICMP).

When a packet is received, it is passed to any raw sockets which have been bound to its protocol before it is passed to other protocol handlers (e.g., kernel protocol modules).

Address format

For sending and receiving datagrams (**sendto**(2), *recvfrom*(2), and similar), raw sockets use the standard *sockaddr_in* address structure defined in *ip*(7). The *sin_port* field could be used to specify the IP protocol number, but it is ignored for sending in Linux 2.2 and later, and should be always set to 0 (see BUGS). For incoming packets, *sin_port* is set to zero.

Socket options

Raw socket options can be set with *setsockopt*(2) and read with *getsockopt*(2) by passing the **IPPROTO_RAW** family flag.

ICMP_FILTER

Enable a special filter for raw sockets bound to the **IPPROTO_ICMP** protocol. The value has a bit set for each ICMP message type which should be filtered out. The default is to filter no ICMP messages.

In addition, all *ip*(7) **IPPROTO_IP** socket options valid for datagram sockets are supported.

Error handling

Errors originating from the network are passed to the user only when the socket is connected or the **IP_RECVERR** flag is enabled. For connected sockets, only **EMSGSIZE** and **EPROTO** are passed for compatibility. With **IP_RECVERR**, all network errors are saved in the error queue.

ERRORS

EACCES
User tried to send to a broadcast address without having the broadcast flag set on the socket.

EFAULT
An invalid memory address was supplied.

EINVAL
Invalid argument.

EMSGSIZE
Packet too big. Either Path MTU Discovery is enabled (the **IP_MTU_DISCOVER** socket flag) or the packet size exceeds the maximum allowed IPv4 packet size of 64 kB.

EOPNOTSUPP
Invalid flag has been passed to a socket call (like **MSG_OOB**).

EPERM
The user doesn't have permission to open raw sockets. Only processes with an effective user ID of 0 or the **CAP_NET_RAW** attribute may do that.

EPROTO
An ICMP error has arrived reporting a parameter problem.

VERSIONS

IP_RECVERR and **ICMP_FILTER** are new in Linux 2.2. They are Linux extensions and should not be used in portable programs.

Linux 2.0 enabled some bug-to-bug compatibility with BSD in the raw socket code when the **SO_BSDCOMPAT** socket option was set; since Linux 2.2, this option no longer has that effect.

NOTES

By default, raw sockets do path MTU (Maximum Transmission Unit) discovery. This means the kernel will keep track of the MTU to a specific target IP address and return **EMSGSIZE** when a raw packet write exceeds it. When this happens, the application should decrease the packet size. Path MTU discovery can be also turned off using the **IP_MTU_DISCOVER** socket option or the */proc/sys/net/ipv4/ip_no_pmtu_disc* file, see *ip*(7) for details. When turned off, raw sockets will fragment outgoing packets that exceed the interface MTU. However, disabling it is not recommended for performance and reliability reasons.

A raw socket can be bound to a specific local address using the *bind*(2) call. If it isn't bound, all packets with the specified IP protocol are received. In addition, a raw socket can be bound to a specific network device using **SO_BINDTODEVICE**; see *socket*(7).

An **IPPROTO_RAW** socket is send only. If you really want to receive all IP packets, use a *packet*(7) socket with the **ETH_P_IP** protocol. Note that packet sockets don't reassemble IP fragments, unlike raw sockets.

If you want to receive all ICMP packets for a datagram socket, it is often better to use **IP_RECVERR** on that particular socket; see *ip*(7).

Raw sockets may tap all IP protocols in Linux, even protocols like ICMP or TCP which have a protocol module in the kernel. In this case, the packets are passed to both the kernel module and the raw socket(s). This should not be relied upon in portable programs, many other BSD socket implementation have limitations here.

Linux never changes headers passed from the user (except for filling in some zeroed fields as described for **IP_HDRINCL**). This differs from many other implementations of raw sockets.

Raw sockets are generally rather unportable and should be avoided in programs intended to be portable.

Sending on raw sockets should take the IP protocol from *sin_port*; this ability was lost in Linux 2.2. The workaround is to use **IP_HDRINCL**.

BUGS

Transparent proxy extensions are not described.

When the **IP_HDRINCL** option is set, datagrams will not be fragmented and are limited to the interface MTU.

Setting the IP protocol for sending in *sin_port* got lost in Linux 2.2. The protocol that the socket was bound to or that was specified in the initial *socket*(2) call is always used.

NAME

regex − POSIX.2 regular expressions

DESCRIPTION

Regular expressions ("RE"s), as defined in POSIX.2, come in two forms: modern REs (roughly those of *egrep*(1); POSIX.2 calls these "extended" REs) and obsolete REs (roughly those of *ed*(1); POSIX.2 "basic" REs). Obsolete REs mostly exist for backward compatibility in some old programs; they will be discussed at the end. POSIX.2 leaves some aspects of RE syntax and semantics open; "†" marks decisions on these aspects that may not be fully portable to other POSIX.2 implementations.

A (modern) RE is one† or more nonempty† *branches*, separated by '|'. It matches anything that matches one of the branches.

A branch is one† or more *pieces*, concatenated. It matches a match for the first, followed by a match for the second, and so on.

A piece is an *atom* possibly followed by a single† '*', '+', '?', or *bound*. An atom followed by '*' matches a sequence of 0 or more matches of the atom. An atom followed by '+' matches a sequence of 1 or more matches of the atom. An atom followed by '?' matches a sequence of 0 or 1 matches of the atom.

A *bound* is '{' followed by an unsigned decimal integer, possibly followed by ',' possibly followed by another unsigned decimal integer, always followed by '}'. The integers must lie between 0 and **RE_DUP_MAX** (255†) inclusive, and if there are two of them, the first may not exceed the second. An atom followed by a bound containing one integer *i* and no comma matches a sequence of exactly *i* matches of the atom. An atom followed by a bound containing one integer *i* and a comma matches a sequence of *i* or more matches of the atom. An atom followed by a bound containing two integers *i* and *j* matches a sequence of *i* through *j* (inclusive) matches of the atom.

An atom is a regular expression enclosed in "*()*" (matching a match for the regular expression), an empty set of "*()*" (matching the null string)†, a *bracket expression* (see below), '.' (matching any single character), '^' (matching the null string at the beginning of a line), '$' (matching the null string at the end of a line), a '\' followed by one of the characters "^.*[$()|*+?{\" (matching that character taken as an ordinary character), a '\' followed by any other character† (matching that character taken as an ordinary character, as if the '\' had not been present†), or a single character with no other significance (matching that character). A '{' followed by a character other than a digit is an ordinary character, not the beginning of a bound†. It is illegal to end an RE with '\'.

A *bracket expression* is a list of characters enclosed in "*[]*". It normally matches any single character from the list (but see below). If the list begins with '^', it matches any single character (but see below) *not* from the rest of the list. If two characters in the list are separated by '−', this is shorthand for the full *range* of characters between those two (inclusive) in the collating sequence, for example, "*[0−9]*" in ASCII matches any decimal digit. It is illegal† for two ranges to share an endpoint, for example, "*a−c−e*". Ranges are very collating-sequence-dependent, and portable programs should avoid relying on them.

To include a literal ']' in the list, make it the first character (following a possible '^'). To include a literal '−', make it the first or last character, or the second endpoint of a range. To use a literal '−' as the first endpoint of a range, enclose it in "*[.*" and "*.]*" to make it a collating element (see below). With the exception of these and some combinations using '[' (see next paragraphs), all other special characters, including '\', lose their special significance within a bracket expression.

Within a bracket expression, a collating element (a character, a multicharacter sequence that collates as if it were a single character, or a collating-sequence name for either) enclosed in "*[.*" and "*.]*" stands for the sequence of characters of that collating element. The sequence is a single element of the bracket expression's list. A bracket expression containing a multicharacter collating element can thus match more than one character, for example, if the collating sequence includes a "ch" collating element, then the RE "*[[.ch.]]*c*" matches the first five characters of "chchcc".

Within a bracket expression, a collating element enclosed in "*[=*" and "*=]*" is an equivalence class, standing for the sequences of characters of all collating elements equivalent to that one, including itself. (If there are no other equivalent collating elements, the treatment is as if the enclosing delimiters were "*[.*" and "*.]*".) For example, if o and ô are the members of an equivalence class, then "*[[=o=]]*", "*[[=ô=]]*", and "*[oô]*" are all synonymous. An equivalence class may not† be an endpoint of a range.

Within a bracket expression, the name of a *character class* enclosed in "*[:*" and "*:]*" stands for the list of all characters belonging to that class. Standard character class names are:

alnum	digit	punct
alpha	graph	space
blank	lower	upper
cntrl	print	xdigit

These stand for the character classes defined in *wctype*(3). A locale may provide others. A character class may not be used as an endpoint of a range.

In the event that an RE could match more than one substring of a given string, the RE matches the one starting earliest in the string. If the RE could match more than one substring starting at that point, it matches the longest. Subexpressions also match the longest possible substrings, subject to the constraint that the whole match be as long as possible, with subexpressions starting earlier in the RE taking priority over ones starting later. Note that higher-level subexpressions thus take priority over their lower-level component subexpressions.

Match lengths are measured in characters, not collating elements. A null string is considered longer than no match at all. For example, "*bb**" matches the three middle characters of "abbbc", "*(wee|week)(knights|nights)*" matches all ten characters of "weeknights", when "*(.*).**" is matched against "abc" the parenthesized subexpression matches all three characters, and when "*(a*)**" is matched against "bc" both the whole RE and the parenthesized subexpression match the null string.

If case-independent matching is specified, the effect is much as if all case distinctions had vanished from the alphabet. When an alphabetic that exists in multiple cases appears as an ordinary character outside a bracket expression, it is effectively transformed into a bracket expression containing both cases, for example, 'x' becomes "*[xX]*". When it appears inside a bracket expression, all case counterparts of it are added to the bracket expression, so that, for example, "*[x]*" becomes "*[xX]*" and "*[^x]*" becomes "*[^xX]*".

No particular limit is imposed on the length of REs†. Programs intended to be portable should not employ REs longer than 256 bytes, as an implementation can refuse to accept such REs and remain POSIX-compliant.

Obsolete ("basic") regular expressions differ in several respects. '|', '+', and '?' are ordinary characters and there is no equivalent for their functionality. The delimiters for bounds are "*\{*" and "*\}*", with '{' and '}' by themselves ordinary characters. The parentheses for nested subexpressions are "*\(*" and "*\)*", with '(' and ')' by themselves ordinary characters. '^' is an ordinary character except at the beginning of the RE or† the beginning of a parenthesized subexpression, '$' is an ordinary character except at the end of the RE or† the end of a parenthesized subexpression, and '*' is an ordinary character if it appears at the beginning of the RE or the beginning of a parenthesized subexpression (after a possible leading '^').

Finally, there is one new type of atom, a *back reference*: '\' followed by a nonzero decimal digit *d* matches the same sequence of characters matched by the *d*th parenthesized subexpression (numbering subexpressions by the positions of their opening parentheses, left to right), so that, for example, "*\([bc]\)\1*" matches "bb" or "cc" but not "bc".

BUGS

Having two kinds of REs is a botch.

The current POSIX.2 spec says that ')' is an ordinary character in the absence of an unmatched '('; this was an unintentional result of a wording error, and change is likely. Avoid relying on it.

Back references are a dreadful botch, posing major problems for efficient implementations. They are also somewhat vaguely defined (does "*a\(\(b\)*\2\)*d*" match "abbbd"?). Avoid using them.

POSIX.2's specification of case-independent matching is vague. The "one case implies all cases" definition given above is current consensus among implementors as to the right interpretation.

NAME

rtld−audit − auditing API for the dynamic linker

SYNOPSIS

```
#define _GNU_SOURCE         /* See feature_test_macros(7) */
#include <link.h>
```

DESCRIPTION

The GNU dynamic linker (run-time linker) provides an auditing API that allows an application to be notified when various dynamic linking events occur. This API is very similar to the auditing interface provided by the Solaris run-time linker. The necessary constants and prototypes are defined by including *<link.h>*.

To use this interface, the programmer creates a shared library that implements a standard set of function names. Not all of the functions need to be implemented: in most cases, if the programmer is not interested in a particular class of auditing event, then no implementation needs to be provided for the corresponding auditing function.

To employ the auditing interface, the environment variable **LD_AUDIT** must be defined to contain a colon-separated list of shared libraries, each of which can implement (parts of) the auditing API. When an auditable event occurs, the corresponding function is invoked in each library, in the order that the libraries are listed.

la_version()

unsigned int la_version(unsigned int *version***);**

This is the only function that *must* be defined by an auditing library: it performs the initial handshake between the dynamic linker and the auditing library. When invoking this function, the dynamic linker passes, in *version*, the highest version of the auditing interface that the linker supports.

A typical implementation of this function simply returns the constant **LAV_CURRENT**, which indicates the version of *<link.h>* that was used to build the audit module. If the dynamic linker does not support this version of the audit interface, it will refuse to activate this audit module. If the function returns zero, the dynamic linker also does not activate this audit module.

In order to enable backwards compatibility with older dynamic linkers, an audit module can examine the *version* argument and return an earlier version than **LAV_CURRENT**, assuming the module can adjust its implementation to match the requirements of the previous version of the audit interface. The **la_version** function should not return the value of *version* without further checks because it could correspond to an interface that does not match the *<link.h>* definitions used to build the audit module.

la_objsearch()

char *la_objsearch(const char ***name*, uintptr_t ***cookie***,**
unsigned int *flag***);**

The dynamic linker invokes this function to inform the auditing library that it is about to search for a shared object. The *name* argument is the filename or pathname that is to be searched for. *cookie* identifies the shared object that initiated the search. *flag* is set to one of the following values:

LA_SER_ORIG This is the original name that is being searched for. Typically, this name comes from an ELF **DT_NEEDED** entry, or is the *filename* argument given to *dlopen*(3).

LA_SER_LIBPATH
name was created using a directory specified in **LD_LIBRARY_PATH**.

LA_SER_RUNPATH
name was created using a directory specified in an ELF **DT_RPATH** or **DT_RUNPATH** list.

LA_SER_CONFIG
name was found via the *ldconfig*(8) cache (*/etc/ld.so.cache*).

LA_SER_DEFAULT
name was found via a search of one of the default directories.

LA_SER_SECURE
name is specific to a secure object (unused on Linux).

As its function result, **la_objsearch**() returns the pathname that the dynamic linker should use for further processing. If NULL is returned, then this pathname is ignored for further processing. If this audit library simply intends to monitor search paths, then *name* should be returned.

la_activity()

void la_activity(uintptr_t **cookie*, unsigned int *flag*);

The dynamic linker calls this function to inform the auditing library that link-map activity is occurring. *cookie* identifies the object at the head of the link map. When the dynamic linker invokes this function, *flag* is set to one of the following values:

LA_ACT_ADD New objects are being added to the link map.

LA_ACT_DELETE Objects are being removed from the link map.

LA_ACT_CONSISTENT
Link-map activity has been completed: the map is once again consistent.

la_objopen()

unsigned int la_objopen(struct link_map **map*, Lmid_t *lmid*,
uintptr_t **cookie*);

The dynamic linker calls this function when a new shared object is loaded. The *map* argument is a pointer to a link-map structure that describes the object. The *lmid* field has one of the following values

LM_ID_BASE Link map is part of the initial namespace.

LM_ID_NEWLM Link map is part of a new namespace requested via *dlmopen*(3).

cookie is a pointer to an identifier for this object. The identifier is provided to later calls to functions in the auditing library in order to identify this object. This identifier is initialized to point to object's link map, but the audit library can change the identifier to some other value that it may prefer to use to identify the object.

As its return value, **la_objopen**() returns a bit mask created by ORing zero or more of the following constants, which allow the auditing library to select the objects to be monitored by **la_symbind***():

LA_FLG_BINDTO
Audit symbol bindings to this object.

LA_FLG_BINDFROM
Audit symbol bindings from this object.

A return value of 0 from **la_objopen**() indicates that no symbol bindings should be audited for this object.

la_objclose()

unsigned int la_objclose(uintptr_t **cookie*);

The dynamic linker invokes this function after any finalization code for the object has been executed, before the object is unloaded. The *cookie* argument is the identifier obtained from a previous invocation of **la_objopen**().

In the current implementation, the value returned by **la_objclose**() is ignored.

la_preinit()

void la_preinit(uintptr_t **cookie*);

The dynamic linker invokes this function after all shared objects have been loaded, before control is passed to the application (i.e., before calling *main*()). Note that *main*() may still later dynamically load objects using *dlopen*(3).

la_symbind*()

uintptr_t la_symbind32(Elf32_Sym *_sym_, unsigned int _ndx_,
uintptr_t *_refcook_, uintptr_t *_defcook_,
unsigned int * _flags_, const char *_symname_);
uintptr_t la_symbind64(Elf64_Sym *_sym_, unsigned int _ndx_,
uintptr_t *_refcook_, uintptr_t *_defcook_,
unsigned int * _flags_, const char *_symname_);

The dynamic linker invokes one of these functions when a symbol binding occurs between two shared objects that have been marked for auditing notification by **la_objopen**(). The **la_symbind32**() function is employed on 32-bit platforms; the **la_symbind64**() function is employed on 64-bit platforms.

The *sym* argument is a pointer to a structure that provides information about the symbol being bound. The structure definition is shown in <*elf.h*>. Among the fields of this structure, *st_value* indicates the address to which the symbol is bound.

The *ndx* argument gives the index of the symbol in the symbol table of the bound shared object.

The *refcook* argument identifies the shared object that is making the symbol reference; this is the same identifier that is provided to the **la_objopen**() function that returned **LA_FLG_BINDFROM**. The *defcook* argument identifies the shared object that defines the referenced symbol; this is the same identifier that is provided to the **la_objopen**() function that returned **LA_FLG_BINDTO**.

The *symname* argument points a string containing the name of the symbol.

The *flags* argument is a bit mask that both provides information about the symbol and can be used to modify further auditing of this PLT (Procedure Linkage Table) entry. The dynamic linker may supply the following bit values in this argument:

LA_SYMB_DLSYM The binding resulted from a call to *dlsym*(3).

LA_SYMB_ALTVALUE
A previous **la_symbind***() call returned an alternate value for this symbol.

By default, if the auditing library implements **la_pltenter**() and **la_pltexit**() functions (see below), then these functions are invoked, after **la_symbind**(), for PLT entries, each time the symbol is referenced. The following flags can be ORed into **flags* to change this default behavior:

LA_SYMB_NOPLTENTER
Don't call **la_pltenter**() for this symbol.

LA_SYMB_NOPLTEXIT
Don't call **la_pltexit**() for this symbol.

The return value of **la_symbind32**() and **la_symbind64**() is the address to which control should be passed after the function returns. If the auditing library is simply monitoring symbol bindings, then it should return *sym->st_value*. A different value may be returned if the library wishes to direct control to an alternate location.

la_pltenter()
The precise name and argument types for this function depend on the hardware platform. (The appropriate definition is supplied by <*link.h*>.) Here is the definition for x86-32:

Elf32_Addr la_i86_gnu_pltenter(Elf32_Sym *_sym_, unsigned int _ndx_,
uintptr_t *_refcook_, uintptr_t *_defcook_,
La_i86_regs *_regs_, unsigned int * _flags_,
const char *_symname_, long * _framesizep_);

This function is invoked just before a PLT entry is called, between two shared objects that have been marked for binding notification.

The *sym*, *ndx*, *refcook*, *defcook*, and *symname* are as for **la_symbind***().

The *regs* argument points to a structure (defined in <*link.h*>) containing the values of registers to be used for the call to this PLT entry.

The *flags* argument points to a bit mask that conveys information about, and can be used to modify subsequent auditing of, this PLT entry, as for **la_symbind***().

The *framesizep* argument points to a *long int* buffer that can be used to explicitly set the frame size used for the call to this PLT entry. If different **la_pltenter**() invocations for this symbol return different values, then the maximum returned value is used. The **la_pltexit**() function is called only if this buffer is explicitly set to a suitable value.

The return value of **la_pltenter**() is as for **la_symbind***().

la_pltexit()

The precise name and argument types for this function depend on the hardware platform. (The appropriate definition is supplied by <*link.h*>.) Here is the definition for x86-32:

unsigned int la_i86_gnu_pltexit(Elf32_Sym ***sym*, unsigned int** *ndx***,**
uintptr_t ***refcook*, uintptr_t ***defcook***,**
const La_i86_regs ***inregs*, La_i86_retval ***outregs***,**
const char ***symname*);**

This function is called when a PLT entry, made between two shared objects that have been marked for binding notification, returns. The function is called just before control returns to the caller of the PLT entry.

The *sym*, *ndx*, *refcook*, *defcook*, and *symname* are as for **la_symbind***().

The *inregs* argument points to a structure (defined in <*link.h*>) containing the values of registers used for the call to this PLT entry. The *outregs* argument points to a structure (defined in <*link.h*>) containing return values for the call to this PLT entry. These values can be modified by the caller, and the changes will be visible to the caller of the PLT entry.

In the current GNU implementation, the return value of **la_pltexit**() is ignored.

VERSIONS

This API is very similar to the Solaris API described in the Solaris *Linker and Libraries Guide*, in the chapter *Runtime Linker Auditing Interface*.

STANDARDS

None.

NOTES

Note the following differences from the Solaris dynamic linker auditing API:

- The Solaris **la_objfilter**() interface is not supported by the GNU implementation.
- The Solaris **la_symbind32**() and **la_pltexit**() functions do not provide a *symname* argument.
- The Solaris **la_pltexit**() function does not provide *inregs* and *outregs* arguments (but does provide a *retval* argument with the function return value).

BUGS

In glibc versions up to and include 2.9, specifying more than one audit library in **LD_AUDIT** results in a run-time crash. This is reportedly fixed in glibc 2.10.

EXAMPLES

```
#include <link.h>
#include <stdio.h>

unsigned int
la_version(unsigned int version)
{
    printf("la_version(): version = %u; LAV_CURRENT = %u\n",
            version, LAV_CURRENT);

    return LAV_CURRENT;
}

char *
la_objsearch(const char *name, uintptr_t *cookie, unsigned int flag)
{
    printf("la_objsearch(): name = %s; cookie = %p", name, cookie);
    printf("; flag = %s\n",
```

```
            (flag == LA_SER_ORIG) ?    "LA_SER_ORIG" :
            (flag == LA_SER_LIBPATH) ? "LA_SER_LIBPATH" :
            (flag == LA_SER_RUNPATH) ? "LA_SER_RUNPATH" :
            (flag == LA_SER_DEFAULT) ? "LA_SER_DEFAULT" :
            (flag == LA_SER_CONFIG) ?  "LA_SER_CONFIG" :
            (flag == LA_SER_SECURE) ?  "LA_SER_SECURE" :
            "???");

    return name;
}

void
la_activity (uintptr_t *cookie, unsigned int flag)
{
    printf("la_activity(): cookie = %p; flag = %s\n", cookie,
            (flag == LA_ACT_CONSISTENT) ? "LA_ACT_CONSISTENT" :
            (flag == LA_ACT_ADD) ?        "LA_ACT_ADD" :
            (flag == LA_ACT_DELETE) ?     "LA_ACT_DELETE" :
            "???");
}

unsigned int
la_objopen(struct link_map *map, Lmid_t lmid, uintptr_t *cookie)
{
    printf("la_objopen(): loading \"%s\"; lmid = %s; cookie=%p\n",
            map->l_name,
            (lmid == LM_ID_BASE) ?  "LM_ID_BASE" :
            (lmid == LM_ID_NEWLM) ? "LM_ID_NEWLM" :
            "???",
            cookie);

    return LA_FLG_BINDTO | LA_FLG_BINDFROM;
}

unsigned int
la_objclose (uintptr_t *cookie)
{
    printf("la_objclose(): %p\n", cookie);

    return 0;
}

void
la_preinit(uintptr_t *cookie)
{
    printf("la_preinit(): %p\n", cookie);
}

uintptr_t
la_symbind32(Elf32_Sym *sym, unsigned int ndx, uintptr_t *refcook,
        uintptr_t *defcook, unsigned int *flags, const char *symname)
{
    printf("la_symbind32(): symname = %s; sym->st_value = %p\n",
            symname, sym->st_value);
    printf("        ndx = %u; flags = %#x", ndx, *flags);
    printf("; refcook = %p; defcook = %p\n", refcook, defcook);

    return sym->st_value;
}
```

```
uintptr_t
la_symbind64(Elf64_Sym *sym, unsigned int ndx, uintptr_t *refcook,
        uintptr_t *defcook, unsigned int *flags, const char *symname)
{
    printf("la_symbind64(): symname = %s; sym->st_value = %p\n",
            symname, sym->st_value);
    printf("        ndx = %u; flags = %#x", ndx, *flags);
    printf("; refcook = %p; defcook = %p\n", refcook, defcook);

    return sym->st_value;
}

Elf32_Addr
la_i86_gnu_pltenter(Elf32_Sym *sym, unsigned int ndx,
        uintptr_t *refcook, uintptr_t *defcook, La_i86_regs *regs,
        unsigned int *flags, const char *symname, long *framesizep)
{
    printf("la_i86_gnu_pltenter(): %s (%p)\n", symname, sym->st_value);

    return sym->st_value;
}
```

NAME

rtnetlink − Linux routing socket

SYNOPSIS

#include <asm/types.h>
#include <linux/netlink.h>
#include <linux/rtnetlink.h>
#include <sys/socket.h>

rtnetlink_socket = socket(AF_NETLINK, int *socket_type***, NETLINK_ROUTE);**

DESCRIPTION

Rtnetlink allows the kernel's routing tables to be read and altered. It is used within the kernel to communicate between various subsystems, though this usage is not documented here, and for communication with user-space programs. Network routes, IP addresses, link parameters, neighbor setups, queueing disciplines, traffic classes and packet classifiers may all be controlled through **NETLINK_ROUTE** sockets. It is based on netlink messages; see *netlink*(7) for more information.

Routing attributes

Some rtnetlink messages have optional attributes after the initial header:

```
struct rtattr {
    unsigned short rta_len;    /* Length of option */
    unsigned short rta_type;   /* Type of option */
    /* Data follows */
};
```

These attributes should be manipulated using only the RTA_* macros or libnetlink, see *rtnetlink*(3).

Messages

Rtnetlink consists of these message types (in addition to standard netlink messages):

RTM_NEWLINK
RTM_DELLINK
RTM_GETLINK

Create, remove, or get information about a specific network interface. These messages contain an *ifinfomsg* structure followed by a series of *rtattr* structures.

```
struct ifinfomsg {
    unsigned char  ifi_family; /* AF_UNSPEC */
    unsigned short ifi_type;   /* Device type */
    int            ifi_index;  /* Interface index */
    unsigned int   ifi_flags;  /* Device flags  */
    unsigned int   ifi_change; /* change mask */
};
```

ifi_flags contains the device flags, see *netdevice*(7); *ifi_index* is the unique interface index (since Linux 3.7, it is possible to feed a nonzero value with the **RTM_NEWLINK** message, thus creating a link with the given *ifindex*); *ifi_change* is reserved for future use and should be always set to 0xFFFFFFFF.

Routing attributes

rta_type	Value type	Description
IFLA_UNSPEC	-	unspecified
IFLA_ADDRESS	hardware address	interface L2 address
IFLA_BROADCAST	hardware address	L2 broadcast address
IFLA_IFNAME	asciiz string	Device name
IFLA_MTU	unsigned int	MTU of the device
IFLA_LINK	int	Link type
IFLA_QDISC	asciiz string	Queueing discipline
IFLA_STATS	see below	Interface Statistics
IFLA_PERM_ADDRESS	hardware address	hardware address provided by device (since Linux 5.5)

The value type for **IFLA_STATS** is *struct rtnl_link_stats* (*struct net_device_stats* in Linux 2.4 and earlier).

RTM_NEWADDR
RTM_DELADDR
RTM_GETADDR

Add, remove, or receive information about an IP address associated with an interface. In Linux 2.2, an interface can carry multiple IP addresses, this replaces the alias device concept in Linux 2.0. In Linux 2.2, these messages support IPv4 and IPv6 addresses. They contain an *ifaddrmsg* structure, optionally followed by *rtattr* routing attributes.

```
struct ifaddrmsg {
    unsigned char ifa_family;    /* Address type */
    unsigned char ifa_prefixlen; /* Prefixlength of address */
    unsigned char ifa_flags;     /* Address flags */
    unsigned char ifa_scope;     /* Address scope */
    unsigned int  ifa_index;     /* Interface index */
};
```

ifa_family is the address family type (currently **AF_INET** or **AF_INET6**), *ifa_prefixlen* is the length of the address mask of the address if defined for the family (like for IPv4), *ifa_scope* is the address scope, *ifa_index* is the interface index of the interface the address is associated with. *ifa_flags* is a flag word of **IFA_F_SECONDARY** for secondary address (old alias interface), **IFA_F_PERMANENT** for a permanent address set by the user and other undocumented flags.

Attributes

rta_type	Value type	Description
IFA_UNSPEC	-	unspecified
IFA_ADDRESS	raw protocol address	interface address
IFA_LOCAL	raw protocol address	local address
IFA_LABEL	asciiz string	name of the interface
IFA_BROADCAST	raw protocol address	broadcast address
IFA_ANYCAST	raw protocol address	anycast address
IFA_CACHEINFO	struct ifa_cacheinfo	Address information

RTM_NEWROUTE
RTM_DELROUTE
RTM_GETROUTE

Create, remove, or receive information about a network route. These messages contain an *rtmsg* structure with an optional sequence of *rtattr* structures following. For **RTM_GETROUTE**, setting *rtm_dst_len* and *rtm_src_len* to 0 means you get all entries for the specified routing table. For the other fields, except *rtm_table* and *rtm_protocol*, 0 is the wildcard.

```
struct rtmsg {
    unsigned char rtm_family;   /* Address family of route */
    unsigned char rtm_dst_len;  /* Length of destination */
    unsigned char rtm_src_len;  /* Length of source */
    unsigned char rtm_tos;      /* TOS filter */
    unsigned char rtm_table;    /* Routing table ID;
                                   see RTA_TABLE below */
    unsigned char rtm_protocol; /* Routing protocol; see below */
    unsigned char rtm_scope;    /* See below */
    unsigned char rtm_type;     /* See below */

    unsigned int  rtm_flags;
};
```

rtm_type	Route type
RTN_UNSPEC	unknown route
RTN_UNICAST	a gateway or direct route
RTN_LOCAL	a local interface route
RTN_BROADCAST	a local broadcast route (sent as a broadcast)

RTN_ANYCAST	a local broadcast route (sent as a unicast)
RTN_MULTICAST	a multicast route
RTN_BLACKHOLE	a packet dropping route
RTN_UNREACHABLE	an unreachable destination
RTN_PROHIBIT	a packet rejection route
RTN_THROW	continue routing lookup in another table
RTN_NAT	a network address translation rule
RTN_XRESOLVE	refer to an external resolver (not implemented)

rtm_protocol	Route origin
RTPROT_UNSPEC	unknown
RTPROT_REDIRECT	by an ICMP redirect (currently unused)
RTPROT_KERNEL	by the kernel
RTPROT_BOOT	during boot
RTPROT_STATIC	by the administrator

Values larger than **RTPROT_STATIC** are not interpreted by the kernel, they are just for user information. They may be used to tag the source of a routing information or to distinguish between multiple routing daemons. See <*linux/rtnetlink.h*> for the routing daemon identifiers which are already assigned.

rtm_scope is the distance to the destination:

RT_SCOPE_UNIVERSE	global route
RT_SCOPE_SITE	interior route in the local autonomous system
RT_SCOPE_LINK	route on this link
RT_SCOPE_HOST	route on the local host
RT_SCOPE_NOWHERE	destination doesn't exist

The values between **RT_SCOPE_UNIVERSE** and **RT_SCOPE_SITE** are available to the user.

The *rtm_flags* have the following meanings:

RTM_F_NOTIFY	if the route changes, notify the user via rtnetlink
RTM_F_CLONED	route is cloned from another route
RTM_F_EQUALIZE	a multipath equalizer (not yet implemented)

rtm_table specifies the routing table

RT_TABLE_UNSPEC	an unspecified routing table
RT_TABLE_DEFAULT	the default table
RT_TABLE_MAIN	the main table
RT_TABLE_LOCAL	the local table

The user may assign arbitrary values between **RT_TABLE_UNSPEC** and **RT_TABLE_DEFAULT**.

Attributes

rta_type	Value type	Description
RTA_UNSPEC	-	ignored
RTA_DST	protocol address	Route destination address
RTA_SRC	protocol address	Route source address
RTA_IIF	int	Input interface index
RTA_OIF	int	Output interface index
RTA_GATEWAY	protocol address	The gateway of the route
RTA_PRIORITY	int	Priority of route
RTA_PREFSRC	protocol address	Preferred source address
RTA_METRICS	int	Route metric
RTA_MULTIPATH		Multipath nexthop data br (see below).
RTA_PROTOINFO		No longer used
RTA_FLOW	int	Route realm
RTA_CACHEINFO	struct rta_cacheinfo	(see linux/rtnetlink.h)
RTA_SESSION		No longer used
RTA_MP_ALGO		No longer used
RTA_TABLE	int	Routing table ID; if set, rtm_table is ignored
RTA_MARK	int	
RTA_MFC_STATS	struct rta_mfc_stats	(see linux/rtnetlink.h)
RTA_VIA	struct rtvia	Gateway in different AF (see below)
RTA_NEWDST	protocol address	Change packet destination address
RTA_PREF	char	RFC4191 IPv6 router preference (see below)
RTA_ENCAP_TYPE	short	Encapsulation type for lwtunnels (see below)
RTA_ENCAP		Defined by RTA_ENCAP_TYPE
RTA_EXPIRES	int	Expire time for IPv6 routes (in seconds)

RTA_MULTIPATH contains several packed instances of *struct rtnexthop* together with nested RTAs (**RTA_GATEWAY**):

```
struct rtnexthop {
    unsigned short rtnh_len;     /* Length of struct + length
                                    of RTAs */
    unsigned char  rtnh_flags;   /* Flags (see
                                    linux/rtnetlink.h) */
    unsigned char  rtnh_hops;    /* Nexthop priority */
    int            rtnh_ifindex; /* Interface index for this
                                    nexthop */
}
```

There exist a bunch of **RTNH_*** macros similar to **RTA_*** and **NLHDR_*** macros useful to handle these structures.

```
struct rtvia {
    unsigned short rtvia_family;
    unsigned char  rtvia_addr[0];
};
```

rtvia_addr is the address, *rtvia_family* is its family type.

RTA_PREF may contain values **ICMPV6_ROUTER_PREF_LOW**, **ICMPV6_ROUTER_PREF_MEDIUM**, and **ICMPV6_ROUTER_PREF_HIGH** defined incw <*linux/icmpv6.h*>.

RTA_ENCAP_TYPE may contain values **LWTUNNEL_ENCAP_MPLS**, **LWTUNNEL_ENCAP_IP**, **LWTUNNEL_ENCAP_ILA**, or **LWTUNNEL_ENCAP_IP6** defined in

<*linux/lwtunnel.h*>.

Fill these values in!

RTM_NEWNEIGH
RTM_DELNEIGH
RTM_GETNEIGH

Add, remove, or receive information about a neighbor table entry (e.g., an ARP entry). The message contains an *ndmsg* structure.

```
struct ndmsg {
    unsigned char ndm_family;
    int           ndm_ifindex;  /* Interface index */
    __u16         ndm_state;    /* State */
    __u8          ndm_flags;    /* Flags */
    __u8          ndm_type;
};

struct nda_cacheinfo {
    __u32         ndm_confirmed;
    __u32         ndm_used;
    __u32         ndm_updated;
    __u32         ndm_refcnt;
};
```

ndm_state is a bit mask of the following states:

NUD_INCOMPLETE a currently resolving cache entry
NUD_REACHABLE a confirmed working cache entry
NUD_STALE an expired cache entry
NUD_DELAY an entry waiting for a timer
NUD_PROBE a cache entry that is currently reprobed
NUD_FAILED an invalid cache entry
NUD_NOARP a device with no destination cache
NUD_PERMANENT a static entry

Valid *ndm_flags* are:

NTF_PROXY a proxy arp entry
NTF_ROUTER an IPv6 router

The *rtattr* struct has the following meanings for the *rta_type* field:

NDA_UNSPEC unknown type
NDA_DST a neighbor cache n/w layer destination address
NDA_LLADDR a neighbor cache link layer address
NDA_CACHEINFO cache statistics

If the *rta_type* field is **NDA_CACHEINFO**, then a *struct nda_cacheinfo* header follows.

RTM_NEWRULE
RTM_DELRULE
RTM_GETRULE

Add, delete, or retrieve a routing rule. Carries a *struct rtmsg*

RTM_NEWQDISC
RTM_DELQDISC
RTM_GETQDISC

Add, remove, or get a queueing discipline. The message contains a *struct tcmsg* and may be followed by a series of attributes.

```
struct tcmsg {
    unsigned char    tcm_family;
    int              tcm_ifindex;   /* interface index */
    __u32            tcm_handle;    /* Qdisc handle */
    __u32            tcm_parent;    /* Parent qdisc */
    __u32            tcm_info;
};
```

Attributes

rta_type	Value type	Description
TCA_UNSPEC	-	unspecified
TCA_KIND	asciiz string	Name of queueing discipline
TCA_OPTIONS	byte sequence	Qdisc-specific options follow
TCA_STATS	struct tc_stats	Qdisc statistics
TCA_XSTATS	qdisc-specific	Module-specific statistics
TCA_RATE	struct tc_estimator	Rate limit

In addition, various other qdisc-module-specific attributes are allowed. For more information see the appropriate include files.

RTM_NEWTCLASS
RTM_DELTCLASS
RTM_GETTCLASS
Add, remove, or get a traffic class. These messages contain a *struct tcmsg* as described above.

RTM_NEWTFILTER
RTM_DELTFILTER
RTM_GETTFILTER
Add, remove, or receive information about a traffic filter. These messages contain a *struct tcmsg* as described above.

VERSIONS

rtnetlink is a new feature of Linux 2.2.

NAME

sched − overview of CPU scheduling

DESCRIPTION

Since Linux 2.6.23, the default scheduler is CFS, the "Completely Fair Scheduler". The CFS scheduler replaced the earlier "O(1)" scheduler.

API summary

Linux provides the following system calls for controlling the CPU scheduling behavior, policy, and priority of processes (or, more precisely, threads).

nice(2) Set a new nice value for the calling thread, and return the new nice value.

getpriority(2)
: Return the nice value of a thread, a process group, or the set of threads owned by a specified user.

setpriority(2)
: Set the nice value of a thread, a process group, or the set of threads owned by a specified user.

sched_setscheduler(2)
: Set the scheduling policy and parameters of a specified thread.

sched_getscheduler(2)
: Return the scheduling policy of a specified thread.

sched_setparam(2)
: Set the scheduling parameters of a specified thread.

sched_getparam(2)
: Fetch the scheduling parameters of a specified thread.

sched_get_priority_max(2)
: Return the maximum priority available in a specified scheduling policy.

sched_get_priority_min(2)
: Return the minimum priority available in a specified scheduling policy.

sched_rr_get_interval(2)
: Fetch the quantum used for threads that are scheduled under the "round-robin" scheduling policy.

sched_yield(2)
: Cause the caller to relinquish the CPU, so that some other thread be executed.

sched_setaffinity(2)
: (Linux-specific) Set the CPU affinity of a specified thread.

sched_getaffinity(2)
: (Linux-specific) Get the CPU affinity of a specified thread.

sched_setattr(2)
: Set the scheduling policy and parameters of a specified thread. This (Linux-specific) system call provides a superset of the functionality of *sched_setscheduler*(2) and *sched_setparam*(2).

sched_getattr(2)
: Fetch the scheduling policy and parameters of a specified thread. This (Linux-specific) system call provides a superset of the functionality of *sched_getscheduler*(2) and *sched_getparam*(2).

Scheduling policies

The scheduler is the kernel component that decides which runnable thread will be executed by the CPU next. Each thread has an associated scheduling policy and a *static* scheduling priority, *sched_priority*. The scheduler makes its decisions based on knowledge of the scheduling policy and static priority of all threads on the system.

For threads scheduled under one of the normal scheduling policies (**SCHED_OTHER**, **SCHED_IDLE**, **SCHED_BATCH**), *sched_priority* is not used in scheduling decisions (it must be specified as 0).

Processes scheduled under one of the real-time policies (**SCHED_FIFO**, **SCHED_RR**) have a *sched_priority* value in the range 1 (low) to 99 (high). (As the numbers imply, real-time threads always

have higher priority than normal threads.) Note well: POSIX.1 requires an implementation to support only a minimum 32 distinct priority levels for the real-time policies, and some systems supply just this minimum. Portable programs should use *sched_get_priority_min*(2) and *sched_get_priority_max*(2) to find the range of priorities supported for a particular policy.

Conceptually, the scheduler maintains a list of runnable threads for each possible *sched_priority* value. In order to determine which thread runs next, the scheduler looks for the nonempty list with the highest static priority and selects the thread at the head of this list.

A thread's scheduling policy determines where it will be inserted into the list of threads with equal static priority and how it will move inside this list.

All scheduling is preemptive: if a thread with a higher static priority becomes ready to run, the currently running thread will be preempted and returned to the wait list for its static priority level. The scheduling policy determines the ordering only within the list of runnable threads with equal static priority.

SCHED_FIFO: First in-first out scheduling

SCHED_FIFO can be used only with static priorities higher than 0, which means that when a **SCHED_FIFO** thread becomes runnable, it will always immediately preempt any currently running **SCHED_OTHER**, **SCHED_BATCH**, or **SCHED_IDLE** thread. **SCHED_FIFO** is a simple scheduling algorithm without time slicing. For threads scheduled under the **SCHED_FIFO** policy, the following rules apply:

- A running **SCHED_FIFO** thread that has been preempted by another thread of higher priority will stay at the head of the list for its priority and will resume execution as soon as all threads of higher priority are blocked again.
- When a blocked **SCHED_FIFO** thread becomes runnable, it will be inserted at the end of the list for its priority.
- If a call to *sched_setscheduler*(2), *sched_setparam*(2), *sched_setattr*(2), *pthread_setschedparam*(3), or *pthread_setschedprio*(3) changes the priority of the running or runnable **SCHED_FIFO** thread identified by *pid* the effect on the thread's position in the list depends on the direction of the change to the thread's priority:

  (a) If the thread's priority is raised, it is placed at the end of the list for its new priority. As a consequence, it may preempt a currently running thread with the same priority.

  (b) If the thread's priority is unchanged, its position in the run list is unchanged.

  (c) If the thread's priority is lowered, it is placed at the front of the list for its new priority.

  According to POSIX.1-2008, changes to a thread's priority (or policy) using any mechanism other than *pthread_setschedprio*(3) should result in the thread being placed at the end of the list for its priority.
- A thread calling *sched_yield*(2) will be put at the end of the list.

No other events will move a thread scheduled under the **SCHED_FIFO** policy in the wait list of runnable threads with equal static priority.

A **SCHED_FIFO** thread runs until either it is blocked by an I/O request, it is preempted by a higher priority thread, or it calls *sched_yield*(2).

SCHED_RR: Round-robin scheduling

SCHED_RR is a simple enhancement of **SCHED_FIFO**. Everything described above for **SCHED_FIFO** also applies to **SCHED_RR**, except that each thread is allowed to run only for a maximum time quantum. If a **SCHED_RR** thread has been running for a time period equal to or longer than the time quantum, it will be put at the end of the list for its priority. A **SCHED_RR** thread that has been preempted by a higher priority thread and subsequently resumes execution as a running thread will complete the unexpired portion of its round-robin time quantum. The length of the time quantum can be retrieved using *sched_rr_get_interval*(2).

SCHED_DEADLINE: Sporadic task model deadline scheduling

Since Linux 3.14, Linux provides a deadline scheduling policy (**SCHED_DEADLINE**). This policy is currently implemented using GEDF (Global Earliest Deadline First) in conjunction with CBS (Constant Bandwidth Server). To set and fetch this policy and associated attributes, one must use the Linux-

specific *sched_setattr*(2) and *sched_getattr*(2) system calls.

A sporadic task is one that has a sequence of jobs, where each job is activated at most once per period. Each job also has a *relative deadline*, before which it should finish execution, and a *computation time*, which is the CPU time necessary for executing the job. The moment when a task wakes up because a new job has to be executed is called the *arrival time* (also referred to as the request time or release time). The *start time* is the time at which a task starts its execution. The *absolute deadline* is thus obtained by adding the relative deadline to the arrival time.

The following diagram clarifies these terms:

```
arrival/wakeup                    absolute deadline
     |    start time                    |
     |        |                        |
     v        v                        v
-----x--------xooooooooooooooooo--------x--------x---
              |<- comp. time ->|
     |<------- relative deadline ------>|
     |<-------------- period ------------------>|
```

When setting a **SCHED_DEADLINE** policy for a thread using *sched_setattr*(2), one can specify three parameters: *Runtime*, *Deadline*, and *Period*. These parameters do not necessarily correspond to the aforementioned terms: usual practice is to set Runtime to something bigger than the average computation time (or worst-case execution time for hard real-time tasks), Deadline to the relative deadline, and Period to the period of the task. Thus, for **SCHED_DEADLINE** scheduling, we have:

```
arrival/wakeup                    absolute deadline
     |    start time                    |
     |        |                        |
     v        v                        v
-----x--------xooooooooooooooooo--------x--------x---
              |<-- Runtime ------->|
     |<----------- Deadline ----------->|
     |<-------------- Period ------------------>|
```

The three deadline-scheduling parameters correspond to the *sched_runtime*, *sched_deadline*, and *sched_period* fields of the *sched_attr* structure; see *sched_setattr*(2). These fields express values in nanoseconds. If *sched_period* is specified as 0, then it is made the same as *sched_deadline*.

The kernel requires that:

```
sched_runtime <= sched_deadline <= sched_period
```

In addition, under the current implementation, all of the parameter values must be at least 1024 (i.e., just over one microsecond, which is the resolution of the implementation), and less than 2^63. If any of these checks fails, *sched_setattr*(2) fails with the error **EINVAL**.

The CBS guarantees non-interference between tasks, by throttling threads that attempt to over-run their specified Runtime.

To ensure deadline scheduling guarantees, the kernel must prevent situations where the set of **SCHED_DEADLINE** threads is not feasible (schedulable) within the given constraints. The kernel thus performs an admittance test when setting or changing **SCHED_DEADLINE** policy and attributes. This admission test calculates whether the change is feasible; if it is not, *sched_setattr*(2) fails with the error **EBUSY**.

For example, it is required (but not necessarily sufficient) for the total utilization to be less than or equal to the total number of CPUs available, where, since each thread can maximally run for Runtime per Period, that thread's utilization is its Runtime divided by its Period.

In order to fulfill the guarantees that are made when a thread is admitted to the **SCHED_DEADLINE** policy, **SCHED_DEADLINE** threads are the highest priority (user controllable) threads in the system; if any **SCHED_DEADLINE** thread is runnable, it will preempt any thread scheduled under one of the other policies.

A call to *fork*(2) by a thread scheduled under the **SCHED_DEADLINE** policy fails with the error **EAGAIN**, unless the thread has its reset-on-fork flag set (see below).

A **SCHED_DEADLINE** thread that calls *sched_yield*(2) will yield the current job and wait for a new period to begin.

SCHED_OTHER: Default Linux time-sharing scheduling

SCHED_OTHER can be used at only static priority 0 (i.e., threads under real-time policies always have priority over **SCHED_OTHER** processes). **SCHED_OTHER** is the standard Linux time-sharing scheduler that is intended for all threads that do not require the special real-time mechanisms.

The thread to run is chosen from the static priority 0 list based on a *dynamic* priority that is determined only inside this list. The dynamic priority is based on the nice value (see below) and is increased for each time quantum the thread is ready to run, but denied to run by the scheduler. This ensures fair progress among all **SCHED_OTHER** threads.

In the Linux kernel source code, the **SCHED_OTHER** policy is actually named **SCHED_NORMAL**.

The nice value

The nice value is an attribute that can be used to influence the CPU scheduler to favor or disfavor a process in scheduling decisions. It affects the scheduling of **SCHED_OTHER** and **SCHED_BATCH** (see below) processes. The nice value can be modified using *nice*(2), *setpriority*(2), or *sched_setattr*(2).

According to POSIX.1, the nice value is a per-process attribute; that is, the threads in a process should share a nice value. However, on Linux, the nice value is a per-thread attribute: different threads in the same process may have different nice values.

The range of the nice value varies across UNIX systems. On modern Linux, the range is −20 (high priority) to +19 (low priority). On some other systems, the range is −20..20. Very early Linux kernels (before Linux 2.0) had the range −infinity..15.

The degree to which the nice value affects the relative scheduling of **SCHED_OTHER** processes likewise varies across UNIX systems and across Linux kernel versions.

With the advent of the CFS scheduler in Linux 2.6.23, Linux adopted an algorithm that causes relative differences in nice values to have a much stronger effect. In the current implementation, each unit of difference in the nice values of two processes results in a factor of 1.25 in the degree to which the scheduler favors the higher priority process. This causes very low nice values (+19) to truly provide little CPU to a process whenever there is any other higher priority load on the system, and makes high nice values (−20) deliver most of the CPU to applications that require it (e.g., some audio applications).

On Linux, the **RLIMIT_NICE** resource limit can be used to define a limit to which an unprivileged process's nice value can be raised; see *setrlimit*(2) for details.

For further details on the nice value, see the subsections on the autogroup feature and group scheduling, below.

SCHED_BATCH: Scheduling batch processes

(Since Linux 2.6.16.) **SCHED_BATCH** can be used only at static priority 0. This policy is similar to **SCHED_OTHER** in that it schedules the thread according to its dynamic priority (based on the nice value). The difference is that this policy will cause the scheduler to always assume that the thread is CPU-intensive. Consequently, the scheduler will apply a small scheduling penalty with respect to wakeup behavior, so that this thread is mildly disfavored in scheduling decisions.

This policy is useful for workloads that are noninteractive, but do not want to lower their nice value, and for workloads that want a deterministic scheduling policy without interactivity causing extra preemptions (between the workload's tasks).

SCHED_IDLE: Scheduling very low priority jobs

(Since Linux 2.6.23.) **SCHED_IDLE** can be used only at static priority 0; the process nice value has no influence for this policy.

This policy is intended for running jobs at extremely low priority (lower even than a +19 nice value with the **SCHED_OTHER** or **SCHED_BATCH** policies).

Resetting scheduling policy for child processes

Each thread has a reset-on-fork scheduling flag. When this flag is set, children created by *fork*(2) do not inherit privileged scheduling policies. The reset-on-fork flag can be set by either:

- ORing the **SCHED_RESET_ON_FORK** flag into the *policy* argument when calling *sched_setscheduler*(2) (since Linux 2.6.32); or
- specifying the **SCHED_FLAG_RESET_ON_FORK** flag in *attr.sched_flags* when calling *sched_setattr*(2).

Note that the constants used with these two APIs have different names. The state of the reset-on-fork flag can analogously be retrieved using *sched_getscheduler*(2) and *sched_getattr*(2).

The reset-on-fork feature is intended for media-playback applications, and can be used to prevent applications evading the **RLIMIT_RTTIME** resource limit (see *getrlimit*(2)) by creating multiple child processes.

More precisely, if the reset-on-fork flag is set, the following rules apply for subsequently created children:

- If the calling thread has a scheduling policy of **SCHED_FIFO** or **SCHED_RR**, the policy is reset to **SCHED_OTHER** in child processes.
- If the calling process has a negative nice value, the nice value is reset to zero in child processes.

After the reset-on-fork flag has been enabled, it can be reset only if the thread has the **CAP_SYS_NICE** capability. This flag is disabled in child processes created by *fork*(2).

Privileges and resource limits

Before Linux 2.6.12, only privileged (**CAP_SYS_NICE**) threads can set a nonzero static priority (i.e., set a real-time scheduling policy). The only change that an unprivileged thread can make is to set the **SCHED_OTHER** policy, and this can be done only if the effective user ID of the caller matches the real or effective user ID of the target thread (i.e., the thread specified by *pid*) whose policy is being changed.

A thread must be privileged (**CAP_SYS_NICE**) in order to set or modify a **SCHED_DEADLINE** policy.

Since Linux 2.6.12, the **RLIMIT_RTPRIO** resource limit defines a ceiling on an unprivileged thread's static priority for the **SCHED_RR** and **SCHED_FIFO** policies. The rules for changing scheduling policy and priority are as follows:

- If an unprivileged thread has a nonzero **RLIMIT_RTPRIO** soft limit, then it can change its scheduling policy and priority, subject to the restriction that the priority cannot be set to a value higher than the maximum of its current priority and its **RLIMIT_RTPRIO** soft limit.
- If the **RLIMIT_RTPRIO** soft limit is 0, then the only permitted changes are to lower the priority, or to switch to a non-real-time policy.
- Subject to the same rules, another unprivileged thread can also make these changes, as long as the effective user ID of the thread making the change matches the real or effective user ID of the target thread.
- Special rules apply for the **SCHED_IDLE** policy. Before Linux 2.6.39, an unprivileged thread operating under this policy cannot change its policy, regardless of the value of its **RLIMIT_RTPRIO** resource limit. Since Linux 2.6.39, an unprivileged thread can switch to either the **SCHED_BATCH** or the **SCHED_OTHER** policy so long as its nice value falls within the range permitted by its **RLIMIT_NICE** resource limit (see *getrlimit*(2)).

Privileged (**CAP_SYS_NICE**) threads ignore the **RLIMIT_RTPRIO** limit; as with older kernels, they can make arbitrary changes to scheduling policy and priority. See *getrlimit*(2) for further information on **RLIMIT_RTPRIO**.

Limiting the CPU usage of real-time and deadline processes

A nonblocking infinite loop in a thread scheduled under the **SCHED_FIFO**, **SCHED_RR**, or **SCHED_DEADLINE** policy can potentially block all other threads from accessing the CPU forever. Before Linux 2.6.25, the only way of preventing a runaway real-time process from freezing the system was to run (at the console) a shell scheduled under a higher static priority than the tested application. This allows an emergency kill of tested real-time applications that do not block or terminate as expected.

Since Linux 2.6.25, there are other techniques for dealing with runaway real-time and deadline processes. One of these is to use the **RLIMIT_RTTIME** resource limit to set a ceiling on the CPU

time that a real-time process may consume. See *getrlimit*(2) for details.

Since Linux 2.6.25, Linux also provides two */proc* files that can be used to reserve a certain amount of CPU time to be used by non-real-time processes. Reserving CPU time in this fashion allows some CPU time to be allocated to (say) a root shell that can be used to kill a runaway process. Both of these files specify time values in microseconds:

/proc/sys/kernel/sched_rt_period_us
: This file specifies a scheduling period that is equivalent to 100% CPU bandwidth. The value in this file can range from 1 to **INT_MAX**, giving an operating range of 1 microsecond to around 35 minutes. The default value in this file is 1,000,000 (1 second).

/proc/sys/kernel/sched_rt_runtime_us
: The value in this file specifies how much of the "period" time can be used by all real-time and deadline scheduled processes on the system. The value in this file can range from −1 to **INT_MAX**-1. Specifying −1 makes the run time the same as the period; that is, no CPU time is set aside for non-real-time processes (which was the behavior before Linux 2.6.25). The default value in this file is 950,000 (0.95 seconds), meaning that 5% of the CPU time is reserved for processes that don't run under a real-time or deadline scheduling policy.

Response time

A blocked high priority thread waiting for I/O has a certain response time before it is scheduled again. The device driver writer can greatly reduce this response time by using a "slow interrupt" interrupt handler.

Miscellaneous

Child processes inherit the scheduling policy and parameters across a *fork*(2). The scheduling policy and parameters are preserved across *execve*(2).

Memory locking is usually needed for real-time processes to avoid paging delays; this can be done with *mlock*(2) or *mlockall*(2).

The autogroup feature

Since Linux 2.6.38, the kernel provides a feature known as autogrouping to improve interactive desktop performance in the face of multiprocess, CPU-intensive workloads such as building the Linux kernel with large numbers of parallel build processes (i.e., the *make*(1) **−j** flag).

This feature operates in conjunction with the CFS scheduler and requires a kernel that is configured with **CONFIG_SCHED_AUTOGROUP**. On a running system, this feature is enabled or disabled via the file */proc/sys/kernel/sched_autogroup_enabled*; a value of 0 disables the feature, while a value of 1 enables it. The default value in this file is 1, unless the kernel was booted with the *noautogroup* parameter.

A new autogroup is created when a new session is created via *setsid*(2); this happens, for example, when a new terminal window is started. A new process created by *fork*(2) inherits its parent's autogroup membership. Thus, all of the processes in a session are members of the same autogroup. An autogroup is automatically destroyed when the last process in the group terminates.

When autogrouping is enabled, all of the members of an autogroup are placed in the same kernel scheduler "task group". The CFS scheduler employs an algorithm that equalizes the distribution of CPU cycles across task groups. The benefits of this for interactive desktop performance can be described via the following example.

Suppose that there are two autogroups competing for the same CPU (i.e., presume either a single CPU system or the use of *taskset*(1) to confine all the processes to the same CPU on an SMP system). The first group contains ten CPU-bound processes from a kernel build started with *make −j10*. The other contains a single CPU-bound process: a video player. The effect of autogrouping is that the two groups will each receive half of the CPU cycles. That is, the video player will receive 50% of the CPU cycles, rather than just 9% of the cycles, which would likely lead to degraded video playback. The situation on an SMP system is more complex, but the general effect is the same: the scheduler distributes CPU cycles across task groups such that an autogroup that contains a large number of CPU-bound processes does not end up hogging CPU cycles at the expense of the other jobs on the system.

A process's autogroup (task group) membership can be viewed via the file */proc/*pid*/autogroup*:

```
$ cat /proc/1/autogroup
```

```
/autogroup-1 nice 0
```

This file can also be used to modify the CPU bandwidth allocated to an autogroup. This is done by writing a number in the "nice" range to the file to set the autogroup's nice value. The allowed range is from +19 (low priority) to −20 (high priority). (Writing values outside of this range causes *write*(2) to fail with the error **EINVAL**.)

The autogroup nice setting has the same meaning as the process nice value, but applies to distribution of CPU cycles to the autogroup as a whole, based on the relative nice values of other autogroups. For a process inside an autogroup, the CPU cycles that it receives will be a product of the autogroup's nice value (compared to other autogroups) and the process's nice value (compared to other processes in the same autogroup.

The use of the *cgroups*(7) CPU controller to place processes in cgroups other than the root CPU cgroup overrides the effect of autogrouping.

The autogroup feature groups only processes scheduled under non-real-time policies (**SCHED_OTHER**, **SCHED_BATCH**, and **SCHED_IDLE**). It does not group processes scheduled under real-time and deadline policies. Those processes are scheduled according to the rules described earlier.

The nice value and group scheduling

When scheduling non-real-time processes (i.e., those scheduled under the **SCHED_OTHER**, **SCHED_BATCH**, and **SCHED_IDLE** policies), the CFS scheduler employs a technique known as "group scheduling", if the kernel was configured with the **CONFIG_FAIR_GROUP_SCHED** option (which is typical).

Under group scheduling, threads are scheduled in "task groups". Task groups have a hierarchical relationship, rooted under the initial task group on the system, known as the "root task group". Task groups are formed in the following circumstances:

- All of the threads in a CPU cgroup form a task group. The parent of this task group is the task group of the corresponding parent cgroup.
- If autogrouping is enabled, then all of the threads that are (implicitly) placed in an autogroup (i.e., the same session, as created by *setsid*(2)) form a task group. Each new autogroup is thus a separate task group. The root task group is the parent of all such autogroups.
- If autogrouping is enabled, then the root task group consists of all processes in the root CPU cgroup that were not otherwise implicitly placed into a new autogroup.
- If autogrouping is disabled, then the root task group consists of all processes in the root CPU cgroup.
- If group scheduling was disabled (i.e., the kernel was configured without **CONFIG_FAIR_GROUP_SCHED**), then all of the processes on the system are notionally placed in a single task group.

Under group scheduling, a thread's nice value has an effect for scheduling decisions *only relative to other threads in the same task group*. This has some surprising consequences in terms of the traditional semantics of the nice value on UNIX systems. In particular, if autogrouping is enabled (which is the default in various distributions), then employing *setpriority*(2) or *nice*(1) on a process has an effect only for scheduling relative to other processes executed in the same session (typically: the same terminal window).

Conversely, for two processes that are (for example) the sole CPU-bound processes in different sessions (e.g., different terminal windows, each of whose jobs are tied to different autogroups), *modifying the nice value of the process in one of the sessions has no effect* in terms of the scheduler's decisions relative to the process in the other session. A possibly useful workaround here is to use a command such as the following to modify the autogroup nice value for *all* of the processes in a terminal session:

```
$ echo 10 > /proc/self/autogroup
```

Real-time features in the mainline Linux kernel

Since Linux 2.6.18, Linux is gradually becoming equipped with real-time capabilities, most of which are derived from the former *realtime-preempt* patch set. Until the patches have been completely merged into the mainline kernel, they must be installed to achieve the best real-time performance. These patches are named:

patch-*kernelversion*-rt*patchversion*

and can be downloaded from .

Without the patches and prior to their full inclusion into the mainline kernel, the kernel configuration offers only the three preemption classes **CONFIG_PREEMPT_NONE**, **CONFIG_PREEMPT_VOLUNTARY**, and **CONFIG_PREEMPT_DESKTOP** which respectively provide no, some, and considerable reduction of the worst-case scheduling latency.

With the patches applied or after their full inclusion into the mainline kernel, the additional configuration item **CONFIG_PREEMPT_RT** becomes available. If this is selected, Linux is transformed into a regular real-time operating system. The FIFO and RR scheduling policies are then used to run a thread with true real-time priority and a minimum worst-case scheduling latency.

NOTES

The *cgroups*(7) CPU controller can be used to limit the CPU consumption of groups of processes.

Originally, Standard Linux was intended as a general-purpose operating system being able to handle background processes, interactive applications, and less demanding real-time applications (applications that need to usually meet timing deadlines). Although the Linux 2.6 allowed for kernel preemption and the newly introduced O(1) scheduler ensures that the time needed to schedule is fixed and deterministic irrespective of the number of active tasks, true real-time computing was not possible up to Linux 2.6.17.

NAME

sem_overview − overview of POSIX semaphores

DESCRIPTION

POSIX semaphores allow processes and threads to synchronize their actions.

A semaphore is an integer whose value is never allowed to fall below zero. Two operations can be performed on semaphores: increment the semaphore value by one (**sem_post**(3)); and decrement the semaphore value by one (**sem_wait**(3)). If the value of a semaphore is currently zero, then a *sem_wait*(3) operation will block until the value becomes greater than zero.

POSIX semaphores come in two forms: named semaphores and unnamed semaphores.

Named semaphores

A named semaphore is identified by a name of the form */somename*; that is, a null-terminated string of up to **NAME_MAX**−*4* (i.e., 251) characters consisting of an initial slash, followed by one or more characters, none of which are slashes. Two processes can operate on the same named semaphore by passing the same name to *sem_open*(3).

The *sem_open*(3) function creates a new named semaphore or opens an existing named semaphore. After the semaphore has been opened, it can be operated on using *sem_post*(3) and *sem_wait*(3). When a process has finished using the semaphore, it can use *sem_close*(3) to close the semaphore. When all processes have finished using the semaphore, it can be removed from the system using *sem_unlink*(3).

Unnamed semaphores (memory-based semaphores)

An unnamed semaphore does not have a name. Instead the semaphore is placed in a region of memory that is shared between multiple threads (a *thread-shared semaphore*) or processes (a *process-shared semaphore*). A thread-shared semaphore is placed in an area of memory shared between the threads of a process, for example, a global variable. A process-shared semaphore must be placed in a shared memory region (e.g., a System V shared memory segment created using *shmget*(2), or a POSIX shared memory object built created using *shm_open*(3)).

Before being used, an unnamed semaphore must be initialized using *sem_init*(3). It can then be operated on using *sem_post*(3) and *sem_wait*(3). When the semaphore is no longer required, and before the memory in which it is located is deallocated, the semaphore should be destroyed using *sem_destroy*(3).

The remainder of this section describes some specific details of the Linux implementation of POSIX semaphores.

Versions

Before Linux 2.6, Linux supported only unnamed, thread-shared semaphores. On a system with Linux 2.6 and a glibc that provides the NPTL threading implementation, a complete implementation of POSIX semaphores is provided.

Persistence

POSIX named semaphores have kernel persistence: if not removed by *sem_unlink*(3), a semaphore will exist until the system is shut down.

Linking

Programs using the POSIX semaphores API must be compiled with *cc −pthread* to link against the real-time library, *librt*.

Accessing named semaphores via the filesystem

On Linux, named semaphores are created in a virtual filesystem, normally mounted under */dev/shm*, with names of the form **sem.***somename*. (This is the reason that semaphore names are limited to **NAME_MAX**−*4* rather than **NAME_MAX** characters.)

Since Linux 2.6.19, ACLs can be placed on files under this directory, to control object permissions on a per-user and per-group basis.

NOTES

System V semaphores (**semget**(2), *semop*(2), etc.) are an older semaphore API. POSIX semaphores provide a simpler, and better designed interface than System V semaphores; on the other hand POSIX semaphores are less widely available (especially on older systems) than System V semaphores.

EXAMPLES

An example of the use of various POSIX semaphore functions is shown in *sem_wait*(3).

NAME

session-keyring − session shared process keyring

DESCRIPTION

The session keyring is a keyring used to anchor keys on behalf of a process. It is typically created by *pam_keyinit*(8) when a user logs in and a link will be added that refers to the *user-keyring*(7). Optionally, *PAM*(7) may revoke the session keyring on logout. (In typical configurations, PAM does do this revocation.) The session keyring has the name (description) *_ses*.

A special serial number value, **KEY_SPEC_SESSION_KEYRING**, is defined that can be used in lieu of the actual serial number of the calling process's session keyring.

From the *keyctl*(1) utility, '**@s**' can be used instead of a numeric key ID in much the same way.

A process's session keyring is inherited across *clone*(2), *fork*(2), and *vfork*(2). The session keyring is preserved across *execve*(2), even when the executable is set-user-ID or set-group-ID or has capabilities. The session keyring is destroyed when the last process that refers to it exits.

If a process doesn't have a session keyring when it is accessed, then, under certain circumstances, the *user-session-keyring*(7) will be attached as the session keyring and under others a new session keyring will be created. (See *user-session-keyring*(7) for further details.)

Special operations

The *keyutils* library provides the following special operations for manipulating session keyrings:

keyctl_join_session_keyring(3)
: This operation allows the caller to change the session keyring that it subscribes to. The caller can join an existing keyring with a specified name (description), create a new keyring with a given name, or ask the kernel to create a new "anonymous" session keyring with the name "_ses". (This function is an interface to the *keyctl*(2) **KEYCTL_JOIN_SESSION_KEYRING** operation.)

keyctl_session_to_parent(3)
: This operation allows the caller to make the parent process's session keyring to the same as its own. For this to succeed, the parent process must have identical security attributes and must be single threaded. (This function is an interface to the *keyctl*(2) **KEYCTL_SESSION_TO_PARENT** operation.)

These operations are also exposed through the *keyctl*(1) utility as:

```
keyctl session
keyctl session - [<prog> <arg1> <arg2> ...]
keyctl session <name> [<prog> <arg1> <arg2> ...]
```

and:

```
keyctl new_session
```

NAME

shm_overview − overview of POSIX shared memory

DESCRIPTION

The POSIX shared memory API allows processes to communicate information by sharing a region of memory.

The interfaces employed in the API are:

shm_open(3) Create and open a new object, or open an existing object. This is analogous to *open*(2). The call returns a file descriptor for use by the other interfaces listed below.

ftruncate(2) Set the size of the shared memory object. (A newly created shared memory object has a length of zero.)

mmap(2) Map the shared memory object into the virtual address space of the calling process.

munmap(2) Unmap the shared memory object from the virtual address space of the calling process.

shm_unlink(3) Remove a shared memory object name.

close(2) Close the file descriptor allocated by *shm_open*(3) when it is no longer needed.

fstat(2) Obtain a *stat* structure that describes the shared memory object. Among the information returned by this call are the object's size (*st_size*), permissions (*st_mode*), owner (*st_uid*), and group (*st_gid*).

fchown(2) To change the ownership of a shared memory object.

fchmod(2) To change the permissions of a shared memory object.

Versions

POSIX shared memory is supported since Linux 2.4 and glibc 2.2.

Persistence

POSIX shared memory objects have kernel persistence: a shared memory object will exist until the system is shut down, or until all processes have unmapped the object and it has been deleted with *shm_unlink*(3)

Linking

Programs using the POSIX shared memory API must be compiled with *cc −lrt* to link against the real-time library, *librt*.

Accessing shared memory objects via the filesystem

On Linux, shared memory objects are created in a (**tmpfs**(5)) virtual filesystem, normally mounted under */dev/shm*. Since Linux 2.6.19, Linux supports the use of access control lists (ACLs) to control the permissions of objects in the virtual filesystem.

NOTES

Typically, processes must synchronize their access to a shared memory object, using, for example, POSIX semaphores.

System V shared memory (**shmget**(2), *shmop*(2), etc.) is an older shared memory API. POSIX shared memory provides a simpler, and better designed interface; on the other hand POSIX shared memory is somewhat less widely available (especially on older systems) than System V shared memory.

NAME

signal − overview of signals

DESCRIPTION

Linux supports both POSIX reliable signals (hereinafter "standard signals") and POSIX real-time signals.

Signal dispositions

Each signal has a current *disposition*, which determines how the process behaves when it is delivered the signal.

The entries in the "Action" column of the table below specify the default disposition for each signal, as follows:

Term Default action is to terminate the process.

Ign Default action is to ignore the signal.

Core Default action is to terminate the process and dump core (see *core*(5)).

Stop Default action is to stop the process.

Cont Default action is to continue the process if it is currently stopped.

A process can change the disposition of a signal using *sigaction*(2) or *signal*(2). (The latter is less portable when establishing a signal handler; see *signal*(2) for details.) Using these system calls, a process can elect one of the following behaviors to occur on delivery of the signal: perform the default action; ignore the signal; or catch the signal with a *signal handler*, a programmer-defined function that is automatically invoked when the signal is delivered.

By default, a signal handler is invoked on the normal process stack. It is possible to arrange that the signal handler uses an alternate stack; see *sigaltstack*(2) for a discussion of how to do this and when it might be useful.

The signal disposition is a per-process attribute: in a multithreaded application, the disposition of a particular signal is the same for all threads.

A child created via *fork*(2) inherits a copy of its parent's signal dispositions. During an *execve*(2), the dispositions of handled signals are reset to the default; the dispositions of ignored signals are left unchanged.

Sending a signal

The following system calls and library functions allow the caller to send a signal:

raise(3)
Sends a signal to the calling thread.

kill(2) Sends a signal to a specified process, to all members of a specified process group, or to all processes on the system.

pidfd_send_signal(2)
Sends a signal to a process identified by a PID file descriptor.

killpg(3)
Sends a signal to all of the members of a specified process group.

pthread_kill(3)
Sends a signal to a specified POSIX thread in the same process as the caller.

tgkill(2)
Sends a signal to a specified thread within a specific process. (This is the system call used to implement *pthread_kill*(3).)

sigqueue(3)
Sends a real-time signal with accompanying data to a specified process.

Waiting for a signal to be caught

The following system calls suspend execution of the calling thread until a signal is caught (or an unhandled signal terminates the process):

pause(2)
: Suspends execution until any signal is caught.

sigsuspend(2)
: Temporarily changes the signal mask (see below) and suspends execution until one of the unmasked signals is caught.

Synchronously accepting a signal

Rather than asynchronously catching a signal via a signal handler, it is possible to synchronously accept the signal, that is, to block execution until the signal is delivered, at which point the kernel returns information about the signal to the caller. There are two general ways to do this:

- *sigwaitinfo*(2), *sigtimedwait*(2), and *sigwait*(3) suspend execution until one of the signals in a specified set is delivered. Each of these calls returns information about the delivered signal.
- *signalfd*(2) returns a file descriptor that can be used to read information about signals that are delivered to the caller. Each *read*(2) from this file descriptor blocks until one of the signals in the set specified in the *signalfd*(2) call is delivered to the caller. The buffer returned by *read*(2) contains a structure describing the signal.

Signal mask and pending signals

A signal may be *blocked*, which means that it will not be delivered until it is later unblocked. Between the time when it is generated and when it is delivered a signal is said to be *pending*.

Each thread in a process has an independent *signal mask*, which indicates the set of signals that the thread is currently blocking. A thread can manipulate its signal mask using *pthread_sigmask*(3). In a traditional single-threaded application, *sigprocmask*(2) can be used to manipulate the signal mask.

A child created via *fork*(2) inherits a copy of its parent's signal mask; the signal mask is preserved across *execve*(2).

A signal may be process-directed or thread-directed. A process-directed signal is one that is targeted at (and thus pending for) the process as a whole. A signal may be process-directed because it was generated by the kernel for reasons other than a hardware exception, or because it was sent using *kill*(2) or *sigqueue*(3). A thread-directed signal is one that is targeted at a specific thread. A signal may be thread-directed because it was generated as a consequence of executing a specific machine-language instruction that triggered a hardware exception (e.g., **SIGSEGV** for an invalid memory access, or **SIGFPE** for a math error), or because it was targeted at a specific thread using interfaces such as *tgkill*(2) or *pthread_kill*(3).

A process-directed signal may be delivered to any one of the threads that does not currently have the signal blocked. If more than one of the threads has the signal unblocked, then the kernel chooses an arbitrary thread to which to deliver the signal.

A thread can obtain the set of signals that it currently has pending using *sigpending*(2). This set will consist of the union of the set of pending process-directed signals and the set of signals pending for the calling thread.

A child created via *fork*(2) initially has an empty pending signal set; the pending signal set is preserved across an *execve*(2).

Execution of signal handlers

Whenever there is a transition from kernel-mode to user-mode execution (e.g., on return from a system call or scheduling of a thread onto the CPU), the kernel checks whether there is a pending unblocked signal for which the process has established a signal handler. If there is such a pending signal, the following steps occur:

(1) The kernel performs the necessary preparatory steps for execution of the signal handler:

  (1.1) The signal is removed from the set of pending signals.

  (1.2) If the signal handler was installed by a call to *sigaction*(2) that specified the **SA_ONSTACK** flag and the thread has defined an alternate signal stack (using *sigaltstack*(2)), then that stack is installed.

  (1.3) Various pieces of signal-related context are saved into a special frame that is created on the stack. The saved information includes:

- the program counter register (i.e., the address of the next instruction in the main program that should be executed when the signal handler returns);
- architecture-specific register state required for resuming the interrupted program;
- the thread's current signal mask;
- the thread's alternate signal stack settings.

(If the signal handler was installed using the *sigaction*(2) **SA_SIGINFO** flag, then the above information is accessible via the *ucontext_t* object that is pointed to by the third argument of the signal handler.)

(1.4) Any signals specified in *act->sa_mask* when registering the handler with *sigprocmask*(2) are added to the thread's signal mask. The signal being delivered is also added to the signal mask, unless **SA_NODEFER** was specified when registering the handler. These signals are thus blocked while the handler executes.

(2) The kernel constructs a frame for the signal handler on the stack. The kernel sets the program counter for the thread to point to the first instruction of the signal handler function, and configures the return address for that function to point to a piece of user-space code known as the signal trampoline (described in *sigreturn*(2)).

(3) The kernel passes control back to user-space, where execution commences at the start of the signal handler function.

(4) When the signal handler returns, control passes to the signal trampoline code.

(5) The signal trampoline calls *sigreturn*(2), a system call that uses the information in the stack frame created in step 1 to restore the thread to its state before the signal handler was called. The thread's signal mask and alternate signal stack settings are restored as part of this procedure. Upon completion of the call to *sigreturn*(2), the kernel transfers control back to user space, and the thread recommences execution at the point where it was interrupted by the signal handler.

Note that if the signal handler does not return (e.g., control is transferred out of the handler using *siglongjmp*(3), or the handler executes a new program with *execve*(2)), then the final step is not performed. In particular, in such scenarios it is the programmer's responsibility to restore the state of the signal mask (using *sigprocmask*(2)), if it is desired to unblock the signals that were blocked on entry to the signal handler. (Note that *siglongjmp*(3) may or may not restore the signal mask, depending on the *savesigs* value that was specified in the corresponding call to *sigsetjmp*(3).)

From the kernel's point of view, execution of the signal handler code is exactly the same as the execution of any other user-space code. That is to say, the kernel does not record any special state information indicating that the thread is currently executing inside a signal handler. All necessary state information is maintained in user-space registers and the user-space stack. The depth to which nested signal handlers may be invoked is thus limited only by the user-space stack (and sensible software design!).

Standard signals

Linux supports the standard signals listed below. The second column of the table indicates which standard (if any) specified the signal: "P1990" indicates that the signal is described in the original POSIX.1-1990 standard; "P2001" indicates that the signal was added in SUSv2 and POSIX.1-2001.

Signal	Standard	Action	Comment
SIGABRT	P1990	Core	Abort signal from *abort*(3)
SIGALRM	P1990	Term	Timer signal from *alarm*(2)
SIGBUS	P2001	Core	Bus error (bad memory access)
SIGCHLD	P1990	Ign	Child stopped or terminated
SIGCLD	−	Ign	A synonym for **SIGCHLD**
SIGCONT	P1990	Cont	Continue if stopped
SIGEMT	−	Term	Emulator trap
SIGFPE	P1990	Core	Floating-point exception
SIGHUP	P1990	Term	Hangup detected on controlling terminal or death of controlling process
SIGILL	P1990	Core	Illegal Instruction
SIGINFO	−		A synonym for **SIGPWR**
SIGINT	P1990	Term	Interrupt from keyboard

SIGIO	−	Term	I/O now possible (4.2BSD)
SIGIOT	−	Core	IOT trap. A synonym for **SIGABRT**
SIGKILL	P1990	Term	Kill signal
SIGLOST	−	Term	File lock lost (unused)
SIGPIPE	P1990	Term	Broken pipe: write to pipe with no readers; see *pipe*(7)
SIGPOLL	P2001	Term	Pollable event (Sys V); synonym for **SIGIO**
SIGPROF	P2001	Term	Profiling timer expired
SIGPWR	−	Term	Power failure (System V)
SIGQUIT	P1990	Core	Quit from keyboard
SIGSEGV	P1990	Core	Invalid memory reference
SIGSTKFLT	−	Term	Stack fault on coprocessor (unused)
SIGSTOP	P1990	Stop	Stop process
SIGTSTP	P1990	Stop	Stop typed at terminal
SIGSYS	P2001	Core	Bad system call (SVr4); see also *seccomp*(2)
SIGTERM	P1990	Term	Termination signal
SIGTRAP	P2001	Core	Trace/breakpoint trap
SIGTTIN	P1990	Stop	Terminal input for background process
SIGTTOU	P1990	Stop	Terminal output for background process
SIGUNUSED	−	Core	Synonymous with **SIGSYS**
SIGURG	P2001	Ign	Urgent condition on socket (4.2BSD)
SIGUSR1	P1990	Term	User-defined signal 1
SIGUSR2	P1990	Term	User-defined signal 2
SIGVTALRM	P2001	Term	Virtual alarm clock (4.2BSD)
SIGXCPU	P2001	Core	CPU time limit exceeded (4.2BSD); see *setrlimit*(2)
SIGXFSZ	P2001	Core	File size limit exceeded (4.2BSD); see *setrlimit*(2)
SIGWINCH	−	Ign	Window resize signal (4.3BSD, Sun)

The signals **SIGKILL** and **SIGSTOP** cannot be caught, blocked, or ignored.

Up to and including Linux 2.2, the default behavior for **SIGSYS**, **SIGXCPU**, **SIGXFSZ**, and (on architectures other than SPARC and MIPS) **SIGBUS** was to terminate the process (without a core dump). (On some other UNIX systems the default action for **SIGXCPU** and **SIGXFSZ** is to terminate the process without a core dump.) Linux 2.4 conforms to the POSIX.1-2001 requirements for these signals, terminating the process with a core dump.

SIGEMT is not specified in POSIX.1-2001, but nevertheless appears on most other UNIX systems, where its default action is typically to terminate the process with a core dump.

SIGPWR (which is not specified in POSIX.1-2001) is typically ignored by default on those other UNIX systems where it appears.

SIGIO (which is not specified in POSIX.1-2001) is ignored by default on several other UNIX systems.

Queueing and delivery semantics for standard signals

If multiple standard signals are pending for a process, the order in which the signals are delivered is unspecified.

Standard signals do not queue. If multiple instances of a standard signal are generated while that signal is blocked, then only one instance of the signal is marked as pending (and the signal will be delivered just once when it is unblocked). In the case where a standard signal is already pending, the *siginfo_t* structure (see *sigaction*(2)) associated with that signal is not overwritten on arrival of subsequent instances of the same signal. Thus, the process will receive the information associated with the first instance of the signal.

Signal numbering for standard signals

The numeric value for each signal is given in the table below. As shown in the table, many signals have different numeric values on different architectures. The first numeric value in each table row shows the signal number on x86, ARM, and most other architectures; the second value is for Alpha and SPARC;

the third is for MIPS; and the last is for PARISC. A dash (−) denotes that a signal is absent on the corresponding architecture.

Signal	x86/ARM most others	Alpha/ SPARC	MIPS	PARISC	Notes
SIGHUP	1	1	1	1	
SIGINT	2	2	2	2	
SIGQUIT	3	3	3	3	
SIGILL	4	4	4	4	
SIGTRAP	5	5	5	5	
SIGABRT	6	6	6	6	
SIGIOT	6	6	6	6	
SIGBUS	7	10	10	10	
SIGEMT	−	7	7	-	
SIGFPE	8	8	8	8	
SIGKILL	9	9	9	9	
SIGUSR1	10	30	16	16	
SIGSEGV	11	11	11	11	
SIGUSR2	12	31	17	17	
SIGPIPE	13	13	13	13	
SIGALRM	14	14	14	14	
SIGTERM	15	15	15	15	
SIGSTKFLT	16	−	−	7	
SIGCHLD	17	20	18	18	
SIGCLD	−	−	18	−	
SIGCONT	18	19	25	26	
SIGSTOP	19	17	23	24	
SIGTSTP	20	18	24	25	
SIGTTIN	21	21	26	27	
SIGTTOU	22	22	27	28	
SIGURG	23	16	21	29	
SIGXCPU	24	24	30	12	
SIGXFSZ	25	25	31	30	
SIGVTALRM	26	26	28	20	
SIGPROF	27	27	29	21	
SIGWINCH	28	28	20	23	
SIGIO	29	23	22	22	
SIGPOLL					Same as SIGIO
SIGPWR	30	29/−	19	19	
SIGINFO	−	29/−	−	−	
SIGLOST	−	−/29	−	−	
SIGSYS	31	12	12	31	
SIGUNUSED	31	−	−	31	

Note the following:

- Where defined, **SIGUNUSED** is synonymous with **SIGSYS**. Since glibc 2.26, **SIGUNUSED** is no longer defined on any architecture.
- Signal 29 is **SIGINFO**/**SIGPWR** (synonyms for the same value) on Alpha but **SIGLOST** on SPARC.

Real-time signals

Starting with Linux 2.2, Linux supports real-time signals as originally defined in the POSIX.1b real-time extensions (and now included in POSIX.1-2001). The range of supported real-time signals is defined by the macros **SIGRTMIN** and **SIGRTMAX**. POSIX.1-2001 requires that an implementation support at least **_POSIX_RTSIG_MAX** (8) real-time signals.

The Linux kernel supports a range of 33 different real-time signals, numbered 32 to 64. However, the glibc POSIX threads implementation internally uses two (for NPTL) or three (for LinuxThreads) real-time signals (see *pthreads*(7)), and adjusts the value of **SIGRTMIN** suitably (to 34 or 35). Because the range of available real-time signals varies according to the glibc threading implementation (and this

variation can occur at run time according to the available kernel and glibc), and indeed the range of real-time signals varies across UNIX systems, programs should *never refer to real-time signals using hard-coded numbers*, but instead should always refer to real-time signals using the notation **SIGRTMIN**+n, and include suitable (run-time) checks that **SIGRTMIN**+n does not exceed **SIGRTMAX**.

Unlike standard signals, real-time signals have no predefined meanings: the entire set of real-time signals can be used for application-defined purposes.

The default action for an unhandled real-time signal is to terminate the receiving process.

Real-time signals are distinguished by the following:

- Multiple instances of real-time signals can be queued. By contrast, if multiple instances of a standard signal are delivered while that signal is currently blocked, then only one instance is queued.
- If the signal is sent using *sigqueue*(3), an accompanying value (either an integer or a pointer) can be sent with the signal. If the receiving process establishes a handler for this signal using the **SA_SIGINFO** flag to *sigaction*(2), then it can obtain this data via the *si_value* field of the *siginfo_t* structure passed as the second argument to the handler. Furthermore, the *si_pid* and *si_uid* fields of this structure can be used to obtain the PID and real user ID of the process sending the signal.
- Real-time signals are delivered in a guaranteed order. Multiple real-time signals of the same type are delivered in the order they were sent. If different real-time signals are sent to a process, they are delivered starting with the lowest-numbered signal. (I.e., low-numbered signals have highest priority.) By contrast, if multiple standard signals are pending for a process, the order in which they are delivered is unspecified.

If both standard and real-time signals are pending for a process, POSIX leaves it unspecified which is delivered first. Linux, like many other implementations, gives priority to standard signals in this case.

According to POSIX, an implementation should permit at least **_POSIX_SIGQUEUE_MAX** (32) real-time signals to be queued to a process. However, Linux does things differently. Up to and including Linux 2.6.7, Linux imposes a system-wide limit on the number of queued real-time signals for all processes. This limit can be viewed and (with privilege) changed via the */proc/sys/kernel/rtsig-max* file. A related file, */proc/sys/kernel/rtsig-nr*, can be used to find out how many real-time signals are currently queued. In Linux 2.6.8, these */proc* interfaces were replaced by the **RLIMIT_SIGPENDING** resource limit, which specifies a per-user limit for queued signals; see *setrlimit*(2) for further details.

The addition of real-time signals required the widening of the signal set structure (*sigset_t*) from 32 to 64 bits. Consequently, various system calls were superseded by new system calls that supported the larger signal sets. The old and new system calls are as follows:

Linux 2.0 and earlier	**Linux 2.2 and later**
sigaction(2)	*rt_sigaction*(2)
sigpending(2)	*rt_sigpending*(2)
sigprocmask(2)	*rt_sigprocmask*(2)
sigreturn(2)	*rt_sigreturn*(2)
sigsuspend(2)	*rt_sigsuspend*(2)
sigtimedwait(2)	*rt_sigtimedwait*(2)

Interruption of system calls and library functions by signal handlers

If a signal handler is invoked while a system call or library function call is blocked, then either:

- the call is automatically restarted after the signal handler returns; or
- the call fails with the error **EINTR**.

Which of these two behaviors occurs depends on the interface and whether or not the signal handler was established using the **SA_RESTART** flag (see *sigaction*(2)). The details vary across UNIX systems; below, the details for Linux.

If a blocked call to one of the following interfaces is interrupted by a signal handler, then the call is automatically restarted after the signal handler returns if the **SA_RESTART** flag was used; otherwise the call fails with the error **EINTR**:

- *read*(2), *readv*(2), *write*(2), *writev*(2), and *ioctl*(2) calls on "slow" devices. A "slow" device is one where the I/O call may block for an indefinite time, for example, a terminal, pipe, or socket. If an I/O call on a slow device has already transferred some data by the time it is interrupted by a signal

handler, then the call will return a success status (normally, the number of bytes transferred). Note that a (local) disk is not a slow device according to this definition; I/O operations on disk devices are not interrupted by signals.

- *open*(2), if it can block (e.g., when opening a FIFO; see *fifo*(7)).
- *wait*(2), *wait3*(2), *wait4*(2), *waitid*(2), and *waitpid*(2).
- Socket interfaces: *accept*(2), *connect*(2), *recv*(2), *recvfrom*(2), *recvmmsg*(2), *recvmsg*(2), *send*(2), *sendto*(2), and *sendmsg*(2), unless a timeout has been set on the socket (see below).
- File locking interfaces: *flock*(2) and the **F_SETLKW** and **F_OFD_SETLKW** operations of *fcntl*(2)
- POSIX message queue interfaces: *mq_receive*(3), *mq_timedreceive*(3), *mq_send*(3), and *mq_timedsend*(3).
- *futex*(2) **FUTEX_WAIT** (since Linux 2.6.22; beforehand, always failed with **EINTR**).
- *getrandom*(2).
- *pthread_mutex_lock*(3), *pthread_cond_wait*(3), and related APIs.
- *futex*(2) **FUTEX_WAIT_BITSET**.
- POSIX semaphore interfaces: *sem_wait*(3) and *sem_timedwait*(3) (since Linux 2.6.22; beforehand, always failed with **EINTR**).
- *read*(2) from an *inotify*(7) file descriptor (since Linux 3.8; beforehand, always failed with **EINTR**).

The following interfaces are never restarted after being interrupted by a signal handler, regardless of the use of **SA_RESTART**; they always fail with the error **EINTR** when interrupted by a signal handler:

- "Input" socket interfaces, when a timeout (**SO_RCVTIMEO**) has been set on the socket using *setsockopt*(2): *accept*(2), *recv*(2), *recvfrom*(2), *recvmmsg*(2) (also with a non-NULL *timeout* argument), and *recvmsg*(2).
- "Output" socket interfaces, when a timeout (**SO_RCVTIMEO**) has been set on the socket using *setsockopt*(2): *connect*(2), *send*(2), *sendto*(2), and *sendmsg*(2).
- Interfaces used to wait for signals: *pause*(2), *sigsuspend*(2), *sigtimedwait*(2), and *sigwaitinfo*(2).
- File descriptor multiplexing interfaces: *epoll_wait*(2), *epoll_pwait*(2), *poll*(2), *ppoll*(2), *select*(2), and *pselect*(2).
- System V IPC interfaces: *msgrcv*(2), *msgsnd*(2), *semop*(2), and *semtimedop*(2).
- Sleep interfaces: *clock_nanosleep*(2), *nanosleep*(2), and *usleep*(3).
- *io_getevents*(2).

The *sleep*(3) function is also never restarted if interrupted by a handler, but gives a success return: the number of seconds remaining to sleep.

In certain circumstances, the *seccomp*(2) user-space notification feature can lead to restarting of system calls that would otherwise never be restarted by **SA_RESTART**; for details, see *seccomp_unotify*(2).

Interruption of system calls and library functions by stop signals

On Linux, even in the absence of signal handlers, certain blocking interfaces can fail with the error **EINTR** after the process is stopped by one of the stop signals and then resumed via **SIGCONT**. This behavior is not sanctioned by POSIX.1, and doesn't occur on other systems.

The Linux interfaces that display this behavior are:

- "Input" socket interfaces, when a timeout (**SO_RCVTIMEO**) has been set on the socket using *setsockopt*(2): *accept*(2), *recv*(2), *recvfrom*(2), *recvmmsg*(2) (also with a non-NULL *timeout* argument), and *recvmsg*(2).
- "Output" socket interfaces, when a timeout (**SO_RCVTIMEO**) has been set on the socket using *setsockopt*(2): *connect*(2), *send*(2), *sendto*(2), and *sendmsg*(2), if a send timeout (**SO_SNDTIMEO**) has been set.

- *epoll_wait*(2), *epoll_pwait*(2).
- *semop*(2), *semtimedop*(2).
- *sigtimedwait*(2), *sigwaitinfo*(2).
- Linux 3.7 and earlier: *read*(2) from an *inotify*(7) file descriptor
- Linux 2.6.21 and earlier: *futex*(2) **FUTEX_WAIT**, *sem_timedwait*(3), *sem_wait*(3).
- Linux 2.6.8 and earlier: *msgrcv*(2), *msgsnd*(2).
- Linux 2.4 and earlier: *nanosleep*(2).

STANDARDS

POSIX.1, except as noted.

NOTES

For a discussion of async-signal-safe functions, see *signal-safety*(7).

The */proc/*pid*/task/*tid*/status* file contains various fields that show the signals that a thread is blocking (*SigBlk*), catching (*SigCgt*), or ignoring (*SigIgn*). (The set of signals that are caught or ignored will be the same across all threads in a process.) Other fields show the set of pending signals that are directed to the thread (*SigPnd*) as well as the set of pending signals that are directed to the process as a whole (*ShdPnd*). The corresponding fields in */proc/*pid*/status* show the information for the main thread. See *proc*(5) for further details.

BUGS

There are six signals that can be delivered as a consequence of a hardware exception: **SIGBUS**, **SIGEMT**, **SIGFPE**, **SIGILL**, **SIGSEGV**, and **SIGTRAP**. Which of these signals is delivered, for any given hardware exception, is not documented and does not always make sense.

For example, an invalid memory access that causes delivery of **SIGSEGV** on one CPU architecture may cause delivery of **SIGBUS** on another architecture, or vice versa.

For another example, using the x86 *int* instruction with a forbidden argument (any number other than 3 or 128) causes delivery of **SIGSEGV**, even though **SIGILL** would make more sense, because of how the CPU reports the forbidden operation to the kernel.

NAME

signal-safety − async-signal-safe functions

DESCRIPTION

An *async-signal-safe* function is one that can be safely called from within a signal handler. Many functions are *not* async-signal-safe. In particular, nonreentrant functions are generally unsafe to call from a signal handler.

The kinds of issues that render a function unsafe can be quickly understood when one considers the implementation of the *stdio* library, all of whose functions are not async-signal-safe.

When performing buffered I/O on a file, the *stdio* functions must maintain a statically allocated data buffer along with associated counters and indexes (or pointers) that record the amount of data and the current position in the buffer. Suppose that the main program is in the middle of a call to a *stdio* function such as *printf*(3) where the buffer and associated variables have been partially updated. If, at that moment, the program is interrupted by a signal handler that also calls *printf*(3), then the second call to *printf*(3) will operate on inconsistent data, with unpredictable results.

To avoid problems with unsafe functions, there are two possible choices:

(a) Ensure that (1) the signal handler calls only async-signal-safe functions, and (2) the signal handler itself is reentrant with respect to global variables in the main program.

(b) Block signal delivery in the main program when calling functions that are unsafe or operating on global data that is also accessed by the signal handler.

Generally, the second choice is difficult in programs of any complexity, so the first choice is taken.

POSIX.1 specifies a set of functions that an implementation must make async-signal-safe. (An implementation may provide safe implementations of additional functions, but this is not required by the standard and other implementations may not provide the same guarantees.)

In general, a function is async-signal-safe either because it is reentrant or because it is atomic with respect to signals (i.e., its execution can't be interrupted by a signal handler).

The set of functions required to be async-signal-safe by POSIX.1 is shown in the following table. The functions not otherwise noted were required to be async-signal-safe in POSIX.1-2001; the table details changes in the subsequent standards.

Notes:

- POSIX.1-2001 and POSIX.1-2001 TC2 required the functions *fpathconf*(3), *pathconf*(3), and *sysconf*(3) to be async-signal-safe, but this requirement was removed in POSIX.1-2008.

- If a signal handler interrupts the execution of an unsafe function, and the handler terminates via a call to *longjmp*(3) or *siglongjmp*(3) and the program subsequently calls an unsafe function, then the behavior of the program is undefined.
- POSIX.1-2001 TC1 clarified that if an application calls *fork*(2) from a signal handler and any of the fork handlers registered by *pthread_atfork*(3) calls a function that is not async-signal-safe, the behavior is undefined. A future revision of the standard is likely to remove *fork*(2) from the list of async-signal-safe functions.
- Asynchronous signal handlers that call functions which are cancelation points and nest over regions of deferred cancelation may trigger cancelation whose behavior is as if asynchronous cancelation had occurred and may cause application state to become inconsistent.

errno

Fetching and setting the value of *errno* is async-signal-safe provided that the signal handler saves *errno* on entry and restores its value before returning.

Deviations in the GNU C library

The following known deviations from the standard occur in the GNU C library:

- Before glibc 2.24, *execl*(3) and *execle*(3) employed *realloc*(3) internally and were consequently not async-signal-safe. This was fixed in glibc 2.24.
- The glibc implementation of *aio_suspend*(3) is not async-signal-safe because it uses *pthread_mutex_lock*(3) internally.

NAME

sock_diag − obtaining information about sockets

SYNOPSIS

#include <sys/socket.h>
#include <linux/sock_diag.h>
#include <linux/unix_diag.h> /* for UNIX domain sockets */
#include <linux/inet_diag.h> /* for IPv4 and IPv6 sockets */

diag_socket = socket(AF_NETLINK, *socket_type***, NETLINK_SOCK_DIAG);**

DESCRIPTION

The sock_diag netlink subsystem provides a mechanism for obtaining information about sockets of various address families from the kernel. This subsystem can be used to obtain information about individual sockets or request a list of sockets.

In the request, the caller can specify additional information it would like to obtain about the socket, for example, memory information or information specific to the address family.

When requesting a list of sockets, the caller can specify filters that would be applied by the kernel to select a subset of sockets to report. For now, there is only the ability to filter sockets by state (connected, listening, and so on.)

Note that sock_diag reports only those sockets that have a name; that is, either sockets bound explicitly with *bind*(2) or sockets that were automatically bound to an address (e.g., by *connect*(2)). This is the same set of sockets that is available via */proc/net/unix*, */proc/net/tcp*, */proc/net/udp*, and so on.

Request

The request starts with a *struct nlmsghdr* header described in *netlink*(7) with *nlmsg_type* field set to **SOCK_DIAG_BY_FAMILY**. It is followed by a header specific to the address family that starts with a common part shared by all address families:

```
struct sock_diag_req {
    __u8 sdiag_family;
    __u8 sdiag_protocol;
};
```

The fields of this structure are as follows:

sdiag_family
: An address family. It should be set to the appropriate **AF_*** constant.

sdiag_protocol
: Depends on *sdiag_family*. It should be set to the appropriate **IPPROTO_*** constant for **AF_INET** and **AF_INET6**, and to 0 otherwise.

If the *nlmsg_flags* field of the *struct nlmsghdr* header has the **NLM_F_DUMP** flag set, it means that a list of sockets is being requested; otherwise it is a query about an individual socket.

Response

The response starts with a *struct nlmsghdr* header and is followed by an array of objects specific to the address family. The array is to be accessed with the standard **NLMSG_*** macros from the *netlink*(3) API.

Each object is the NLA (netlink attributes) list that is to be accessed with the **RTA_*** macros from *rtnetlink*(3) API.

UNIX domain sockets

For UNIX domain sockets the request is represented in the following structure:

```
struct unix_diag_req {
    __u8    sdiag_family;
    __u8    sdiag_protocol;
    __u16   pad;
    __u32   udiag_states;
    __u32   udiag_ino;
    __u32   udiag_show;
    __u32   udiag_cookie[2];
```

```
};
```

The fields of this structure are as follows:

sdiag_family
: The address family; it should be set to **AF_UNIX**.

sdiag_protocol
pad
: These fields should be set to 0.

udiag_states
: This is a bit mask that defines a filter of sockets states. Only those sockets whose states are in this mask will be reported. Ignored when querying for an individual socket. Supported values are:

1 << **TCP_ESTABLISHED**

1 << **TCP_LISTEN**

udiag_ino
: This is an inode number when querying for an individual socket. Ignored when querying for a list of sockets.

udiag_show
: This is a set of flags defining what kind of information to report. Each requested kind of information is reported back as a netlink attribute as described below:

UDIAG_SHOW_NAME
: The attribute reported in answer to this request is **UNIX_DIAG_NAME**. The payload associated with this attribute is the pathname to which the socket was bound (a sequence of bytes up to **UNIX_PATH_MAX** length).

UDIAG_SHOW_VFS
: The attribute reported in answer to this request is **UNIX_DIAG_VFS**. The payload associated with this attribute is represented in the following structure:

```
struct unix_diag_vfs {
    __u32 udiag_vfs_dev;
    __u32 udiag_vfs_ino;
};
```

The fields of this structure are as follows:

udiag_vfs_dev
: The device number of the corresponding on-disk socket inode.

udiag_vfs_ino
: The inode number of the corresponding on-disk socket inode.

UDIAG_SHOW_PEER
: The attribute reported in answer to this request is **UNIX_DIAG_PEER**. The payload associated with this attribute is a __u32 value which is the peer's inode number. This attribute is reported for connected sockets only.

UDIAG_SHOW_ICONS
: The attribute reported in answer to this request is **UNIX_DIAG_ICONS**. The payload associated with this attribute is an array of __u32 values which are inode numbers of sockets that has passed the *connect*(2) call, but hasn't been processed with *accept*(2) yet. This attribute is reported for listening sockets only.

UDIAG_SHOW_RQLEN
: The attribute reported in answer to this request is **UNIX_DIAG_RQLEN**. The payload associated with this attribute is represented in the following structure:

```
struct unix_diag_rqlen {
    __u32 udiag_rqueue;
    __u32 udiag_wqueue;
};
```

The fields of this structure are as follows:

udiag_rqueue
: For listening sockets: the number of pending connections. The length of the array associated with the **UNIX_DIAG_ICONS** response attribute is equal to this value.

  For established sockets: the amount of data in incoming queue.

udiag_wqueue
: For listening sockets: the backlog length which equals to the value passed as the second argument to *listen*(2).

  For established sockets: the amount of memory available for sending.

UDIAG_SHOW_MEMINFO
: The attribute reported in answer to this request is **UNIX_DIAG_MEMINFO**. The payload associated with this attribute is an array of __u32 values described below in the subsection "Socket memory information".

The following attributes are reported back without any specific request:

UNIX_DIAG_SHUTDOWN
: The payload associated with this attribute is __u8 value which represents bits of *shutdown*(2) state.

udiag_cookie
: This is an array of opaque identifiers that could be used along with *udiag_ino* to specify an individual socket. It is ignored when querying for a list of sockets, as well as when all its elements are set to −1.

The response to a query for UNIX domain sockets is represented as an array of

```
struct unix_diag_msg {
    __u8    udiag_family;
    __u8    udiag_type;
    __u8    udiag_state;
    __u8    pad;
    __u32   udiag_ino;
    __u32   udiag_cookie[2];
};
```

followed by netlink attributes.

The fields of this structure are as follows:

udiag_family
: This field has the same meaning as in *struct unix_diag_req*.

udiag_type
: This is set to one of **SOCK_PACKET**, **SOCK_STREAM**, or **SOCK_SEQPACKET**.

udiag_state
: This is set to one of **TCP_LISTEN** or **TCP_ESTABLISHED**.

pad This field is set to 0.

udiag_ino
: This is the socket inode number.

udiag_cookie
: This is an array of opaque identifiers that could be used in subsequent queries.

IPv4 and IPv6 sockets

For IPv4 and IPv6 sockets, the request is represented in the following structure:

```
struct inet_diag_req_v2 {
    __u8    sdiag_family;
    __u8    sdiag_protocol;
    __u8    idiag_ext;
    __u8    pad;
```

```
        __u32   idiag_states;
        struct inet_diag_sockid id;
    };
```

where *struct inet_diag_sockid* is defined as follows:

```
    struct inet_diag_sockid {
        __be16  idiag_sport;
        __be16  idiag_dport;
        __be32  idiag_src[4];
        __be32  idiag_dst[4];
        __u32   idiag_if;
        __u32   idiag_cookie[2];
    };
```

The fields of *struct inet_diag_req_v2* are as follows:

sdiag_family
: This should be set to either **AF_INET** or **AF_INET6** for IPv4 or IPv6 sockets respectively.

sdiag_protocol
: This should be set to one of **IPPROTO_TCP**, **IPPROTO_UDP**, or **IPPROTO_UDPLITE**.

idiag_ext
: This is a set of flags defining what kind of extended information to report. Each requested kind of information is reported back as a netlink attribute as described below:

  INET_DIAG_TOS
  : The payload associated with this attribute is a __u8 value which is the TOS of the socket.

  INET_DIAG_TCLASS
  : The payload associated with this attribute is a __u8 value which is the TClass of the socket. IPv6 sockets only. For LISTEN and CLOSE sockets, this is followed by **INET_DIAG_SKV6ONLY** attribute with associated __u8 payload value meaning whether the socket is IPv6-only or not.

  INET_DIAG_MEMINFO
  : The payload associated with this attribute is represented in the following structure:

    ```
    struct inet_diag_meminfo {
        __u32 idiag_rmem;
        __u32 idiag_wmem;
        __u32 idiag_fmem;
        __u32 idiag_tmem;
    };
    ```

    The fields of this structure are as follows:

    idiag_rmem The amount of data in the receive queue.

    idiag_wmem The amount of data that is queued by TCP but not yet sent.

    idiag_fmem The amount of memory scheduled for future use (TCP only).

    idiag_tmem The amount of data in send queue.

  INET_DIAG_SKMEMINFO
  : The payload associated with this attribute is an array of __u32 values described below in the subsection "Socket memory information".

  INET_DIAG_INFO
  : The payload associated with this attribute is specific to the address family. For TCP sockets, it is an object of type *struct tcp_info*.

  INET_DIAG_CONG
  : The payload associated with this attribute is a string that describes the congestion control algorithm used. For TCP sockets only.

pad This should be set to 0.

idiag_states
: This is a bit mask that defines a filter of socket states. Only those sockets whose states are in this mask will be reported. Ignored when querying for an individual socket.

id This is a socket ID object that is used in dump requests, in queries about individual sockets, and is reported back in each response. Unlike UNIX domain sockets, IPv4 and IPv6 sockets are identified using addresses and ports. All values are in network byte order.

The fields of *struct inet_diag_sockid* are as follows:

idiag_sport
: The source port.

idiag_dport
: The destination port.

idiag_src
: The source address.

idiag_dst
: The destination address.

idiag_if
: The interface number the socket is bound to.

idiag_cookie
: This is an array of opaque identifiers that could be used along with other fields of this structure to specify an individual socket. It is ignored when querying for a list of sockets, as well as when all its elements are set to −1.

The response to a query for IPv4 or IPv6 sockets is represented as an array of

```
struct inet_diag_msg {
    __u8    idiag_family;
    __u8    idiag_state;
    __u8    idiag_timer;
    __u8    idiag_retrans;

    struct inet_diag_sockid id;

    __u32   idiag_expires;
    __u32   idiag_rqueue;
    __u32   idiag_wqueue;
    __u32   idiag_uid;
    __u32   idiag_inode;
};
```

followed by netlink attributes.

The fields of this structure are as follows:

idiag_family
: This is the same field as in *struct inet_diag_req_v2*.

idiag_state
: This denotes socket state as in *struct inet_diag_req_v2*.

idiag_timer
: For TCP sockets, this field describes the type of timer that is currently active for the socket. It is set to one of the following constants:

  0 no timer is active
  1 a retransmit timer
  2 a keep-alive timer
  3 a TIME_WAIT timer

4 a zero window probe timer

For non-TCP sockets, this field is set to 0.

idiag_retrans
For *idiag_timer* values 1, 2, and 4, this field contains the number of retransmits. For other *idiag_timer* values, this field is set to 0.

idiag_expires
For TCP sockets that have an active timer, this field describes its expiration time in milliseconds. For other sockets, this field is set to 0.

idiag_rqueue
For listening sockets: the number of pending connections.

For other sockets: the amount of data in the incoming queue.

idiag_wqueue
For listening sockets: the backlog length.

For other sockets: the amount of memory available for sending.

idiag_uid
This is the socket owner UID.

idiag_inode
This is the socket inode number.

Socket memory information

The payload associated with **UNIX_DIAG_MEMINFO** and **INET_DIAG_SKMEMINFO** netlink attributes is an array of the following __u32 values:

SK_MEMINFO_RMEM_ALLOC
The amount of data in receive queue.

SK_MEMINFO_RCVBUF
The receive socket buffer as set by **SO_RCVBUF**.

SK_MEMINFO_WMEM_ALLOC
The amount of data in send queue.

SK_MEMINFO_SNDBUF
The send socket buffer as set by **SO_SNDBUF**.

SK_MEMINFO_FWD_ALLOC
The amount of memory scheduled for future use (TCP only).

SK_MEMINFO_WMEM_QUEUED
The amount of data queued by TCP, but not yet sent.

SK_MEMINFO_OPTMEM
The amount of memory allocated for the socket's service needs (e.g., socket filter).

SK_MEMINFO_BACKLOG
The amount of packets in the backlog (not yet processed).

VERSIONS

NETLINK_INET_DIAG was introduced in Linux 2.6.14 and supported **AF_INET** and **AF_INET6** sockets only. In Linux 3.3, it was renamed to **NETLINK_SOCK_DIAG** and extended to support **AF_UNIX** sockets.

UNIX_DIAG_MEMINFO and **INET_DIAG_SKMEMINFO** were introduced in Linux 3.6.

STANDARDS

Linux.

EXAMPLES

The following example program prints inode number, peer's inode number, and name of all UNIX domain sockets in the current namespace.

```
#include <errno.h>
#include <stdio.h>
```

```
#include <string.h>
#include <unistd.h>
#include <sys/socket.h>
#include <sys/un.h>
#include <linux/netlink.h>
#include <linux/rtnetlink.h>
#include <linux/sock_diag.h>
#include <linux/unix_diag.h>

static int
send_query(int fd)
{
    struct sockaddr_nl nladdr = {
        .nl_family = AF_NETLINK
    };
    struct
    {
        struct nlmsghdr nlh;
        struct unix_diag_req udr;
    } req = {
        .nlh = {
            .nlmsg_len = sizeof(req),
            .nlmsg_type = SOCK_DIAG_BY_FAMILY,
            .nlmsg_flags = NLM_F_REQUEST | NLM_F_DUMP
        },
        .udr = {

                if (h->nlmsg_type != SOCK_DIAG_BY_FAMILY) {
                    fprintf(stderr, "unexpected nlmsg_type %u\n",
                            (unsigned) h->nlmsg_type);
                    return -1;
                }

                if (print_diag(NLMSG_DATA(h), h->nlmsg_len))
                    return -1;
            }
        }
    }
```

```
int
main(void)
{
    int fd = socket(AF_NETLINK, SOCK_RAW, NETLINK_SOCK_DIAG);

    if (fd < 0) {
        perror("socket");
        return 1;
    }

    int ret = send_query(fd) || receive_responses(fd);

    close(fd);
    return ret;
}
```

NAME

socket − Linux socket interface

SYNOPSIS

#include <sys/socket.h>

sockfd = **socket(int** *socket_family***, int** *socket_type***, int** *protocol***);**

DESCRIPTION

This manual page describes the Linux networking socket layer user interface. The BSD compatible sockets are the uniform interface between the user process and the network protocol stacks in the kernel. The protocol modules are grouped into *protocol families* such as **AF_INET**, **AF_IPX**, and **AF_PACKET**, and *socket types* such as **SOCK_STREAM** or **SOCK_DGRAM**. See *socket*(2) for more information on families and types.

Socket-layer functions

These functions are used by the user process to send or receive packets and to do other socket operations. For more information, see their respective manual pages.

socket(2) creates a socket, *connect*(2) connects a socket to a remote socket address, the *bind*(2) function binds a socket to a local socket address, *listen*(2) tells the socket that new connections shall be accepted, and *accept*(2) is used to get a new socket with a new incoming connection. *socketpair*(2) returns two connected anonymous sockets (implemented only for a few local families like **AF_UNIX**)

send(2), *sendto*(2), and *sendmsg*(2) send data over a socket, and *recv*(2), *recvfrom*(2), *recvmsg*(2) receive data from a socket. *poll*(2) and *select*(2) wait for arriving data or a readiness to send data. In addition, the standard I/O operations like *write*(2), *writev*(2), *sendfile*(2), *read*(2), and *readv*(2) can be used to read and write data.

getsockname(2) returns the local socket address and *getpeername*(2) returns the remote socket address. *getsockopt*(2) and *setsockopt*(2) are used to set or get socket layer or protocol options. *ioctl*(2) can be used to set or read some other options.

close(2) is used to close a socket. *shutdown*(2) closes parts of a full-duplex socket connection.

Seeking, or calling *pread*(2) or *pwrite*(2) with a nonzero position is not supported on sockets.

It is possible to do nonblocking I/O on sockets by setting the **O_NONBLOCK** flag on a socket file descriptor using *fcntl*(2). Then all operations that would block will (usually) return with **EAGAIN** (operation should be retried later); *connect*(2) will return **EINPROGRESS** error. The user can then wait for various events via *poll*(2) or *select*(2).

I/O events		
Event	Poll flag	Occurrence
Read	POLLIN	New data arrived.
Read	POLLIN	A connection setup has been completed (for connection-oriented sockets)
Read	POLLHUP	A disconnection request has been initiated by the other end.
Read	POLLHUP	A connection is broken (only for connection-oriented protocols). When the socket is written **SIGPIPE** is also sent.
Write	POLLOUT	Socket has enough send buffer space for writing new data.
Read/Write	POLLIN | POLLOUT	An outgoing *connect*(2) finished.
Read/Write	POLLERR	An asynchronous error occurred.
Read/Write	POLLHUP	The other end has shut down one direction.
Exception	POLLPRI	Urgent data arrived. **SIGURG** is sent then.

An alternative to *poll*(2) and *select*(2) is to let the kernel inform the application about events via a **SIGIO** signal. For that the **O_ASYNC** flag must be set on a socket file descriptor via *fcntl*(2) and a valid signal handler for **SIGIO** must be installed via *sigaction*(2). See the *Signals* discussion below.

Socket address structures

Each socket domain has its own format for socket addresses, with a domain-specific address structure. Each of these structures begins with an integer "family" field (typed as *sa_family_t*) that indicates the type of the address structure. This allows the various system calls (e.g., *connect*(2), *bind*(2), *accept*(2),

getsockname(2), *getpeername*(2)), which are generic to all socket domains, to determine the domain of a particular socket address.

To allow any type of socket address to be passed to interfaces in the sockets API, the type *struct sockaddr* is defined. The purpose of this type is purely to allow casting of domain-specific socket address types to a "generic" type, so as to avoid compiler warnings about type mismatches in calls to the sockets API.

In addition, the sockets API provides the data type *struct sockaddr_storage*. This type is suitable to accommodate all supported domain-specific socket address structures; it is large enough and is aligned properly. (In particular, it is large enough to hold IPv6 socket addresses.) The structure includes the following field, which can be used to identify the type of socket address actually stored in the structure:

```
sa_family_t ss_family;
```

The *sockaddr_storage* structure is useful in programs that must handle socket addresses in a generic way (e.g., programs that must deal with both IPv4 and IPv6 socket addresses).

Socket options

The socket options listed below can be set by using *setsockopt*(2) and read with *getsockopt*(2) with the socket level set to **SOL_SOCKET** for all sockets. Unless otherwise noted, *optval* is a pointer to an *int*.

SO_ACCEPTCONN
: Returns a value indicating whether or not this socket has been marked to accept connections with *listen*(2). The value 0 indicates that this is not a listening socket, the value 1 indicates that this is a listening socket. This socket option is read-only.

SO_ATTACH_FILTER (since Linux 2.2)
SO_ATTACH_BPF (since Linux 3.19)
: Attach a classic BPF (**SO_ATTACH_FILTER**) or an extended BPF (**SO_ATTACH_BPF**) program to the socket for use as a filter of incoming packets. A packet will be dropped if the filter program returns zero. If the filter program returns a nonzero value which is less than the packet's data length, the packet will be truncated to the length returned. If the value returned by the filter is greater than or equal to the packet's data length, the packet is allowed to proceed unmodified.

  The argument for **SO_ATTACH_FILTER** is a *sock_fprog* structure, defined in <*linux/filter.h*>:

```
struct sock_fprog {
    unsigned short      len;
    struct sock_filter *filter;
};
```

  The argument for **SO_ATTACH_BPF** is a file descriptor returned by the *bpf*(2) system call and must refer to a program of type **BPF_PROG_TYPE_SOCKET_FILTER**.

  These options may be set multiple times for a given socket, each time replacing the previous filter program. The classic and extended versions may be called on the same socket, but the previous filter will always be replaced such that a socket never has more than one filter defined.

  Both classic and extended BPF are explained in the kernel source file *Documentation/networking/filter.txt*

SO_ATTACH_REUSEPORT_CBPF
SO_ATTACH_REUSEPORT_EBPF
: For use with the **SO_REUSEPORT** option, these options allow the user to set a classic BPF (**SO_ATTACH_REUSEPORT_CBPF**) or an extended BPF (**SO_ATTACH_REUSEPORT_EBPF**) program which defines how packets are assigned to the sockets in the reuseport group (that is, all sockets which have **SO_REUSEPORT** set and are using the same local address to receive packets).

  The BPF program must return an index between 0 and N−1 representing the socket which should receive the packet (where N is the number of sockets in the group). If the BPF program returns an invalid index, socket selection will fall back to the plain **SO_REUSEPORT**

mechanism.

Sockets are numbered in the order in which they are added to the group (that is, the order of *bind*(2) calls for UDP sockets or the order of *listen*(2) calls for TCP sockets). New sockets added to a reuseport group will inherit the BPF program. When a socket is removed from a reuseport group (via *close*(2)), the last socket in the group will be moved into the closed socket's position.

These options may be set repeatedly at any time on any socket in the group to replace the current BPF program used by all sockets in the group.

SO_ATTACH_REUSEPORT_CBPF takes the same argument type as **SO_ATTACH_FILTER** and **SO_ATTACH_REUSEPORT_EBPF** takes the same argument type as **SO_ATTACH_BPF**.

UDP support for this feature is available since Linux 4.5; TCP support is available since Linux 4.6.

SO_BINDTODEVICE
Bind this socket to a particular device like "eth0", as specified in the passed interface name. If the name is an empty string or the option length is zero, the socket device binding is removed. The passed option is a variable-length null-terminated interface name string with the maximum size of **IFNAMSIZ**. If a socket is bound to an interface, only packets received from that particular interface are processed by the socket. Note that this works only for some socket types, particularly **AF_INET** sockets. It is not supported for packet sockets (use normal *bind*(2) there).

Before Linux 3.8, this socket option could be set, but could not retrieved with *getsockopt*(2). Since Linux 3.8, it is readable. The *optlen* argument should contain the buffer size available to receive the device name and is recommended to be **IFNAMSIZ** bytes. The real device name length is reported back in the *optlen* argument.

SO_BROADCAST
Set or get the broadcast flag. When enabled, datagram sockets are allowed to send packets to a broadcast address. This option has no effect on stream-oriented sockets.

SO_BSDCOMPAT
Enable BSD bug-to-bug compatibility. This is used by the UDP protocol module in Linux 2.0 and 2.2. If enabled, ICMP errors received for a UDP socket will not be passed to the user program. In later kernel versions, support for this option has been phased out: Linux 2.4 silently ignores it, and Linux 2.6 generates a kernel warning (printk()) if a program uses this option. Linux 2.0 also enabled BSD bug-to-bug compatibility options (random header changing, skipping of the broadcast flag) for raw sockets with this option, but that was removed in Linux 2.2.

SO_DEBUG
Enable socket debugging. Allowed only for processes with the **CAP_NET_ADMIN** capability or an effective user ID of 0.

SO_DETACH_FILTER (since Linux 2.2)
SO_DETACH_BPF (since Linux 3.19)
These two options, which are synonyms, may be used to remove the classic or extended BPF program attached to a socket with either **SO_ATTACH_FILTER** or **SO_ATTACH_BPF**. The option value is ignored.

SO_DOMAIN (since Linux 2.6.32)
Retrieves the socket domain as an integer, returning a value such as **AF_INET6**. See *socket*(2) for details. This socket option is read-only.

SO_ERROR
Get and clear the pending socket error. This socket option is read-only. Expects an integer.

SO_DONTROUTE
Don't send via a gateway, send only to directly connected hosts. The same effect can be achieved by setting the **MSG_DONTROUTE** flag on a socket *send*(2) operation. Expects an integer boolean flag.

SO_INCOMING_CPU (gettable since Linux 3.19, settable since Linux 4.4)
Sets or gets the CPU affinity of a socket. Expects an integer flag.

```
int cpu = 1;
setsockopt(fd, SOL_SOCKET, SO_INCOMING_CPU, &cpu,
           sizeof(cpu));
```

Because all of the packets for a single stream (i.e., all packets for the same 4-tuple) arrive on the single RX queue that is associated with a particular CPU, the typical use case is to employ one listening process per RX queue, with the incoming flow being handled by a listener on the same CPU that is handling the RX queue. This provides optimal NUMA behavior and keeps CPU caches hot.

SO_INCOMING_NAPI_ID (gettable since Linux 4.12)
Returns a system-level unique ID called NAPI ID that is associated with a RX queue on which the last packet associated with that socket is received.

This can be used by an application to split the incoming flows among worker threads based on the RX queue on which the packets associated with the flows are received. It allows each worker thread to be associated with a NIC HW receive queue and service all the connection requests received on that RX queue. This mapping between an app thread and a HW NIC queue streamlines the flow of data from the NIC to the application.

SO_KEEPALIVE
Enable sending of keep-alive messages on connection-oriented sockets. Expects an integer boolean flag.

SO_LINGER
Sets or gets the **SO_LINGER** option. The argument is a *linger* structure.

```
struct linger {
    int l_onoff;    /* linger active */
    int l_linger;   /* how many seconds to linger for */
};
```

When enabled, a *close*(2) or *shutdown*(2) will not return until all queued messages for the socket have been successfully sent or the linger timeout has been reached. Otherwise, the call returns immediately and the closing is done in the background. When the socket is closed as part of *exit*(2), it always lingers in the background.

SO_LOCK_FILTER
When set, this option will prevent changing the filters associated with the socket. These filters include any set using the socket options **SO_ATTACH_FILTER**, **SO_ATTACH_BPF**, **SO_ATTACH_REUSEPORT_CBPF**, and **SO_ATTACH_REUSEPORT_EBPF**.

The typical use case is for a privileged process to set up a raw socket (an operation that requires the **CAP_NET_RAW** capability), apply a restrictive filter, set the **SO_LOCK_FILTER** option, and then either drop its privileges or pass the socket file descriptor to an unprivileged process via a UNIX domain socket.

Once the **SO_LOCK_FILTER** option has been enabled, attempts to change or remove the filter attached to a socket, or to disable the **SO_LOCK_FILTER** option will fail with the error **EPERM**.

SO_MARK (since Linux 2.6.25)
Set the mark for each packet sent through this socket (similar to the netfilter MARK target but socket-based). Changing the mark can be used for mark-based routing without netfilter or for packet filtering. Setting this option requires the **CAP_NET_ADMIN** or **CAP_NET_RAW** (since Linux 5.17) capability.

SO_OOBINLINE
If this option is enabled, out-of-band data is directly placed into the receive data stream. Otherwise, out-of-band data is passed only when the **MSG_OOB** flag is set during receiving.

SO_PASSCRED
Enable or disable the receiving of the **SCM_CREDENTIALS** control message. For more information, see *unix*(7).

SO_PASSSEC
Enable or disable the receiving of the **SCM_SECURITY** control message. For more information, see *unix*(7).

SO_PEEK_OFF (since Linux 3.4)
This option, which is currently supported only for *unix*(7) sockets, sets the value of the "peek offset" for the *recv*(2) system call when used with **MSG_PEEK** flag.

When this option is set to a negative value (it is set to −1 for all new sockets), traditional behavior is provided: *recv*(2) with the **MSG_PEEK** flag will peek data from the front of the queue.

When the option is set to a value greater than or equal to zero, then the next peek at data queued in the socket will occur at the byte offset specified by the option value. At the same time, the "peek offset" will be incremented by the number of bytes that were peeked from the queue, so that a subsequent peek will return the next data in the queue.

If data is removed from the front of the queue via a call to *recv*(2) (or similar) without the **MSG_PEEK** flag, the "peek offset" will be decreased by the number of bytes removed. In other words, receiving data without the **MSG_PEEK** flag will cause the "peek offset" to be adjusted to maintain the correct relative position in the queued data, so that a subsequent peek will retrieve the data that would have been retrieved had the data not been removed.

For datagram sockets, if the "peek offset" points to the middle of a packet, the data returned will be marked with the **MSG_TRUNC** flag.

The following example serves to illustrate the use of **SO_PEEK_OFF**. Suppose a stream socket has the following queued input data:

```
aabbccddeeff
```

The following sequence of *recv*(2) calls would have the effect noted in the comments:

```
int ov = 4;                  // Set peek offset to 4
setsockopt(fd, SOL_SOCKET, SO_PEEK_OFF, &ov, sizeof(ov));

recv(fd, buf, 2, MSG_PEEK);  // Peeks "cc"; offset set to 6
recv(fd, buf, 2, MSG_PEEK);  // Peeks "dd"; offset set to 8
recv(fd, buf, 2, 0);         // Reads "aa"; offset set to 6
recv(fd, buf, 2, MSG_PEEK);  // Peeks "ee"; offset set to 8
```

SO_PEERCRED
Return the credentials of the peer process connected to this socket. For further details, see *unix*(7).

SO_PEERSEC (since Linux 2.6.2)
Return the security context of the peer socket connected to this socket. For further details, see *unix*(7) and *ip*(7).

SO_PRIORITY
Set the protocol-defined priority for all packets to be sent on this socket. Linux uses this value to order the networking queues: packets with a higher priority may be processed first depending on the selected device queueing discipline. Setting a priority outside the range 0 to 6 requires the **CAP_NET_ADMIN** capability.

SO_PROTOCOL (since Linux 2.6.32)
Retrieves the socket protocol as an integer, returning a value such as **IPPROTO_SCTP**. See *socket*(2) for details. This socket option is read-only.

SO_RCVBUF
Sets or gets the maximum socket receive buffer in bytes. The kernel doubles this value (to allow space for bookkeeping overhead) when it is set using *setsockopt*(2), and this doubled value is returned by *getsockopt*(2). The default value is set by the */proc/sys/net/core/rmem_default* file, and the maximum allowed value is set by the */proc/sys/net/core/rmem_max* file. The minimum (doubled) value for this option is 256.

SO_RCVBUFFORCE (since Linux 2.6.14)
Using this socket option, a privileged (**CAP_NET_ADMIN**) process can perform the same task as **SO_RCVBUF**, but the *rmem_max* limit can be overridden.

SO_RCVLOWAT and **SO_SNDLOWAT**
Specify the minimum number of bytes in the buffer until the socket layer will pass the data to the protocol (**SO_SNDLOWAT**) or the user on receiving (**SO_RCVLOWAT**). These two values are initialized to 1. **SO_SNDLOWAT** is not changeable on Linux (**setsockopt**(2) fails with the error **ENOPROTOOPT**). **SO_RCVLOWAT** is changeable only since Linux 2.4.

Before Linux 2.6.28 *select*(2), *poll*(2), and *epoll*(7) did not respect the **SO_RCVLOWAT** setting on Linux, and indicated a socket as readable when even a single byte of data was available. A subsequent read from the socket would then block until **SO_RCVLOWAT** bytes are available. Since Linux 2.6.28, *select*(2), *poll*(2), and *epoll*(7) indicate a socket as readable only if at least **SO_RCVLOWAT** bytes are available.

SO_RCVTIMEO and **SO_SNDTIMEO**
Specify the receiving or sending timeouts until reporting an error. The argument is a *struct timeval*. If an input or output function blocks for this period of time, and data has been sent or received, the return value of that function will be the amount of data transferred; if no data has been transferred and the timeout has been reached, then −1 is returned with *errno* set to **EAGAIN** or **EWOULDBLOCK**, or **EINPROGRESS** (for *connect*(2)) just as if the socket was specified to be nonblocking. If the timeout is set to zero (the default), then the operation will never timeout. Timeouts only have effect for system calls that perform socket I/O (e.g., *accept*(2), *connect*(2), *read*(2), *recvmsg*(2), *send*(2), *sendmsg*(2)); timeouts have no effect for *select*(2), *poll*(2), *epoll_wait*(2), and so on.

SO_REUSEADDR
Indicates that the rules used in validating addresses supplied in a *bind*(2) call should allow reuse of local addresses. For **AF_INET** sockets this means that a socket may bind, except when there is an active listening socket bound to the address. When the listening socket is bound to **INADDR_ANY** with a specific port then it is not possible to bind to this port for any local address. Argument is an integer boolean flag.

SO_REUSEPORT (since Linux 3.9)
Permits multiple **AF_INET** or **AF_INET6** sockets to be bound to an identical socket address. This option must be set on each socket (including the first socket) prior to calling *bind*(2) on the socket. To prevent port hijacking, all of the processes binding to the same address must have the same effective UID. This option can be employed with both TCP and UDP sockets.

For TCP sockets, this option allows *accept*(2) load distribution in a multi-threaded server to be improved by using a distinct listener socket for each thread. This provides improved load distribution as compared to traditional techniques such using a single *accept*(2)ing thread that distributes connections, or having multiple threads that compete to *accept*(2) from the same socket.

For UDP sockets, the use of this option can provide better distribution of incoming datagrams to multiple processes (or threads) as compared to the traditional technique of having multiple processes compete to receive datagrams on the same socket.

SO_RXQ_OVFL (since Linux 2.6.33)
Indicates that an unsigned 32-bit value ancillary message (cmsg) should be attached to received skbs indicating the number of packets dropped by the socket since its creation.

SO_SELECT_ERR_QUEUE (since Linux 3.10)
When this option is set on a socket, an error condition on a socket causes notification not only via the *exceptfds* set of *select*(2). Similarly, *poll*(2) also returns a **POLLPRI** whenever an **POLLERR** event is returned.

Background: this option was added when waking up on an error condition occurred only via the *readfds* and *writefds* sets of *select*(2). The option was added to allow monitoring for error conditions via the *exceptfds* argument without simultaneously having to receive notifications (via *readfds*) for regular data that can be read from the socket. After changes in Linux 4.16, the use of this flag to achieve the desired notifications is no longer necessary. This option is nevertheless retained for backwards compatibility.

SO_SNDBUF
Sets or gets the maximum socket send buffer in bytes. The kernel doubles this value (to allow space for bookkeeping overhead) when it is set using *setsockopt*(2), and this doubled value is returned by *getsockopt*(2). The default value is set by the */proc/sys/net/core/wmem_default* file and the maximum allowed value is set by the */proc/sys/net/core/wmem_max* file. The minimum (doubled) value for this option is 2048.

SO_SNDBUFFORCE (since Linux 2.6.14)
Using this socket option, a privileged (**CAP_NET_ADMIN**) process can perform the same task as **SO_SNDBUF**, but the *wmem_max* limit can be overridden.

SO_TIMESTAMP
Enable or disable the receiving of the **SO_TIMESTAMP** control message. The timestamp control message is sent with level **SOL_SOCKET** and a *cmsg_type* of **SCM_TIMESTAMP**. The *cmsg_data* field is a *struct timeval* indicating the reception time of the last packet passed to the user in this call. See *cmsg*(3) for details on control messages.

SO_TIMESTAMPNS (since Linux 2.6.22)
Enable or disable the receiving of the **SO_TIMESTAMPNS** control message. The timestamp control message is sent with level **SOL_SOCKET** and a *cmsg_type* of **SCM_TIMESTAMPNS**. The *cmsg_data* field is a *struct timespec* indicating the reception time of the last packet passed to the user in this call. The clock used for the timestamp is **CLOCK_REALTIME**. See *cmsg*(3) for details on control messages.

A socket cannot mix **SO_TIMESTAMP** and **SO_TIMESTAMPNS**: the two modes are mutually exclusive.

SO_TYPE
Gets the socket type as an integer (e.g., **SOCK_STREAM**). This socket option is read-only.

SO_BUSY_POLL (since Linux 3.11)
Sets the approximate time in microseconds to busy poll on a blocking receive when there is no data. Increasing this value requires **CAP_NET_ADMIN**. The default for this option is controlled by the */proc/sys/net/core/busy_read* file.

The value in the */proc/sys/net/core/busy_poll* file determines how long *select*(2) and *poll*(2) will busy poll when they operate on sockets with **SO_BUSY_POLL** set and no events to report are found.

In both cases, busy polling will only be done when the socket last received data from a network device that supports this option.

While busy polling may improve latency of some applications, care must be taken when using it since this will increase both CPU utilization and power usage.

Signals

When writing onto a connection-oriented socket that has been shut down (by the local or the remote end) **SIGPIPE** is sent to the writing process and **EPIPE** is returned. The signal is not sent when the write call specified the **MSG_NOSIGNAL** flag.

When requested with the **FIOSETOWN** *fcntl*(2) or **SIOCSPGRP** *ioctl*(2), **SIGIO** is sent when an I/O event occurs. It is possible to use *poll*(2) or *select*(2) in the signal handler to find out which socket the event occurred on. An alternative (in Linux 2.2) is to set a real-time signal using the **F_SETSIG** *fcntl*(2); the handler of the real time signal will be called with the file descriptor in the *si_fd* field of its *siginfo_t*. See *fcntl*(2) for more information.

Under some circumstances (e.g., multiple processes accessing a single socket), the condition that caused the **SIGIO** may have already disappeared when the process reacts to the signal. If this happens, the process should wait again because Linux will resend the signal later.

/proc interfaces

The core socket networking parameters can be accessed via files in the directory */proc/sys/net/core/*.

rmem_default
contains the default setting in bytes of the socket receive buffer.

rmem_max
: contains the maximum socket receive buffer size in bytes which a user may set by using the **SO_RCVBUF** socket option.

wmem_default
: contains the default setting in bytes of the socket send buffer.

wmem_max
: contains the maximum socket send buffer size in bytes which a user may set by using the **SO_SNDBUF** socket option.

message_cost and *message_burst*
: configure the token bucket filter used to load limit warning messages caused by external network events.

netdev_max_backlog
: Maximum number of packets in the global input queue.

optmem_max
: Maximum length of ancillary data and user control data like the iovecs per socket.

Ioctls

These operations can be accessed using *ioctl*(2):

```
error = ioctl(ip_socket, ioctl_type, &value_result);
```

SIOCGSTAMP
: Return a *struct timeval* with the receive timestamp of the last packet passed to the user. This is useful for accurate round trip time measurements. See *setitimer*(2) for a description of *struct timeval*. This ioctl should be used only if the socket options **SO_TIMESTAMP** and **SO_TIMESTAMPNS** are not set on the socket. Otherwise, it returns the timestamp of the last packet that was received while **SO_TIMESTAMP** and **SO_TIMESTAMPNS** were not set, or it fails if no such packet has been received, (i.e., *ioctl*(2) returns −1 with *errno* set to **ENOENT**).

SIOCSPGRP
: Set the process or process group that is to receive **SIGIO** or **SIGURG** signals when I/O becomes possible or urgent data is available. The argument is a pointer to a *pid_t*. For further details, see the description of **F_SETOWN** in *fcntl*(2).

FIOASYNC
: Change the **O_ASYNC** flag to enable or disable asynchronous I/O mode of the socket. Asynchronous I/O mode means that the **SIGIO** signal or the signal set with **F_SETSIG** is raised when a new I/O event occurs.

  Argument is an integer boolean flag. (This operation is synonymous with the use of *fcntl*(2) to set the **O_ASYNC** flag.)

SIOCGPGRP
: Get the current process or process group that receives **SIGIO** or **SIGURG** signals, or 0 when none is set.

Valid *fcntl*(2) operations:

FIOGETOWN
: The same as the **SIOCGPGRP** *ioctl*(2).

FIOSETOWN
: The same as the **SIOCSPGRP** *ioctl*(2).

VERSIONS

SO_BINDTODEVICE was introduced in Linux 2.0.30. **SO_PASSCRED** is new in Linux 2.2. The */proc* interfaces were introduced in Linux 2.2. **SO_RCVTIMEO** and **SO_SNDTIMEO** are supported since Linux 2.3.41. Earlier, timeouts were fixed to a protocol-specific setting, and could not be read or written.

NOTES

Linux assumes that half of the send/receive buffer is used for internal kernel structures; thus the values in the corresponding */proc* files are twice what can be observed on the wire.

Linux will allow port reuse only with the **SO_REUSEADDR** option when this option was set both in the previous program that performed a *bind*(2) to the port and in the program that wants to reuse the port. This differs from some implementations (e.g., FreeBSD) where only the later program needs to set the **SO_REUSEADDR** option. Typically this difference is invisible, since, for example, a server program is designed to always set this option.

spufs − SPU filesystem

DESCRIPTION

The SPU filesystem is used on PowerPC machines that implement the Cell Broadband Engine Architecture in order to access Synergistic Processor Units (SPUs).

The filesystem provides a name space similar to POSIX shared memory or message queues. Users that have write permissions on the filesystem can use *spu_create*(2) to establish SPU contexts under the **spufs** root directory.

Every SPU context is represented by a directory containing a predefined set of files. These files can be used for manipulating the state of the logical SPU. Users can change permissions on the files, but can't add or remove files.

Mount options

uid=<uid>
: Set the user owning the mount point; the default is 0 (root).

gid=<gid>
: Set the group owning the mount point; the default is 0 (root).

mode=<mode>
: Set the mode of the top-level directory in **spufs**, as an octal mode string. The default is 0775.

Files

The files in **spufs** mostly follow the standard behavior for regular system calls like *read*(2) or *write*(2), but often support only a subset of the operations supported on regular filesystems. This list details the supported operations and the deviations from the standard behavior described in the respective man pages.

All files that support the *read*(2) operation also support *readv*(2) and all files that support the *write*(2) operation also support *writev*(2). All files support the *access*(2) and *stat*(2) family of operations, but for the latter call, the only fields of the returned *stat* structure that contain reliable information are *st_mode*, *st_nlink*, *st_uid*, and *st_gid*.

All files support the *chmod*(2)/*fchmod*(2) and *chown*(2)/*fchown*(2) operations, but will not be able to grant permissions that contradict the possible operations (e.g., read access on the *wbox* file).

The current set of files is:

/capabilities
: Contains a comma-delimited string representing the capabilities of this SPU context. Possible capabilities are:

  sched This context may be scheduled.

  step This context can be run in single-step mode, for debugging.

  New capabilities flags may be added in the future.

/mem
: the contents of the local storage memory of the SPU. This can be accessed like a regular shared memory file and contains both code and data in the address space of the SPU. The possible operations on an open *mem* file are:

  read(2)
  pread(2)
  write(2)
  pwrite(2)
  lseek(2)
  : These operate as usual, with the exception that *lseek*(2), *write*(2), and *pwrite*(2) are not supported beyond the end of the file. The file size is the size of the local storage of the SPU, which is normally 256 kilobytes.

  mmap(2)
  : Mapping *mem* into the process address space provides access to the SPU local storage within the process address space. Only **MAP_SHARED** mappings are allowed.

/regs Contains the saved general-purpose registers of the SPU context. This file contains the 128-bit values of each register, from register 0 to register 127, in order. This allows the general-purpose registers to be inspected for debugging.

Reading to or writing from this file requires that the context is scheduled out, so use of this file is not recommended in normal program operation.

The *regs* file is not present on contexts that have been created with the **SPU_CREATE_NOSCHED** flag.

/mbox The first SPU-to-CPU communication mailbox. This file is read-only and can be read in units of 4 bytes. The file can be used only in nonblocking mode − even *poll*(2) cannot be used to block on this file. The only possible operation on an open *mbox* file is:

read(2) If *count* is smaller than four, *read*(2) returns −1 and sets *errno* to **EINVAL**. If there is no data available in the mailbox (i.e., the SPU has not sent a mailbox message), the return value is set to −1 and *errno* is set to **EAGAIN**. When data has been read successfully, four bytes are placed in the data buffer and the value four is returned.

/ibox The second SPU-to-CPU communication mailbox. This file is similar to the first mailbox file, but can be read in blocking I/O mode, thus calling *read*(2) on an open *ibox* file will block until the SPU has written data to its interrupt mailbox channel (unless the file has been opened with **O_NONBLOCK**, see below). Also, *poll*(2) and similar system calls can be used to monitor for the presence of mailbox data.

The possible operations on an open *ibox* file are:

read(2) If *count* is smaller than four, *read*(2) returns −1 and sets *errno* to **EINVAL**. If there is no data available in the mailbox and the file descriptor has been opened with **O_NONBLOCK**, the return value is set to −1 and *errno* is set to **EAGAIN**.

If there is no data available in the mailbox and the file descriptor has been opened without **O_NONBLOCK**, the call will block until the SPU writes to its interrupt mailbox channel. When data has been read successfully, four bytes are placed in the data buffer and the value four is returned.

poll(2) Poll on the *ibox* file returns *(POLLIN | POLLRDNORM)* whenever data is available for reading.

/wbox The CPU-to-SPU communication mailbox. It is write-only and can be written in units of four bytes. If the mailbox is full, *write*(2) will block, and *poll*(2) can be used to block until the mailbox is available for writing again. The possible operations on an open *wbox* file are:

write(2)

If *count* is smaller than four, *write*(2) returns −1 and sets *errno* to **EINVAL**. If there is no space available in the mailbox and the file descriptor has been opened with **O_NONBLOCK**, the return value is set to −1 and *errno* is set to **EAGAIN**.

If there is no space available in the mailbox and the file descriptor has been opened without **O_NONBLOCK**, the call will block until the SPU reads from its PPE (PowerPC Processing Element) mailbox channel. When data has been written successfully, the system call returns four as its function result.

poll(2) A poll on the *wbox* file returns *(POLLOUT | POLLWRNORM)* whenever space is available for writing.

/mbox_stat
/ibox_stat
/wbox_stat

These are read-only files that contain the length of the current queue of each mailbox—that is, how many words can be read from *mbox* or *ibox* or how many words can be written to *wbox* without blocking. The files can be read only in four-byte units and return a big-endian binary integer number. The only possible operation on an open **box_stat* file is:

read(2) If *count* is smaller than four, *read*(2) returns −1 and sets *errno* to **EINVAL**. Otherwise, a four-byte value is placed in the data buffer. This value is the number of elements that can be read from (for *mbox_stat* and *ibox_stat*) or written to (for *wbox_stat*) the respective mailbox without blocking or returning an **EAGAIN** error.

/npc
/decr
/decr_status
/spu_tag_mask
/event_mask
/event_status
/srr0
/lslr Internal registers of the SPU. These files contain an ASCII string representing the hex value of the specified register. Reads and writes on these files (except for *npc*, see below) require that the SPU context be scheduled out, so frequent access to these files is not recommended for normal program operation.

The contents of these files are:

npc	Next Program Counter − valid only when the SPU is in a stopped state.
decr	SPU Decrementer
decr_status	Decrementer Status
spu_tag_mask	MFC tag mask for SPU DMA
event_mask	Event mask for SPU interrupts
event_status	Number of SPU events pending (read-only)
srr0	Interrupt Return address register
lslr	Local Store Limit Register

The possible operations on these files are:

read(2) Reads the current register value. If the register value is larger than the buffer passed to the *read*(2) system call, subsequent reads will continue reading from the same buffer, until the end of the buffer is reached.

When a complete string has been read, all subsequent read operations will return zero bytes and a new file descriptor needs to be opened to read a new value.

write(2)
A *write*(2) operation on the file sets the register to the value given in the string. The string is parsed from the beginning until the first nonnumeric character or the end of the buffer. Subsequent writes to the same file descriptor overwrite the previous setting.

Except for the *npc* file, these files are not present on contexts that have been created with the **SPU_CREATE_NOSCHED** flag.

/fpcr This file provides access to the Floating Point Status and Control Register (fcpr) as a binary, four-byte file. The operations on the *fpcr* file are:

read(2) If *count* is smaller than four, *read*(2) returns −1 and sets *errno* to **EINVAL**. Otherwise, a four-byte value is placed in the data buffer; this is the current value of the *fpcr* register.

write(2)
If *count* is smaller than four, *write*(2) returns −1 and sets *errno* to **EINVAL**. Otherwise, a four-byte value is copied from the data buffer, updating the value of the *fpcr* register.

/signal1
/signal2
The files provide access to the two signal notification channels of an SPU. These are read-write files that operate on four-byte words. Writing to one of these files triggers an interrupt on the SPU. The value written to the signal files can be read from the SPU through a channel read or from host user space through the file. After the value has been read by the SPU, it is reset to zero. The possible operations on an open *signal1* or *signal2* file are:

read(2) If *count* is smaller than four, *read*(2) returns −1 and sets *errno* to **EINVAL**. Otherwise, a four-byte value is placed in the data buffer; this is the current value of the specified signal notification register.

write(2)
If *count* is smaller than four, *write*(2) returns −1 and sets *errno* to **EINVAL**. Otherwise, a four-byte value is copied from the data buffer, updating the value of the specified signal notification register. The signal notification register will either be replaced with the input data or will be updated to the bitwise OR operation of the old value and the input data, depending on the contents of the *signal1_type* or *signal2_type* files respectively.

/signal1_type
/signal2_type
These two files change the behavior of the *signal1* and *signal2* notification files. They contain a numeric ASCII string which is read as either "1" or "0". In mode 0 (overwrite), the hardware replaces the contents of the signal channel with the data that is written to it. In mode 1 (logical OR), the hardware accumulates the bits that are subsequently written to it. The possible operations on an open *signal1_type* or *signal2_type* file are:

read(2) When the count supplied to the *read*(2) call is shorter than the required length for the digit (plus a newline character), subsequent reads from the same file descriptor will complete the string. When a complete string has been read, all subsequent read operations will return zero bytes and a new file descriptor needs to be opened to read the value again.

write(2)
A *write*(2) operation on the file sets the register to the value given in the string. The string is parsed from the beginning until the first nonnumeric character or the end of the buffer. Subsequent writes to the same file descriptor overwrite the previous setting.

/mbox_info
/ibox_info
/wbox_info
/dma_into
/proxydma_info
Read-only files that contain the saved state of the SPU mailboxes and DMA queues. This allows the SPU status to be inspected, mainly for debugging. The *mbox_info* and *ibox_info* files each contain the four-byte mailbox message that has been written by the SPU. If no message has been written to these mailboxes, then contents of these files is undefined. The *mbox_stat*, *ibox_stat*, and *wbox_stat* files contain the available message count.

The *wbox_info* file contains an array of four-byte mailbox messages, which have been sent to the SPU. With current CBEA machines, the array is four items in length, so up to 4 * 4 = 16 bytes can be read from this file. If any mailbox queue entry is empty, then the bytes read at the corresponding location are undefined.

The *dma_info* file contains the contents of the SPU MFC DMA queue, represented as the following structure:

```
struct spu_dma_info {
    uint64_t         dma_info_type;
    uint64_t         dma_info_mask;
    uint64_t         dma_info_status;
    uint64_t         dma_info_stall_and_notify;
    uint64_t         dma_info_atomic_command_status;
    struct mfc_cq_sr dma_info_command_data[16];
};
```

The last member of this data structure is the actual DMA queue, containing 16 entries. The *mfc_cq_sr* structure is defined as:

```
struct mfc_cq_sr {
    uint64_t mfc_cq_data0_RW;
```

```
    uint64_t mfc_cq_data1_RW;
    uint64_t mfc_cq_data2_RW;
    uint64_t mfc_cq_data3_RW;
};
```

The *proxydma_info* file contains similar information, but describes the proxy DMA queue (i.e., DMAs initiated by entities outside the SPU) instead. The file is in the following format:

```
struct spu_proxydma_info {
    uint64_t         proxydma_info_type;
    uint64_t         proxydma_info_mask;
    uint64_t         proxydma_info_status;
    struct mfc_cq_sr proxydma_info_command_data[8];
};
```

Accessing these files requires that the SPU context is scheduled out - frequent use can be inefficient. These files should not be used for normal program operation.

These files are not present on contexts that have been created with the **SPU_CREATE_NOSCHED** flag.

/cntl This file provides access to the SPU Run Control and SPU status registers, as an ASCII string. The following operations are supported:

read(2) Reads from the *cntl* file will return an ASCII string with the hex value of the SPU Status register.

write(2)
Writes to the *cntl* file will set the context's SPU Run Control register.

/mfc Provides access to the Memory Flow Controller of the SPU. Reading from the file returns the contents of the SPU's MFC Tag Status register, and writing to the file initiates a DMA from the MFC. The following operations are supported:

write(2)
Writes to this file need to be in the format of a MFC DMA command, defined as follows:

```
struct mfc_dma_command {
    int32_t  pad;    /* reserved */
    uint32_t lsa;    /* local storage address */
    uint64_t ea;     /* effective address */
    uint16_t size;   /* transfer size */
    uint16_t tag;    /* command tag */
    uint16_t class;  /* class ID */
    uint16_t cmd;    /* command opcode */
};
```

Writes are required to be exactly *sizeof(struct mfc_dma_command)* bytes in size. The command will be sent to the SPU's MFC proxy queue, and the tag stored in the kernel (see below).

read(2) Reads the contents of the tag status register. If the file is opened in blocking mode (i.e., without **O_NONBLOCK**), then the read will block until a DMA tag (as performed by a previous write) is complete. In nonblocking mode, the MFC tag status register will be returned without waiting.

poll(2) Calling *poll*(2) on the *mfc* file will block until a new DMA can be started (by checking for **POLLOUT**) or until a previously started DMA (by checking for **POLLIN**) has been completed.

/mss Provides access to the MFC MultiSource Synchronization (MSS) facility. By *mmap*(2)-ing this file, processes can access the MSS area of the SPU.

The following operations are supported:

mmap(2)
: Mapping **mss** into the process address space gives access to the SPU MSS area within the process address space. Only **MAP_SHARED** mappings are allowed.

/psmap Provides access to the whole problem-state mapping of the SPU. Applications can use this area to interface to the SPU, rather than writing to individual register files in **spufs**.

The following operations are supported:

mmap(2)
: Mapping **psmap** gives a process a direct map of the SPU problem state area. Only **MAP_SHARED** mappings are supported.

/phys−id
: Read-only file containing the physical SPU number that the SPU context is running on. When the context is not running, this file contains the string "−1".

The physical SPU number is given by an ASCII hex string.

/object−id
: Allows applications to store (or retrieve) a single 64-bit ID into the context. This ID is later used by profiling tools to uniquely identify the context.

write(2)
: By writing an ASCII hex value into this file, applications can set the object ID of the SPU context. Any previous value of the object ID is overwritten.

read(2) Reading this file gives an ASCII hex string representing the object ID for this SPU context.

EXAMPLES

To automatically *mount*(8) the SPU filesystem when booting, at the location */spu* chosen by the user, put this line into the *fstab*(5) configuration file:

```
none /spu spufs gid=spu 0 0
```

The Cell Broadband Engine Architecture (CBEA) specification

NAME

standards − C and UNIX Standards

DESCRIPTION

The STANDARDS section that appears in many manual pages identifies various standards to which the documented interface conforms. The following list briefly describes these standards.

V7 Version 7 (also known as Seventh Edition) UNIX, released by AT&T/Bell Labs in 1979. After this point, UNIX systems diverged into two main dialects: BSD and System V.

4.2BSD

This is an implementation standard defined by the 4.2 release of the *Berkeley Software Distribution*, released by the University of California at Berkeley. This was the first Berkeley release that contained a TCP/IP stack and the sockets API. 4.2BSD was released in 1983.

Earlier major BSD releases included *3BSD* (1980), *4BSD* (1980), and *4.1BSD* (1981).

4.3BSD

The successor to 4.2BSD, released in 1986.

4.4BSD

The successor to 4.3BSD, released in 1993. This was the last major Berkeley release.

System V

This is an implementation standard defined by AT&T's milestone 1983 release of its commercial System V (five) release. The previous major AT&T release was *System III*, released in 1981.

System V release 2 (SVr2)

This was the next System V release, made in 1985. The SVr2 was formally described in the *System V Interface Definition version 1* (*SVID 1*) published in 1985.

System V release 3 (SVr3)

This was the successor to SVr2, released in 1986. This release was formally described in the *System V Interface Definition version 2* (*SVID 2*).

System V release 4 (SVr4)

This was the successor to SVr3, released in 1989. This version of System V is described in the "Programmer's Reference Manual: Operating System API (Intel processors)" (Prentice-Hall 1992, ISBN 0-13-951294-2) This release was formally described in the *System V Interface Definition version 3* (*SVID 3*), and is considered the definitive System V release.

SVID 4

System V Interface Definition version 4, issued in 1995. Available online at .

C89 This was the first C language standard, ratified by ANSI (American National Standards Institute) in 1989 (*X3.159-1989*). Sometimes this is known as *ANSI C*, but since C99 is also an ANSI standard, this term is ambiguous. This standard was also ratified by ISO (International Standards Organization) in 1990 (*ISO/IEC 9899:1990*), and is thus occasionally referred to as *ISO C90*.

C99 This revision of the C language standard was ratified by ISO in 1999 (*ISO/IEC 9899:1999*). Available online at .

C11 This revision of the C language standard was ratified by ISO in 2011 (*ISO/IEC 9899:2011*).

LFS The Large File Summit specification, completed in 1996. This specification defined mechanisms that allowed 32-bit systems to support the use of large files (i.e., 64-bit file offsets). See .

POSIX.1-1988

This was the first POSIX standard, ratified by IEEE as IEEE Std 1003.1-1988, and subsequently adopted (with minor revisions) as an ISO standard in 1990. The term "POSIX" was coined by Richard Stallman.

POSIX.1-1990

"Portable Operating System Interface for Computing Environments". IEEE 1003.1-1990 part 1, ratified by ISO in 1990 (*ISO/IEC 9945-1:1990*).

POSIX.2
IEEE Std 1003.2-1992, describing commands and utilities, ratified by ISO in 1993 (*ISO/IEC 9945-2:1993*).

POSIX.1b (formerly known as *POSIX.4*)
IEEE Std 1003.1b-1993, describing real-time facilities for portable operating systems, ratified by ISO in 1996 (*ISO/IEC 9945-1:1996*).

POSIX.1c (formerly known as *POSIX.4a*)
IEEE Std 1003.1c-1995, which describes the POSIX threads interfaces.

POSIX.1d
IEEE Std 1003.1d-1999, which describes additional real-time extensions.

POSIX.1g
IEEE Std 1003.1g-2000, which describes networking APIs (including sockets).

POSIX.1j
IEEE Std 1003.1j-2000, which describes advanced real-time extensions.

POSIX.1-1996
A 1996 revision of POSIX.1 which incorporated POSIX.1b and POSIX.1c.

XPG3 Released in 1989, this was the first release of the X/Open Portability Guide to be based on a POSIX standard (POSIX.1-1988). This multivolume guide was developed by the X/Open Group, a multivendor consortium.

XPG4 A revision of the X/Open Portability Guide, released in 1992. This revision incorporated POSIX.2.

XPG4v2
A 1994 revision of XPG4. This is also referred to as *Spec 1170*, where 1170 referred to the number of interfaces defined by this standard.

SUS (SUSv1)
Single UNIX Specification. This was a repackaging of XPG4v2 and other X/Open standards (X/Open Curses Issue 4 version 2, X/Open Networking Service (XNS) Issue 4). Systems conforming to this standard can be branded *UNIX 95*.

SUSv2 Single UNIX Specification version 2. Sometimes also referred to (incorrectly) as *XPG5*. This standard appeared in 1997. Systems conforming to this standard can be branded *UNIX 98*. See also .)

POSIX.1-2001

SUSv3 This was a 2001 revision and consolidation of the POSIX.1, POSIX.2, and SUS standards into a single document, conducted under the auspices of the Austin Group . The standard is available online at .

The standard defines two levels of conformance: *POSIX conformance*, which is a baseline set of interfaces required of a conforming system; and *XSI Conformance*, which additionally mandates a set of interfaces (the "XSI extension") which are only optional for POSIX conformance. XSI-conformant systems can be branded *UNIX 03*.

The POSIX.1-2001 document is broken into four parts:

XBD: Definitions, terms, and concepts, header file specifications.

XSH: Specifications of functions (i.e., system calls and library functions in actual implementations).

XCU: Specifications of commands and utilities (i.e., the area formerly described by POSIX.2).

XRAT: Informative text on the other parts of the standard.

POSIX.1-2001 is aligned with C99, so that all of the library functions standardized in C99 are also standardized in POSIX.1-2001.

The Single UNIX Specification version 3 (SUSv3) comprises the Base Specifications containing XBD, XSH, XCU, and XRAT as above, plus X/Open Curses Issue 4 version 2 as an extra volume that is not in POSIX.1-2001.

Two Technical Corrigenda (minor fixes and improvements) of the original 2001 standard have occurred: TC1 in 2003 and TC2 in 2004.

POSIX.1-2008

SUSv4 Work on the next revision of POSIX.1/SUS was completed and ratified in 2008. The standard is available online at .

The changes in this revision are not as large as those that occurred for POSIX.1-2001/SUSv3, but a number of new interfaces are added and various details of existing specifications are modified. Many of the interfaces that were optional in POSIX.1-2001 become mandatory in the 2008 revision of the standard. A few interfaces that are present in POSIX.1-2001 are marked as obsolete in POSIX.1-2008, or removed from the standard altogether.

The revised standard is structured in the same way as its predecessor. The Single UNIX Specification version 4 (SUSv4) comprises the Base Specifications containing XBD, XSH, XCU, and XRAT, plus X/Open Curses Issue 7 as an extra volume that is not in POSIX.1-2008.

Again there are two levels of conformance: the baseline *POSIX Conformance*, and *XSI Conformance*, which mandates an additional set of interfaces beyond those in the base specification.

In general, where the STANDARDS section of a manual page lists POSIX.1-2001, it can be assumed that the interface also conforms to POSIX.1-2008, unless otherwise noted.

Technical Corrigendum 1 (minor fixes and improvements) of this standard was released in 2013.

Technical Corrigendum 2 of this standard was released in 2016.

Further information can be found on the Austin Group web site, .

SUSv4 2016 edition

This is equivalent to POSIX.1-2008, with the addition of Technical Corrigenda 1 and 2 and the XCurses specification.

POSIX.1-2017

This revision of POSIX is technically identical to POSIX.1-2008 with Technical Corrigenda 1 and 2 applied.

SUSv4 2018 edition

This is equivalent to POSIX.1-2017, with the addition of the XCurses specification.

The interfaces documented in POSIX.1/SUS are available as manual pages under sections 0p (header files), 1p (commands), and 3p (functions); thus one can write "man 3p open".

NAME

stpcpy, strcpy, strcat, stpecpy, strtcpy, strlcpy, strlcat, stpncpy, strncpy, strncat − copying strings and character sequences

SYNOPSIS

Strings

```
// Chain-copy a string.
char *stpcpy(char *restrict dst, const char *restrict src);

// Copy/catenate a string.
char *strcpy(char *restrict dst, const char *restrict src);
char *strcat(char *restrict dst, const char *restrict src);

// Chain-copy a string with truncation.
char *stpecpy(char *dst, char end[0], const char *restrict src);

// Copy/catenate a string with truncation.
ssize_t strtcpy(char dst[restrict .dsize], const char *restrict src,
                size_t dsize);
size_t strlcpy(char dst[restrict .dsize], const char *restrict src,
               size_t dsize);
size_t strlcat(char dst[restrict .dsize], const char *restrict src,
               size_t dsize);
```

Null-padded character sequences

```
// Fill a fixed-size buffer with characters from a string
// and pad with null bytes.
char *strncpy(char dst[restrict .dsize], const char *restrict src,
              size_t dsize);
char *stpncpy(char dst[restrict .dsize], const char *restrict src,
              size_t dsize);

// Chain-copy a null-padded character sequence into a character sequence.
mempcpy(dst, src, strnlen(src, NITEMS(src)));

// Chain-copy a null-padded character sequence into a string.
stpcpy(mempcpy(dst, src, strnlen(src, NITEMS(src))), "");

// Catenate a null-padded character sequence into a string.
char *strncat(char *restrict dst, const char src[restrict .ssize],
              size_t ssize);
```

Known-length character sequences

```
// Chain-copy a known-length character sequence.
void *mempcpy(void dst[restrict .len], const void src[restrict .len],
              size_t len);

// Chain-copy a known-length character sequence into a string.
stpcpy(mempcpy(dst, src, len), "");
```

DESCRIPTION

Terms (and abbreviations)

string (*str*)
: is a sequence of zero or more non-null characters followed by a null character.

character sequence
: is a sequence of zero or more non-null characters. A program should never use a character sequence where a string is required. However, with appropriate care, a string can be used in the place of a character sequence.

  null-padded character sequence
  : Character sequences can be contained in fixed-size buffers, which contain padding null bytes after the character sequence, to fill the rest of the buffer without affecting the character sequence; however, those padding null bytes are not part of the character sequence. Don’t confuse null-padded with null-terminated: null-padded means 0 or more padding null bytes, while null-terminated means exactly 1 terminating null

character.

known-length character sequence
Character sequence delimited by its length. It may be a slice of a larger character sequence, or even of a string.

length (*len*)
is the number of non-null characters in a string or character sequence. It is the return value of *strlen(str)* and of *strnlen(buf, size)*.

size refers to the entire buffer where the string or character sequence is contained.

end is the name of a pointer to one past the last element of a buffer. It is equivalent to *&str[size]*. It is used as a sentinel value, to be able to truncate strings or character sequences instead of overrunning the containing buffer.

copy This term is used when the writing starts at the first element pointed to by *dst*.

catenate
This term is used when a function first finds the terminating null character in *dst*, and then starts writing at that position.

chain This term is used when it's the programmer who provides a pointer to the terminating null character in the string *dst* (or one after the last character in a character sequence), and the function starts writing at that location. The function returns a pointer to the new location of the terminating null character (or one after the last character in a character sequence) after the call, so that the programmer can use it to chain such calls.

Copy, catenate, and chain-copy

Originally, there was a distinction between functions that copy and those that catenate. However, newer functions that copy while allowing chaining cover both use cases with a single API. They are also algorithmically faster, since they don't need to search for the terminating null character of the existing string. However, functions that catenate have a much simpler use, so if performance is not important, it can make sense to use them for improving readability.

The pointer returned by functions that allow chaining is a byproduct of the copy operation, so it has no performance costs. Functions that return such a pointer, and thus can be chained, have names of the form *__stp__*(), since it's common to name the pointer just *p*.

Chain-copying functions that truncate should accept a pointer to the end of the destination buffer, and have names of the form *__stpe__*(). This allows not having to recalculate the remaining size after each call.

Truncate or not?

The first thing to note is that programmers should be careful with buffers, so they always have the correct size, and truncation is not necessary.

In most cases, truncation is not desired, and it is simpler to just do the copy. Simpler code is safer code. Programming against programming mistakes by adding more code just adds more points where mistakes can be made.

Nowadays, compilers can detect most programmer errors with features like compiler warnings, static analyzers, and **_FORTIFY_SOURCE** (see *ftm*(7)). Keeping the code simple helps these overflow-detection features be more precise.

When validating user input, code should normally not truncate, but instead fail and prevent the copy at all.

In some cases, however, it makes sense to truncate.

Functions that truncate:

- **stpecpy**()
- **strtcpy**()
- *strlcpy*(3bsd) and *strlcat*(3bsd) are similar, but have important performance problems; see BUGS.
- *stpncpy*(3) and *strncpy*(3) also truncate, but they don't write strings, but rather null-padded character sequences.

Null-padded character sequences

For historic reasons, some standard APIs and file formats, such as *utmpx*(5) and *tar*(1), use null-padded character sequences in fixed-size buffers. To interface with them, specialized functions need to be used.

To copy bytes from strings into these buffers, use *strncpy*(3) or *stpncpy*(3).

To read a null-padded character sequence, use *strnlen(src, NITEMS(src))*, and then you can treat it as a known-length character sequence; or use *strncat*(3) directly.

Known-length character sequences

The simplest character sequence copying function is *mempcpy*(3). It requires always knowing the length of your character sequences, for which structures can be used. It makes the code much faster, since you always know the length of your character sequences, and can do the minimal copies and length measurements. *mempcpy*(3) copies character sequences, so you need to explicitly set the terminating null character if you need a string.

In programs that make considerable use of strings or character sequences, and need the best performance, using overlapping character sequences can make a big difference. It allows holding subsequences of a larger character sequence, while not duplicating memory nor using time to do a copy.

However, this is delicate, since it requires using character sequences. C library APIs use strings, so programs that use character sequences will have to take care of differentiating strings from character sequences.

To copy a known-length character sequence, use *mempcpy*(3).

To copy a known-length character sequence into a string, use *stpcpy(mempcpy(dst, src, len), "")*.

A string is also accepted as input, because *mempcpy*(3) asks for the length, and a string is composed of a character sequence of the same length plus a terminating null character.

String vs character sequence

Some functions only operate on strings. Those require that the input *src* is a string, and guarantee an output string (even when truncation occurs). Functions that catenate also require that *dst* holds a string before the call. List of functions:

- *stpcpy*(3)
- *strcpy*(3), *strcat*(3)
- **stpecpy**()
- **strtcpy**()
- *strlcpy*(3bsd), *strlcat*(3bsd)

Other functions require an input string, but create a character sequence as output. These functions have confusing names, and have a long history of misuse. List of functions:

- *stpncpy*(3)
- *strncpy*(3)

Other functions operate on an input character sequence, and create an output string. Functions that catenate also require that *dst* holds a string before the call. *strncat*(3) has an even more misleading name than the functions above. List of functions:

- *strncat*(3)

Other functions operate on an input character sequence to create an output character sequence. List of functions:

- *mempcpy*(3)

Functions

stpcpy(3)

Copy the input string into a destination string. The programmer is responsible for allocating a buffer large enough. It returns a pointer suitable for chaining.

strcpy(3)
strcat(3)

Copy and catenate the input string into a destination string. The programmer is responsible for allocating a buffer large enough. The return value is useless.

stpcpy(3) is a faster alternative to these functions.

stpecpy()
: Chain-copy the input string into a destination string. If the destination buffer, limited by a pointer to its end, isn't large enough to hold the copy, the resulting string is truncated (but it is guaranteed to be null-terminated). It returns a pointer suitable for chaining. Truncation needs to be detected only once after the last chained call.

  This function is not provided by any library; see EXAMPLES for a reference implementation.

strtcpy()
: Copy the input string into a destination string. If the destination buffer isn't large enough to hold the copy, the resulting string is truncated (but it is guaranteed to be null-terminated). It returns the length of the string, or −1 if it truncated.

  This function is not provided by any library; see EXAMPLES for a reference implementation.

strlcpy(3bsd)
strlcat(3bsd)
: Copy and catenate the input string into a destination string. If the destination buffer, limited by its size, isn't large enough to hold the copy, the resulting string is truncated (but it is guaranteed to be null-terminated). They return the length of the total string they tried to create.

  Check BUGS before using these functions.

  strtcpy() and **stpecpy**() are better alternatives to these functions.

stpncpy(3)
: Copy the input string into a destination null-padded character sequence in a fixed-size buffer. If the destination buffer, limited by its size, isn't large enough to hold the copy, the resulting character sequence is truncated. Since it creates a character sequence, it doesn't need to write a terminating null character. It's impossible to distinguish truncation by the result of the call, from a character sequence that just fits the destination buffer; truncation should be detected by comparing the length of the input string with the size of the destination buffer.

strncpy(3)
: This function is identical to *stpncpy*(3) except for the useless return value.

  stpncpy(3) is a more useful alternative to this function.

strncat(3)
: Catenate the input character sequence, contained in a null-padded fixed-size buffer, into a destination string. The programmer is responsible for allocating a buffer large enough. The return value is useless.

  Do not confuse this function with *strncpy*(3); they are not related at all.

  stpcpy(mempcpy(dst, src, strnlen(src, NITEMS(src))), "") is a faster alternative to this function.

mempcpy(3)
: Copy the input character sequence, limited by its length, into a destination character sequence. The programmer is responsible for allocating a buffer large enough. It returns a pointer suitable for chaining.

RETURN VALUE

stpcpy(3)
: A pointer to the terminating null character in the destination string.

stpecpy()
: A pointer to the terminating null character in the destination string, on success. On error, NULL is returned, and *errno* is set to indicate the error.

mempcpy(3)
stpncpy(3)
: A pointer to one after the last character in the destination character sequence.

strtcpy()
: The length of the string, on success. On error, −1 is returned, and *errno* is set to indicate the error.

strlcpy(3bsd)
strlcat(3bsd)
: The length of the total string that they tried to create (as if truncation didn't occur).

strcpy(3)
strcat(3)
strncpy(3)
strncat(3)
: The *dst* pointer, which is useless.

ERRORS

Most of these functions don't set *errno*.

stpecpy()
strtcpy()

ENOBUFS
: *dsize* was **0**.

E2BIG The string has been truncated.

NOTES

The Linux kernel has an internal function for copying strings, *strscpy*(9), which is identical to **strtcpy**(), except that it returns **−E2BIG** instead of −1 and it doesn't set *errno*.

CAVEATS

Don't mix chain calls to truncating and non-truncating functions. It is conceptually wrong unless you know that the first part of a copy will always fit. Anyway, the performance difference will probably be negligible, so it will probably be more clear if you use consistent semantics: either truncating or non-truncating. Calling a non-truncating function after a truncating one is necessarily wrong.

BUGS

All catenation functions share the same performance problem: Shlemiel the painter. As a mitigation, compilers are able to transform some calls to catenation functions into normal copy functions, since *strlen(dst)* is usually a byproduct of the previous copy.

strlcpy(3) and *strlcat*(3) need to read the entire *src* string, even if the destination buffer is small. This makes them vulnerable to Denial of Service (DoS) attacks if an attacker can control the length of the *src* string. And if not, they're still unnecessarily slow.

EXAMPLES

The following are examples of correct use of each of these functions.

stpcpy(3)

```
p = buf;
p = stpcpy(p, "Hello ");
p = stpcpy(p, "world");
p = stpcpy(p, "!");
len = p - buf;
puts(buf);
```

strcpy(3)
strcat(3)

```
strcpy(buf, "Hello ");
strcat(buf, "world");
strcat(buf, "!");
len = strlen(buf);
puts(buf);
```

stpecpy()

```
end = buf + NITEMS(buf);
p = buf;
p = stpecpy(p, end, "Hello ");
p = stpecpy(p, end, "world");
p = stpecpy(p, end, "!");
if (p == NULL) {
```

```
            len = NITEMS(buf) - 1;
            goto toolong;
        }
        len = p - buf;
        puts(buf);
```

strtcpy()

```
        len = strtcpy(buf, "Hello world!", NITEMS(buf));
        if (len == -1)
            goto toolong;
        puts(buf);
```

strlcpy(3bsd)
strlcat(3bsd)

```
        if (strlcpy(buf, "Hello ", NITEMS(buf)) >= NITEMS(buf))
            goto toolong;
        if (strlcat(buf, "world", NITEMS(buf)) >= NITEMS(buf))
            goto toolong;
        len = strlcat(buf, "!", NITEMS(buf));
        if (len >= NITEMS(buf))
            goto toolong;
        puts(buf);
```

stpncpy(3)

```
        p = stpncpy(u->ut_user, "alx", NITEMS(u->ut_user));
        if (NITEMS(u->ut_user) < strlen("alx"))
            goto toolong;
        len = p - u->ut_user;
        fwrite(u->ut_user, 1, len, stdout);
```

strncpy(3)

```
        strncpy(u->ut_user, "alx", NITEMS(u->ut_user));
        if (NITEMS(u->ut_user) < strlen("alx"))
            goto toolong;
        len = strnlen(u->ut_user, NITEMS(u->ut_user));
        fwrite(u->ut_user, 1, len, stdout);
```

mempcpy(dst, src, strnlen(src, NITEMS(src)))

```
        char  buf[NITEMS(u->ut_user)];
        p = buf;
        p = mempcpy(p, u->ut_user, strnlen(u->ut_user, NITEMS(u->ut_user)));
        len = p - buf;
        fwrite(buf, 1, len, stdout);
```

stpcpy(mempcpy(dst, src, strnlen(src, NITEMS(src))), "")

```
        char  buf[NITEMS(u->ut_user) + 1];
        p = buf;
        p = mempcpy(p, u->ut_user, strnlen(u->ut_user, NITEMS(u->ut_user)));
        p = stpcpy(p, "");
        len = p - buf;
        puts(buf);
```

strncat(3)

```
        char  buf[NITEMS(u->ut_user) + 1];
        strcpy(buf, "");
        strncat(buf, u->ut_user, NITEMS(u->ut_user));
        len = strlen(buf);
        puts(buf);
```

mempcpy(3)

```
        p = buf;
        p = mempcpy(p, "Hello ", 6);
        p = mempcpy(p, "world", 5);
```

```
    p = mempcpy(p, "!", 1);
    len = p - buf;
    fwrite(buf, 1, len, stdout);
```

stpcpy(mempcpy(dst, src, len), "")

```
    p = buf;
    p = mempcpy(p, "Hello ", 6);
    p = mempcpy(p, "world", 5);
    p = mempcpy(p, "!", 1);
    p = stpcpy(p, "");
    len = p - buf;
    puts(buf);
```

Implementations

Here are reference implementations for functions not provided by libc.

```
/* This code is in the public domain. */

char *
stpecpy(char *dst, char end[0], const char *restrict src)
{
    size_t  dlen;

    if (dst == NULL)
        return NULL;

    dlen = strtcpy(dst, src, end - dst);
    return (dlen == -1) ? NULL : dst + dlen;
}

ssize_t
strtcpy(char *restrict dst, const char *restrict src, size_t dsize)
{
    bool    trunc;
    size_t  dlen, slen;

    if (dsize == 0) {
        errno = ENOBUFS;
        return -1;
    }

    slen = strnlen(src, dsize);
    trunc = (slen == dsize);
    dlen = slen - trunc;

    stpcpy(mempcpy(dst, src, dlen), "");
    if (trunc)
        errno = E2BIG;
    return trunc ? -1 : slen;
}
```

NAME

suffixes − list of file suffixes

DESCRIPTION

It is customary to indicate the contents of a file with the file suffix, which (typically) consists of a period, followed by one or more letters. Many standard utilities, such as compilers, use this to recognize the type of file they are dealing with. The *make*(1) utility is driven by rules based on file suffix.

Following is a list of suffixes which are likely to be found on a Linux system.

Suffix	File type
,v	files for RCS (Revision Control System)
-	backup file
.C	C++ source code, equivalent to *.cc*
.F	Fortran source with*cpp*(1) directives or file compressed using freeze
.S	assembler source with*cpp*(1) directives
.Y	file compressed using yabba
.Z	file compressed using*compress*(1)
.[0−9]+gf	TeX generic font files
.[0−9]+pk	TeX packed font files
.[1−9]	manual page for the corresponding section
.[1−9][a-z]	manual page for section plus subsection
.a	static object code library
.ad	X application default resource file
.ada	Ada source (may be body, spec, or combination)
.adb	Ada body source
.ads	Ada spec source
.afm	PostScript font metrics
.al	Perl autoload file
.am	*automake*(1) input file
.arc	*arc*(1) archive
.arj	*arj*(1) archive
.asc	PGP ASCII-armored data
.asm	(GNU) assembler source file
.au	Audio sound file
.aux	LaTeX auxiliary file
.avi	(msvideo) movie
.awk	AWK language program
.b	LILO boot loader image
.bak	backup file
.bash	*bash*(1) shell script
.bb	basic block list data produced by gcc −ftest−coverage
.bbg	basic block graph data produced by gcc −ftest−coverage
.bbl	BibTeX output
.bdf	X font file
.bib	TeX bibliographic database, BibTeX input
.bm	bitmap source
.bmp	bitmap
.bz2	file compressed using*bzip2*(1)
.c	C source
.cat	message catalog files
.cc	C++ source
.cf	configuration file
.cfg	configuration file
.cgi	WWW content generating script or program
.cls	LaTeX Class definition

.class	Java compiled byte-code
.conf	configuration file
.config	configuration file
.cpp	equivalent to *.cc*
.csh	*csh*(1) shell script
.cxx	equivalent to *.cc*
.dat	data file
.deb	Debian software package
.def	Modula-2 source for definition modules
.def	other definition files
.desc	initial part of mail message unpacked with *munpack*(1)
.diff	file differences (*diff*(1) command output)
.dir	dbm data base directory file
.doc	documentation file
.dsc	Debian Source Control (source package)
.dtx	LaTeX package source file
.dvi	TeX's device independent output
.el	Emacs-Lisp source
.elc	compiled Emacs-Lisp source
.eps	encapsulated PostScript
.exp	Expect source code
.f	Fortran source
.f77	Fortran 77 source
.f90	Fortran 90 source
.fas	precompiled Common-Lisp
.fi	Fortran include files
.fig	FIG image file (used by*xfig*(1))
.fmt	TeX format file
.gif	Compuserve Graphics Image File format
.gmo	GNU format message catalog
.gsf	Ghostscript fonts
.gz	file compressed using*gzip*(1)
.h	C or C++ header files
.help	help file
.hf	equivalent to *.help*
.hlp	equivalent to *.help*
.htm	poor man's *.html*
.html	HTML document used with the World Wide Web
.hqx	7-bit encoded Macintosh file
.i	C source after preprocessing
.icon	bitmap source
.idx	reference or datum-index file for hypertext or database system
.image	bitmap source
.in	configuration template, especially for GNU Autoconf
.info	files for the Emacs info browser
.info-[0−9]+	split info files
.ins	LaTeX package install file for docstrip
.itcl	itcl source code; itcl ([incr Tcl]) is an OO extension of tcl
.java	a Java source file
.jpeg	Joint Photographic Experts Group format
.jpg	poor man's *.jpeg*
.js	JavaScript source code
.jsx	JSX (JavaScript XML-like extension) source code
.kmap	*lyx*(1) keymap
.l	equivalent to *.lex* or *.lisp*

.lex	*lex*(1) or*flex*(1) files
.lha	lharc archive
.lib	Common-Lisp library
.lisp	Lisp source
.ln	files for use with*lint*(1)
.log	log file, in particular produced by TeX
.lsm	Linux Software Map entry
.lsp	Common-Lisp source
.lzh	lharc archive
.m	Objective-C source code
.m4	*m4*(1) source
.mac	macro files for various programs
.man	manual page (usually source rather than formatted)
.map	map files for various programs
.me	Nroff source using the me macro package
.mf	Metafont (font generator for TeX) source
.mgp	MagicPoint file
.mm	sources for*groff*(1) in mm - format
.mo	Message catalog binary file
.mod	Modula-2 source for implementation modules
.mov	(quicktime) movie
.mp	Metapost source
.mp2	MPEG Layer 2 (audio) file
.mp3	MPEG Layer 3 (audio) file
.mpeg	movie file
.o	object file
.old	old or backup file
.orig	backup (original) version of a file, from*patch*(1)
.out	output file, often executable program (a.out)
.p	Pascal source
.pag	dbm data base data file
.patch	file differences for*patch*(1)
.pbm	portable bitmap format
.pcf	X11 font files
.pdf	Adobe Portable Data Format (use Acrobat/**acroread** or **xpdf**)
.perl	Perl source (see .ph, .pl, and .pm)
.pfa	PostScript font definition files, ASCII format
.pfb	PostScript font definition files, binary format
.pgm	portable greymap format
.pgp	PGP binary data
.ph	Perl header file
.php	PHP program file
.php3	PHP3 program file
.pid	File to store daemon PID (e.g., crond.pid)
.pl	TeX property list file or Perl library file
.pm	Perl module
.png	Portable Network Graphics file
.po	Message catalog source
.pod	*perldoc*(1) file
.ppm	portable pixmap format
.pr	bitmap source
.ps	PostScript file
.py	Python source
.pyc	compiled python
.qt	quicktime movie
.r	RATFOR source (obsolete)
.rej	patches that*patch*(1) couldn’t apply

.rpm	RPM software package
.rtf	Rich Text Format file
.rules	rules for something
.s	assembler source
.sa	stub libraries for a.out shared libraries
.sc	*sc*(1) spreadsheet commands
.scm	Scheme source code
.sed	sed source file
.sgml	SGML source file
.sh	*sh*(1) scripts
.shar	archive created by the*shar*(1) utility
.shtml	HTML using Server Side Includes
.so	Shared library or dynamically loadable object
.sql	SQL source
.sqml	SQML schema or query program
.sty	LaTeX style files
.sym	Modula-2 compiled definition modules
.tar	archive created by the*tar*(1) utility
.tar.Z	tar(1) archive compressed with*compress*(1)
.tar.bz2	tar(1) archive compressed with*bzip2*(1)
.tar.gz	tar(1) archive compressed with*gzip*(1)
.taz	tar(1) archive compressed with*compress*(1)
.tcl	tcl source code
.tex	TeX or LaTeX source
.texi	equivalent to *.texinfo*
.texinfo	Texinfo documentation source
.text	text file
.tfm	TeX font metric file
.tgz	tar archive compressed with*gzip*(1)
.tif	poor man's *.tiff*
.tiff	Tagged Image File Format
.tk	tcl/tk script
.tmp	temporary file
.tmpl	template files
.ts	TypeScript source code
.tsx	TypeScript with JSX source code (*.ts* + *.jsx*)
.txt	equivalent to *.text*
.uu	equivalent to *.uue*
.uue	binary file encoded with*uuencode*(1)
.vf	TeX virtual font file
.vpl	TeX virtual property list file
.w	Silvio Levi's CWEB
.wav	wave sound file
.web	Donald Knuth's WEB
.wml	Source file for Web Meta Language
.xbm	X11 bitmap source
.xcf	GIMP graphic
.xml	eXtended Markup Language file
.xpm	X11 pixmap source
.xs	Perl xsub file produced by h2xs
.xsl	XSL stylesheet
.y	*yacc*(1) or*bison*(1) (parser generator) files
.z	File compressed using*pack*(1) (or an old*gzip*(1))
.zip	*zip*(1) archive
.zoo	*zoo*(1) archive
~	Emacs or*patch*(1) backup file
rc	startup ('run control') file, e.g., *.newsrc*

STANDARDS

General UNIX conventions.

BUGS

This list is not exhaustive.

NAME

symlink − symbolic link handling

DESCRIPTION

Symbolic links are files that act as pointers to other files. To understand their behavior, you must first understand how hard links work.

A hard link to a file is indistinguishable from the original file because it is a reference to the object underlying the original filename. (To be precise: each of the hard links to a file is a reference to the same *inode number*, where an inode number is an index into the inode table, which contains metadata about all files on a filesystem. See *stat*(2).) Changes to a file are independent of the name used to reference the file. Hard links may not refer to directories (to prevent the possibility of loops within the filesystem tree, which would confuse many programs) and may not refer to files on different filesystems (because inode numbers are not unique across filesystems).

A symbolic link is a special type of file whose contents are a string that is the pathname of another file, the file to which the link refers. (The contents of a symbolic link can be read using *readlink*(2).) In other words, a symbolic link is a pointer to another name, and not to an underlying object. For this reason, symbolic links may refer to directories and may cross filesystem boundaries.

There is no requirement that the pathname referred to by a symbolic link should exist. A symbolic link that refers to a pathname that does not exist is said to be a *dangling link*.

Because a symbolic link and its referenced object coexist in the filesystem name space, confusion can arise in distinguishing between the link itself and the referenced object. On historical systems, commands and system calls adopted their own link-following conventions in a somewhat ad-hoc fashion. Rules for a more uniform approach, as they are implemented on Linux and other systems, are outlined here. It is important that site-local applications also conform to these rules, so that the user interface can be as consistent as possible.

Magic links

There is a special class of symbolic-link-like objects known as "magic links", which can be found in certain pseudofilesystems such as *proc*(5) (examples include */proc/*pid*/exe* and */proc/*pid*/fd/**). Unlike normal symbolic links, magic links are not resolved through pathname-expansion, but instead act as direct references to the kernel's own representation of a file handle. As such, these magic links allow users to access files which cannot be referenced with normal paths (such as unlinked files still referenced by a running program).

Because they can bypass ordinary *mount_namespaces*(7)-based restrictions, magic links have been used as attack vectors in various exploits.

Symbolic link ownership, permissions, and timestamps

The owner and group of an existing symbolic link can be changed using *lchown*(2). The ownership of a symbolic link matters when the link is being removed or renamed in a directory that has the sticky bit set (see *inode*(7)), and when the *fs.protected_symlinks* sysctl is set (see *proc*(5)).

The last access and last modification timestamps of a symbolic link can be changed using *utimensat*(2) or *lutimes*(3).

On Linux, the permissions of an ordinary symbolic link are not used in any operations; the permissions are always 0777 (read, write, and execute for all user categories), and can't be changed.

However, magic links do not follow this rule. They can have a non-0777 mode, though this mode is not currently used in any permission checks.

Obtaining a file descriptor that refers to a symbolic link

Using the combination of the **O_PATH** and **O_NOFOLLOW** flags to *open*(2) yields a file descriptor that can be passed as the *dirfd* argument in system calls such as *fstatat*(2), *fchownat*(2), *fchmodat*(2), *linkat*(2), and *readlinkat*(2), in order to operate on the symbolic link itself (rather than the file to which it refers).

By default (i.e., if the **AT_SYMLINK_FOLLOW** flag is not specified), if *name_to_handle_at*(2) is applied to a symbolic link, it yields a handle for the symbolic link (rather than the file to which it refers). One can then obtain a file descriptor for the symbolic link (rather than the file to which it refers) by specifying the **O_PATH** flag in a subsequent call to *open_by_handle_at*(2). Again, that file descriptor can be used in the aforementioned system calls to operate on the symbolic link itself.

Handling of symbolic links by system calls and commands

Symbolic links are handled either by operating on the link itself, or by operating on the object referred to by the link. In the latter case, an application or system call is said to *follow* the link. Symbolic links may refer to other symbolic links, in which case the links are dereferenced until an object that is not a symbolic link is found, a symbolic link that refers to a file which does not exist is found, or a loop is detected. (Loop detection is done by placing an upper limit on the number of links that may be followed, and an error results if this limit is exceeded.)

There are three separate areas that need to be discussed. They are as follows:

- Symbolic links used as filename arguments for system calls.
- Symbolic links specified as command-line arguments to utilities that are not traversing a file tree.
- Symbolic links encountered by utilities that are traversing a file tree (either specified on the command line or encountered as part of the file hierarchy walk).

Before describing the treatment of symbolic links by system calls and commands, we require some terminology. Given a pathname of the form *a/b/c*, the part preceding the final slash (i.e., *a/b*) is called the *dirname* component, and the part following the final slash (i.e., *c*) is called the *basename* component.

Treatment of symbolic links in system calls

The first area is symbolic links used as filename arguments for system calls.

The treatment of symbolic links within a pathname passed to a system call is as follows:

(1) Within the dirname component of a pathname, symbolic links are always followed in nearly every system call. (This is also true for commands.) The one exception is *openat2*(2), which provides flags that can be used to explicitly prevent following of symbolic links in the dirname component.

(2) Except as noted below, all system calls follow symbolic links in the basename component of a pathname. For example, if there were a symbolic link *slink* which pointed to a file named *afile*, the system call *open("slink" ...)* would return a file descriptor referring to the file *afile*.

Various system calls do not follow links in the basename component of a pathname, and operate on the symbolic link itself. They are: *lchown*(2), *lgetxattr*(2), *llistxattr*(2), *lremovexattr*(2), *lsetxattr*(2), *lstat*(2), *readlink*(2), *rename*(2), *rmdir*(2), and *unlink*(2).

Certain other system calls optionally follow symbolic links in the basename component of a pathname. They are: *faccessat*(2), *fchownat*(2), *fstatat*(2), *linkat*(2), *name_to_handle_at*(2), *open*(2), *openat*(2), *open_by_handle_at*(2), and *utimensat*(2); see their manual pages for details. Because *remove*(3) is an alias for *unlink*(2), that library function also does not follow symbolic links. When *rmdir*(2) is applied to a symbolic link, it fails with the error **ENOTDIR**.

link(2) warrants special discussion. POSIX.1-2001 specifies that *link*(2) should dereference *oldpath* if it is a symbolic link. However, Linux does not do this. (By default, Solaris is the same, but the POSIX.1-2001 specified behavior can be obtained with suitable compiler options.) POSIX.1-2008 changed the specification to allow either behavior in an implementation.

Commands not traversing a file tree

The second area is symbolic links, specified as command-line filename arguments, to commands which are not traversing a file tree.

Except as noted below, commands follow symbolic links named as command-line arguments. For example, if there were a symbolic link *slink* which pointed to a file named *afile*, the command *cat slink* would display the contents of the file *afile*.

It is important to realize that this rule includes commands which may optionally traverse file trees; for example, the command *chown file* is included in this rule, while the command *chown −R file*, which performs a tree traversal, is not. (The latter is described in the third area, below.)

If it is explicitly intended that the command operate on the symbolic link instead of following the symbolic link—for example, it is desired that *chown slink* change the ownership of the file that *slink* is, whether it is a symbolic link or not—then the *−h* option should be used. In the above example, *chown root slink* would change the ownership of the file referred to by *slink*, while *chown −h root slink* would change the ownership of *slink* itself.

There are some exceptions to this rule:

- The *mv*(1) and *rm*(1) commands do not follow symbolic links named as arguments, but respectively attempt to rename and delete them. (Note, if the symbolic link references a file via a relative path, moving it to another directory may very well cause it to stop working, since the path may no longer be correct.)
- The *ls*(1) command is also an exception to this rule. For compatibility with historic systems (when *ls*(1) is not doing a tree walk—that is, *−R* option is not specified), the *ls*(1) command follows symbolic links named as arguments if the *−H* or *−L* option is specified, or if the *−F*, *−d*, or *−l* options are not specified. (The *ls*(1) command is the only command where the *−H* and *−L* options affect its behavior even though it is not doing a walk of a file tree.)
- The *file*(1) command is also an exception to this rule. The *file*(1) command does not follow symbolic links named as argument by default. The *file*(1) command does follow symbolic links named as argument if the *−L* option is specified.

Commands traversing a file tree

The following commands either optionally or always traverse file trees: *chgrp*(1), *chmod*(1), *chown*(1), *cp*(1), *du*(1), *find*(1), *ls*(1), *pax*(1), *rm*(1), and *tar*(1)

It is important to realize that the following rules apply equally to symbolic links encountered during the file tree traversal and symbolic links listed as command-line arguments.

The *first rule* applies to symbolic links that reference files other than directories. Operations that apply to symbolic links are performed on the links themselves, but otherwise the links are ignored.

The command *rm −r slink directory* will remove *slink*, as well as any symbolic links encountered in the tree traversal of *directory*, because symbolic links may be removed. In no case will *rm*(1) affect the file referred to by *slink*.

The *second rule* applies to symbolic links that refer to directories. Symbolic links that refer to directories are never followed by default. This is often referred to as a "physical" walk, as opposed to a "logical" walk (where symbolic links that refer to directories are followed).

Certain conventions are (should be) followed as consistently as possible by commands that perform file tree walks:

- A command can be made to follow any symbolic links named on the command line, regardless of the type of file they reference, by specifying the *−H* (for "half-logical") flag. This flag is intended to make the command-line name space look like the logical name space. (Note, for commands that do not always do file tree traversals, the *−H* flag will be ignored if the *−R* flag is not also specified.)

  For example, the command *chown −HR user slink* will traverse the file hierarchy rooted in the file pointed to by *slink*. Note, the *−H* is not the same as the previously discussed *−h* flag. The *−H* flag causes symbolic links specified on the command line to be dereferenced for the purposes of both the action to be performed and the tree walk, and it is as if the user had specified the name of the file to which the symbolic link pointed.
- A command can be made to follow any symbolic links named on the command line, as well as any symbolic links encountered during the traversal, regardless of the type of file they reference, by specifying the *−L* (for "logical") flag. This flag is intended to make the entire name space look like the logical name space. (Note, for commands that do not always do file tree traversals, the *−L* flag will be ignored if the *−R* flag is not also specified.)

  For example, the command *chown −LR user slink* will change the owner of the file referred to by *slink*. If *slink* refers to a directory, **chown** will traverse the file hierarchy rooted in the directory that it references. In addition, if any symbolic links are encountered in any file tree that **chown** traverses, they will be treated in the same fashion as *slink*.
- A command can be made to provide the default behavior by specifying the *−P* (for "physical") flag. This flag is intended to make the entire name space look like the physical name space.

For commands that do not by default do file tree traversals, the *−H*, *−L*, and *−P* flags are ignored if the *−R* flag is not also specified. In addition, you may specify the *−H*, *−L*, and *−P* options more than once; the last one specified determines the command's behavior. This is intended to permit you to alias commands to behave one way or the other, and then override that behavior on the command line.

The *ls*(1) and *rm*(1) commands have exceptions to these rules:

- The *rm*(1) command operates on the symbolic link, and not the file it references, and therefore never follows a symbolic link. The *rm*(1) command does not support the *−H*, *−L*, or *−P* options.
- To maintain compatibility with historic systems, the *ls*(1) command acts a little differently. If you do not specify the *−F*, *−d*, or *−l* options, *ls*(1) will follow symbolic links specified on the command line. If the *−L* flag is specified, *ls*(1) follows all symbolic links, regardless of their type, whether specified on the command line or encountered in the tree walk.

NAME

system_data_types − overview of system data types

DESCRIPTION

siginfo_t

Include: <*signal.h*>. Alternatively, <*sys/wait.h*>.

```
typedef struct {
    int      si_signo;  /* Signal number */
    int      si_code;   /* Signal code */
    pid_t    si_pid;    /* Sending process ID */
    uid_t    si_uid;    /* Real user ID of sending process */
    void    *si_addr;   /* Memory location which caused fault */
    int      si_status; /* Exit value or signal */
    union sigval si_value;  /* Signal value */
} siginfo_t;
```

Information associated with a signal. For further details on this structure (including additional, Linux-specific fields), see *sigaction*(2).

Conforming to: POSIX.1-2001 and later.

See also: *pidfd_send_signal*(2), *rt_sigqueueinfo*(2), *sigaction*(2), *sigwaitinfo*(2), *psiginfo*(3)

sigset_t

Include: <*signal.h*>. Alternatively, <*spawn.h*>, or <*sys/select.h*>.

This is a type that represents a set of signals. According to POSIX, this shall be an integer or structure type.

Conforming to: POSIX.1-2001 and later.

See also: *epoll_pwait*(2), *ppoll*(2), *pselect*(2), *sigaction*(2), *signalfd*(2), *sigpending*(2), *sigprocmask*(2), *sigsuspend*(2), *sigwaitinfo*(2), *signal*(7)

NOTES

The structures described in this manual page shall contain, at least, the members shown in their definition, in no particular order.

Most of the integer types described in this page don't have a corresponding length modifier for the *printf*(3) and the *scanf*(3) families of functions. To print a value of an integer type that doesn't have a length modifier, it should be converted to *intmax_t* or *uintmax_t* by an explicit cast. To scan into a variable of an integer type that doesn't have a length modifier, an intermediate temporary variable of type *intmax_t* or *uintmax_t* should be used. When copying from the temporary variable to the destination variable, the value could overflow. If the type has upper and lower limits, the user should check that the value is within those limits, before actually copying the value. The example below shows how these conversions should be done.

Conventions used in this page

In "Conforming to" we only concern ourselves with C99 and later and POSIX.1-2001 and later. Some types may be specified in earlier versions of one of these standards, but in the interests of simplicity we omit details from earlier standards.

In "Include", we first note the "primary" header(s) that define the type according to either the C or POSIX.1 standards. Under "Alternatively", we note additional headers that the standards specify shall define the type.

EXAMPLES

The program shown below scans from a string and prints a value stored in a variable of an integer type that doesn't have a length modifier. The appropriate conversions from and to *intmax_t*, and the appropriate range checks, are used as explained in the notes section above.

```
#include <stdint.h>
#include <stdio.h>
#include <stdlib.h>
#include <sys/types.h>

int
```

```
main (void)
{
    static const char *const str = "500000 us in half a second";
    suseconds_t us;
    intmax_t    tmp;

    /* Scan the number from the string into the temporary variable. */

    sscanf(str, "%jd", &tmp);

    /* Check that the value is within the valid range of suseconds_t. */

    if (tmp < −1 || tmp > 1000000) {
        fprintf(stderr, "Scanned value outside valid range!\n");
        exit(EXIT_FAILURE);
    }

    /* Copy the value to the suseconds_t variable 'us'. */

    us = tmp;

    /* Even though suseconds_t can hold the value −1, this isn't
       a sensible number of microseconds. */

    if (us < 0) {
        fprintf(stderr, "Scanned value shouldn't be negative!\n");
        exit(EXIT_FAILURE);
    }

    /* Print the value. */

    printf("There are %jd microseconds in half a second.\n",
            (intmax_t) us);

    exit(EXIT_SUCCESS);
}
```

NAME

sysvipc − System V interprocess communication mechanisms

DESCRIPTION

System V IPC is the name given to three interprocess communication mechanisms that are widely available on UNIX systems: message queues, semaphore, and shared memory.

Message queues

System V message queues allow data to be exchanged in units called messages. Each message can have an associated priority. POSIX message queues provide an alternative API for achieving the same result; see *mq_overview*(7).

The System V message queue API consists of the following system calls:

msgget(2)
: Create a new message queue or obtain the ID of an existing message queue. This call returns an identifier that is used in the remaining APIs.

msgsnd(2)
: Add a message to a queue.

msgrcv(2)
: Remove a message from a queue.

msgctl(2)
: Perform various control operations on a queue, including deletion.

Semaphore sets

System V semaphores allow processes to synchronize their actions. System V semaphores are allocated in groups called sets; each semaphore in a set is a counting semaphore. POSIX semaphores provide an alternative API for achieving the same result; see *sem_overview*(7).

The System V semaphore API consists of the following system calls:

semget(2)
: Create a new set or obtain the ID of an existing set. This call returns an identifier that is used in the remaining APIs.

semop(2)
: Perform operations on the semaphores in a set.

semctl(2)
: Perform various control operations on a set, including deletion.

Shared memory segments

System V shared memory allows processes to share a region a memory (a "segment"). POSIX shared memory is an alternative API for achieving the same result; see *shm_overview*(7).

The System V shared memory API consists of the following system calls:

shmget(2)
: Create a new segment or obtain the ID of an existing segment. This call returns an identifier that is used in the remaining APIs.

shmat(2)
: Attach an existing shared memory object into the calling process’s address space.

shmdt(2)
: Detach a segment from the calling process’s address space.

shmctl(2)
: Perform various control operations on a segment, including deletion.

IPC namespaces

For a discussion of the interaction of System V IPC objects and IPC namespaces, see *ipc_namespaces*(7).

NAME

tcp − TCP protocol

SYNOPSIS

#include <sys/socket.h>
#include <netinet/in.h>
#include <netinet/tcp.h>

tcp_socket **= socket(AF_INET, SOCK_STREAM, 0);**

DESCRIPTION

This is an implementation of the TCP protocol defined in RFC 793, RFC 1122 and RFC 2001 with the NewReno and SACK extensions. It provides a reliable, stream-oriented, full-duplex connection between two sockets on top of *ip*(7), for both v4 and v6 versions. TCP guarantees that the data arrives in order and retransmits lost packets. It generates and checks a per-packet checksum to catch transmission errors. TCP does not preserve record boundaries.

A newly created TCP socket has no remote or local address and is not fully specified. To create an outgoing TCP connection use *connect*(2) to establish a connection to another TCP socket. To receive new incoming connections, first *bind*(2) the socket to a local address and port and then call *listen*(2) to put the socket into the listening state. After that a new socket for each incoming connection can be accepted using *accept*(2). A socket which has had *accept*(2) or *connect*(2) successfully called on it is fully specified and may transmit data. Data cannot be transmitted on listening or not yet connected sockets.

Linux supports RFC 1323 TCP high performance extensions. These include Protection Against Wrapped Sequence Numbers (PAWS), Window Scaling and Timestamps. Window scaling allows the use of large (> 64 kB) TCP windows in order to support links with high latency or bandwidth. To make use of them, the send and receive buffer sizes must be increased. They can be set globally with the */proc/sys/net/ipv4/tcp_wmem* and */proc/sys/net/ipv4/tcp_rmem* files, or on individual sockets by using the **SO_SNDBUF** and **SO_RCVBUF** socket options with the *setsockopt*(2) call.

The maximum sizes for socket buffers declared via the **SO_SNDBUF** and **SO_RCVBUF** mechanisms are limited by the values in the */proc/sys/net/core/rmem_max* and */proc/sys/net/core/wmem_max* files. Note that TCP actually allocates twice the size of the buffer requested in the *setsockopt*(2) call, and so a succeeding *getsockopt*(2) call will not return the same size of buffer as requested in the *setsockopt*(2) call. TCP uses the extra space for administrative purposes and internal kernel structures, and the */proc* file values reflect the larger sizes compared to the actual TCP windows. On individual connections, the socket buffer size must be set prior to the *listen*(2) or *connect*(2) calls in order to have it take effect. See *socket*(7) for more information.

TCP supports urgent data. Urgent data is used to signal the receiver that some important message is part of the data stream and that it should be processed as soon as possible. To send urgent data specify the **MSG_OOB** option to *send*(2). When urgent data is received, the kernel sends a **SIGURG** signal to the process or process group that has been set as the socket "owner" using the **SIOCSPGRP** or **FIOSETOWN** ioctls (or the POSIX.1-specified *fcntl*(2) **F_SETOWN** operation). When the **SO_OOBINLINE** socket option is enabled, urgent data is put into the normal data stream (a program can test for its location using the **SIOCATMARK** ioctl described below), otherwise it can be received only when the **MSG_OOB** flag is set for *recv*(2) or *recvmsg*(2).

When out-of-band data is present, *select*(2) indicates the file descriptor as having an exceptional condition and *poll (2)* indicates a **POLLPRI** event.

Linux 2.4 introduced a number of changes for improved throughput and scaling, as well as enhanced functionality. Some of these features include support for zero-copy *sendfile*(2), Explicit Congestion Notification, new management of TIME_WAIT sockets, keep-alive socket options and support for Duplicate SACK extensions.

Address formats

TCP is built on top of IP (see *ip*(7)). The address formats defined by *ip*(7) apply to TCP. TCP supports point-to-point communication only; broadcasting and multicasting are not supported.

/proc interfaces

System-wide TCP parameter settings can be accessed by files in the directory */proc/sys/net/ipv4/*. In addition, most IP */proc* interfaces also apply to TCP; see *ip*(7). Variables described as *Boolean* take an

integer value, with a nonzero value ("true") meaning that the corresponding option is enabled, and a zero value ("false") meaning that the option is disabled.

tcp_abc (Integer; default: 0; Linux 2.6.15 to Linux 3.8)
Control the Appropriate Byte Count (ABC), defined in RFC 3465. ABC is a way of increasing the congestion window (*cwnd*) more slowly in response to partial acknowledgements. Possible values are:

0 increase *cwnd* once per acknowledgement (no ABC)

1 increase *cwnd* once per acknowledgement of full sized segment

2 allow increase *cwnd* by two if acknowledgement is of two segments to compensate for delayed acknowledgements.

tcp_abort_on_overflow (Boolean; default: disabled; since Linux 2.4)
Enable resetting connections if the listening service is too slow and unable to keep up and accept them. It means that if overflow occurred due to a burst, the connection will recover. Enable this option *only* if you are really sure that the listening daemon cannot be tuned to accept connections faster. Enabling this option can harm the clients of your server.

tcp_adv_win_scale (integer; default: 2; since Linux 2.4)
Count buffering overhead as *bytes/2^tcp_adv_win_scale*, if *tcp_adv_win_scale* is greater than 0; or *bytes−bytes/2^(−tcp_adv_win_scale)*, if *tcp_adv_win_scale* is less than or equal to zero.

The socket receive buffer space is shared between the application and kernel. TCP maintains part of the buffer as the TCP window, this is the size of the receive window advertised to the other end. The rest of the space is used as the "application" buffer, used to isolate the network from scheduling and application latencies. The *tcp_adv_win_scale* default value of 2 implies that the space used for the application buffer is one fourth that of the total.

tcp_allowed_congestion_control (String; default: see text; since Linux 2.4.20)
Show/set the congestion control algorithm choices available to unprivileged processes (see the description of the **TCP_CONGESTION** socket option). The items in the list are separated by white space and terminated by a newline character. The list is a subset of those listed in *tcp_available_congestion_control*. The default value for this list is "reno" plus the default setting of *tcp_congestion_control*.

tcp_autocorking (Boolean; default: enabled; since Linux 3.14)
If this option is enabled, the kernel tries to coalesce small writes (from consecutive *write*(2) and *sendmsg*(2) calls) as much as possible, in order to decrease the total number of sent packets. Coalescing is done if at least one prior packet for the flow is waiting in Qdisc queues or device transmit queue. Applications can still use the **TCP_CORK** socket option to obtain optimal behavior when they know how/when to uncork their sockets.

tcp_available_congestion_control (String; read-only; since Linux 2.4.20)
Show a list of the congestion-control algorithms that are registered. The items in the list are separated by white space and terminated by a newline character. This list is a limiting set for the list in *tcp_allowed_congestion_control*. More congestion-control algorithms may be available as modules, but not loaded.

tcp_app_win (integer; default: 31; since Linux 2.4)
This variable defines how many bytes of the TCP window are reserved for buffering overhead.

A maximum of (*window/2^tcp_app_win*, mss) bytes in the window are reserved for the application buffer. A value of 0 implies that no amount is reserved.

tcp_base_mss (Integer; default: 512; since Linux 2.6.17)
The initial value of *search_low* to be used by the packetization layer Path MTU discovery (MTU probing). If MTU probing is enabled, this is the initial MSS used by the connection.

tcp_bic (Boolean; default: disabled; Linux 2.4.27/2.6.6 to Linux 2.6.13)
Enable BIC TCP congestion control algorithm. BIC-TCP is a sender-side-only change that ensures a linear RTT fairness under large windows while offering both scalability and bounded TCP-friendliness. The protocol combines two schemes called additive increase and binary search increase. When the congestion window is large, additive increase with a large increment ensures linear RTT fairness as well as good scalability. Under small congestion

windows, binary search increase provides TCP friendliness.

tcp_bic_low_window (integer; default: 14; Linux 2.4.27/2.6.6 to Linux 2.6.13)
Set the threshold window (in packets) where BIC TCP starts to adjust the congestion window. Below this threshold BIC TCP behaves the same as the default TCP Reno.

tcp_bic_fast_convergence (Boolean; default: enabled; Linux 2.4.27/2.6.6 to Linux 2.6.13)
Force BIC TCP to more quickly respond to changes in congestion window. Allows two flows sharing the same connection to converge more rapidly.

tcp_congestion_control (String; default: see text; since Linux 2.4.13)
Set the default congestion-control algorithm to be used for new connections. The algorithm "reno" is always available, but additional choices may be available depending on kernel configuration. The default value for this file is set as part of kernel configuration.

tcp_dma_copybreak (integer; default: 4096; since Linux 2.6.24)
Lower limit, in bytes, of the size of socket reads that will be offloaded to a DMA copy engine, if one is present in the system and the kernel was configured with the **CONFIG_NET_DMA** option.

tcp_dsack (Boolean; default: enabled; since Linux 2.4)
Enable RFC 2883 TCP Duplicate SACK support.

tcp_fastopen (Bitmask; default: 0x1; since Linux 3.7)
Enables RFC 7413 Fast Open support. The flag is used as a bitmap with the following values:

0x1 Enables client side Fast Open support

0x2 Enables server side Fast Open support

0x4 Allows client side to transmit data in SYN without Fast Open option

0x200 Allows server side to accept SYN data without Fast Open option

0x400 Enables Fast Open on all listeners without **TCP_FASTOPEN** socket option

tcp_fastopen_key (since Linux 3.7)
Set server side RFC 7413 Fast Open key to generate Fast Open cookie when server side Fast Open support is enabled.

tcp_ecn (Integer; default: see below; since Linux 2.4)
Enable RFC 3168 Explicit Congestion Notification.

This file can have one of the following values:

0 Disable ECN. Neither initiate nor accept ECN. This was the default up to and including Linux 2.6.30.

1 Enable ECN when requested by incoming connections and also request ECN on outgoing connection attempts.

2 Enable ECN when requested by incoming connections, but do not request ECN on outgoing connections. This value is supported, and is the default, since Linux 2.6.31.

When enabled, connectivity to some destinations could be affected due to older, misbehaving middle boxes along the path, causing connections to be dropped. However, to facilitate and encourage deployment with option 1, and to work around such buggy equipment, the **tcp_ecn_fallback** option has been introduced.

tcp_ecn_fallback (Boolean; default: enabled; since Linux 4.1)
Enable RFC 3168, Section 6.1.1.1. fallback. When enabled, outgoing ECN-setup SYNs that time out within the normal SYN retransmission timeout will be resent with CWR and ECE cleared.

tcp_fack (Boolean; default: enabled; since Linux 2.2)
Enable TCP Forward Acknowledgement support.

tcp_fin_timeout (integer; default: 60; since Linux 2.2)
This specifies how many seconds to wait for a final FIN packet before the socket is forcibly closed. This is strictly a violation of the TCP specification, but required to prevent denial-of-service attacks. In Linux 2.2, the default value was 180.

tcp_frto (integer; default: see below; since Linux 2.4.21/2.6)
Enable F-RTO, an enhanced recovery algorithm for TCP retransmission timeouts (RTOs). It is particularly beneficial in wireless environments where packet loss is typically due to random radio interference rather than intermediate router congestion. See RFC 4138 for more details.

This file can have one of the following values:

0 Disabled. This was the default up to and including Linux 2.6.23.

1 The basic version F-RTO algorithm is enabled.

2 Enable SACK-enhanced F-RTO if flow uses SACK. The basic version can be used also when SACK is in use though in that case scenario(s) exists where F-RTO interacts badly with the packet counting of the SACK-enabled TCP flow. This value is the default since Linux 2.6.24.

Before Linux 2.6.22, this parameter was a Boolean value, supporting just values 0 and 1 above.

tcp_frto_response (integer; default: 0; since Linux 2.6.22)
When F-RTO has detected that a TCP retransmission timeout was spurious (i.e., the timeout would have been avoided had TCP set a longer retransmission timeout), TCP has several options concerning what to do next. Possible values are:

0 Rate halving based; a smooth and conservative response, results in halved congestion window (*cwnd*) and slow-start threshold (*ssthresh*) after one RTT.

1 Very conservative response; not recommended because even though being valid, it interacts poorly with the rest of Linux TCP; halves *cwnd* and *ssthresh* immediately.

2 Aggressive response; undoes congestion-control measures that are now known to be unnecessary (ignoring the possibility of a lost retransmission that would require TCP to be more cautious); *cwnd* and *ssthresh* are restored to the values prior to timeout.

tcp_keepalive_intvl (integer; default: 75; since Linux 2.4)
The number of seconds between TCP keep-alive probes.

tcp_keepalive_probes (integer; default: 9; since Linux 2.2)
The maximum number of TCP keep-alive probes to send before giving up and killing the connection if no response is obtained from the other end.

tcp_keepalive_time (integer; default: 7200; since Linux 2.2)
The number of seconds a connection needs to be idle before TCP begins sending out keep-alive probes. Keep-alives are sent only when the **SO_KEEPALIVE** socket option is enabled. The default value is 7200 seconds (2 hours). An idle connection is terminated after approximately an additional 11 minutes (9 probes an interval of 75 seconds apart) when keep-alive is enabled.

Note that underlying connection tracking mechanisms and application timeouts may be much shorter.

tcp_low_latency (Boolean; default: disabled; since Linux 2.4.21/2.6; obsolete since Linux 4.14)
If enabled, the TCP stack makes decisions that prefer lower latency as opposed to higher throughput. It this option is disabled, then higher throughput is preferred. An example of an application where this default should be changed would be a Beowulf compute cluster. Since Linux 4.14, this file still exists, but its value is ignored.

tcp_max_orphans (integer; default: see below; since Linux 2.4)
The maximum number of orphaned (not attached to any user file handle) TCP sockets allowed in the system. When this number is exceeded, the orphaned connection is reset and a warning is printed. This limit exists only to prevent simple denial-of-service attacks. Lowering this limit is not recommended. Network conditions might require you to increase the number of orphans allowed, but note that each orphan can eat up to ~64 kB of unswappable memory. The default initial value is set equal to the kernel parameter NR_FILE. This initial default is adjusted depending on the memory in the system.

tcp_max_syn_backlog (integer; default: see below; since Linux 2.2)
The maximum number of queued connection requests which have still not received an acknowledgement from the connecting client. If this number is exceeded, the kernel will begin dropping requests. The default value of 256 is increased to 1024 when the memory present in the system is adequate or greater (>= 128 MB), and reduced to 128 for those systems with very low memory (<= 32 MB).

Before Linux 2.6.20, it was recommended that if this needed to be increased above 1024, the size of the SYNACK hash table (**TCP_SYNQ_HSIZE**) in *include/net/tcp.h* should be modified to keep

```
TCP_SYNQ_HSIZE * 16 <= tcp_max_syn_backlog
```

and the kernel should be recompiled. In Linux 2.6.20, the fixed sized **TCP_SYNQ_HSIZE** was removed in favor of dynamic sizing.

tcp_max_tw_buckets (integer; default: see below; since Linux 2.4)
The maximum number of sockets in TIME_WAIT state allowed in the system. This limit exists only to prevent simple denial-of-service attacks. The default value of NR_FILE*2 is adjusted depending on the memory in the system. If this number is exceeded, the socket is closed and a warning is printed.

tcp_moderate_rcvbuf (Boolean; default: enabled; since Linux 2.4.17/2.6.7)
If enabled, TCP performs receive buffer auto-tuning, attempting to automatically size the buffer (no greater than *tcp_rmem[2]*) to match the size required by the path for full throughput.

tcp_mem (since Linux 2.4)
This is a vector of 3 integers: [low, pressure, high]. These bounds, measured in units of the system page size, are used by TCP to track its memory usage. The defaults are calculated at boot time from the amount of available memory. (TCP can only use *low memory* for this, which is limited to around 900 megabytes on 32-bit systems. 64-bit systems do not suffer this limitation.)

low TCP doesn't regulate its memory allocation when the number of pages it has allocated globally is below this number.

pressure
When the amount of memory allocated by TCP exceeds this number of pages, TCP moderates its memory consumption. This memory pressure state is exited once the number of pages allocated falls below the *low* mark.

high The maximum number of pages, globally, that TCP will allocate. This value overrides any other limits imposed by the kernel.

tcp_mtu_probing (integer; default: 0; since Linux 2.6.17)
This parameter controls TCP Packetization-Layer Path MTU Discovery. The following values may be assigned to the file:

0 Disabled

1 Disabled by default, enabled when an ICMP black hole detected

2 Always enabled, use initial MSS of *tcp_base_mss*.

tcp_no_metrics_save (Boolean; default: disabled; since Linux 2.6.6)
By default, TCP saves various connection metrics in the route cache when the connection closes, so that connections established in the near future can use these to set initial conditions. Usually, this increases overall performance, but it may sometimes cause performance degradation. If *tcp_no_metrics_save* is enabled, TCP will not cache metrics on closing connections.

tcp_orphan_retries (integer; default: 8; since Linux 2.4)
The maximum number of attempts made to probe the other end of a connection which has been closed by our end.

tcp_reordering (integer; default: 3; since Linux 2.4)
The maximum a packet can be reordered in a TCP packet stream without TCP assuming packet loss and going into slow start. It is not advisable to change this number. This is a

packet reordering detection metric designed to minimize unnecessary back off and retransmits provoked by reordering of packets on a connection.

tcp_retrans_collapse (Boolean; default: enabled; since Linux 2.2)
Try to send full-sized packets during retransmit.

tcp_retries1 (integer; default: 3; since Linux 2.2)
The number of times TCP will attempt to retransmit a packet on an established connection normally, without the extra effort of getting the network layers involved. Once we exceed this number of retransmits, we first have the network layer update the route if possible before each new retransmit. The default is the RFC specified minimum of 3.

tcp_retries2 (integer; default: 15; since Linux 2.2)
The maximum number of times a TCP packet is retransmitted in established state before giving up. The default value is 15, which corresponds to a duration of approximately between 13 to 30 minutes, depending on the retransmission timeout. The RFC 1122 specified minimum limit of 100 seconds is typically deemed too short.

tcp_rfc1337 (Boolean; default: disabled; since Linux 2.2)
Enable TCP behavior conformant with RFC 1337. When disabled, if a RST is received in TIME_WAIT state, we close the socket immediately without waiting for the end of the TIME_WAIT period.

tcp_rmem (since Linux 2.4)
This is a vector of 3 integers: [min, default, max]. These parameters are used by TCP to regulate receive buffer sizes. TCP dynamically adjusts the size of the receive buffer from the defaults listed below, in the range of these values, depending on memory available in the system.

min minimum size of the receive buffer used by each TCP socket. The default value is the system page size. (On Linux 2.4, the default value is 4 kB, lowered to **PAGE_SIZE** bytes in low-memory systems.) This value is used to ensure that in memory pressure mode, allocations below this size will still succeed. This is not used to bound the size of the receive buffer declared using **SO_RCVBUF** on a socket.

default the default size of the receive buffer for a TCP socket. This value overwrites the initial default buffer size from the generic global *net.core.rmem_default* defined for all protocols. The default value is 87380 bytes. (On Linux 2.4, this will be lowered to 43689 in low-memory systems.) If larger receive buffer sizes are desired, this value should be increased (to affect all sockets). To employ large TCP windows, the *net.ipv4.tcp_window_scaling* must be enabled (default).

max the maximum size of the receive buffer used by each TCP socket. This value does not override the global *net.core.rmem_max*. This is not used to limit the size of the receive buffer declared using **SO_RCVBUF** on a socket. The default value is calculated using the formula

```
max(87380, min(4 MB, tcp_mem[1]*PAGE_SIZE/128))
```

(On Linux 2.4, the default is 87380*2 bytes, lowered to 87380 in low-memory systems).

tcp_sack (Boolean; default: enabled; since Linux 2.2)
Enable RFC 2018 TCP Selective Acknowledgements.

tcp_slow_start_after_idle (Boolean; default: enabled; since Linux 2.6.18)
If enabled, provide RFC 2861 behavior and time out the congestion window after an idle period. An idle period is defined as the current RTO (retransmission timeout). If disabled, the congestion window will not be timed out after an idle period.

tcp_stdurg (Boolean; default: disabled; since Linux 2.2)
If this option is enabled, then use the RFC 1122 interpretation of the TCP urgent-pointer field. According to this interpretation, the urgent pointer points to the last byte of urgent data. If this option is disabled, then use the BSD-compatible interpretation of the urgent pointer: the urgent pointer points to the first byte after the urgent data. Enabling this option may lead to interoperability problems.

tcp_syn_retries (integer; default: 6; since Linux 2.2)
The maximum number of times initial SYNs for an active TCP connection attempt will be retransmitted. This value should not be higher than 255. The default value is 6, which corresponds to retrying for up to approximately 127 seconds. Before Linux 3.7, the default value was 5, which (in conjunction with calculation based on other kernel parameters) corresponded to approximately 180 seconds.

tcp_synack_retries (integer; default: 5; since Linux 2.2)
The maximum number of times a SYN/ACK segment for a passive TCP connection will be retransmitted. This number should not be higher than 255.

tcp_syncookies (integer; default: 1; since Linux 2.2)
Enable TCP syncookies. The kernel must be compiled with **CONFIG_SYN_COOKIES**. The syncookies feature attempts to protect a socket from a SYN flood attack. This should be used as a last resort, if at all. This is a violation of the TCP protocol, and conflicts with other areas of TCP such as TCP extensions. It can cause problems for clients and relays. It is not recommended as a tuning mechanism for heavily loaded servers to help with overloaded or misconfigured conditions. For recommended alternatives see *tcp_max_syn_backlog*, *tcp_synack_retries*, and *tcp_abort_on_overflow*. Set to one of the following values:

0 Disable TCP syncookies.

1 Send out syncookies when the syn backlog queue of a socket overflows.

2 (since Linux 3.12) Send out syncookies unconditionally. This can be useful for network testing.

tcp_timestamps (integer; default: 1; since Linux 2.2)
Set to one of the following values to enable or disable RFC 1323 TCP timestamps:

0 Disable timestamps.

1 Enable timestamps as defined in RFC1323 and use random offset for each connection rather than only using the current time.

2 As for the value 1, but without random offsets. Setting *tcp_timestamps* to this value is meaningful since Linux 4.10.

tcp_tso_win_divisor (integer; default: 3; since Linux 2.6.9)
This parameter controls what percentage of the congestion window can be consumed by a single TCP Segmentation Offload (TSO) frame. The setting of this parameter is a tradeoff between burstiness and building larger TSO frames.

tcp_tw_recycle (Boolean; default: disabled; Linux 2.4 to Linux 4.11)
Enable fast recycling of TIME_WAIT sockets. Enabling this option is not recommended as the remote IP may not use monotonically increasing timestamps (devices behind NAT, devices with per-connection timestamp offsets). See RFC 1323 (PAWS) and RFC 6191.

tcp_tw_reuse (Boolean; default: disabled; since Linux 2.4.19/2.6)
Allow to reuse TIME_WAIT sockets for new connections when it is safe from protocol viewpoint. It should not be changed without advice/request of technical experts.

tcp_vegas_cong_avoid (Boolean; default: disabled; Linux 2.2 to Linux 2.6.13)
Enable TCP Vegas congestion avoidance algorithm. TCP Vegas is a sender-side-only change to TCP that anticipates the onset of congestion by estimating the bandwidth. TCP Vegas adjusts the sending rate by modifying the congestion window. TCP Vegas should provide less packet loss, but it is not as aggressive as TCP Reno.

tcp_westwood (Boolean; default: disabled; Linux 2.4.26/2.6.3 to Linux 2.6.13)
Enable TCP Westwood+ congestion control algorithm. TCP Westwood+ is a sender-side-only modification of the TCP Reno protocol stack that optimizes the performance of TCP congestion control. It is based on end-to-end bandwidth estimation to set congestion window and slow start threshold after a congestion episode. Using this estimation, TCP Westwood+ adaptively sets a slow start threshold and a congestion window which takes into account the bandwidth used at the time congestion is experienced. TCP Westwood+ significantly increases fairness with respect to TCP Reno in wired networks and throughput over wireless links.

tcp_window_scaling (Boolean; default: enabled; since Linux 2.2)
: Enable RFC 1323 TCP window scaling. This feature allows the use of a large window (> 64 kB) on a TCP connection, should the other end support it. Normally, the 16 bit window length field in the TCP header limits the window size to less than 64 kB. If larger windows are desired, applications can increase the size of their socket buffers and the window scaling option will be employed. If *tcp_window_scaling* is disabled, TCP will not negotiate the use of window scaling with the other end during connection setup.

tcp_wmem (since Linux 2.4)
: This is a vector of 3 integers: [min, default, max]. These parameters are used by TCP to regulate send buffer sizes. TCP dynamically adjusts the size of the send buffer from the default values listed below, in the range of these values, depending on memory available.

  min
  : Minimum size of the send buffer used by each TCP socket. The default value is the system page size. (On Linux 2.4, the default value is 4 kB.) This value is used to ensure that in memory pressure mode, allocations below this size will still succeed. This is not used to bound the size of the send buffer declared using **SO_SNDBUF** on a socket.

  default
  : The default size of the send buffer for a TCP socket. This value overwrites the initial default buffer size from the generic global */proc/sys/net/core/wmem_default* defined for all protocols. The default value is 16 kB. If larger send buffer sizes are desired, this value should be increased (to affect all sockets). To employ large TCP windows, the */proc/sys/net/ipv4/tcp_window_scaling* must be set to a nonzero value (default).

  max
  : The maximum size of the send buffer used by each TCP socket. This value does not override the value in */proc/sys/net/core/wmem_max*. This is not used to limit the size of the send buffer declared using **SO_SNDBUF** on a socket. The default value is calculated using the formula

    ```
    max(65536, min(4 MB, tcp_mem[1]*PAGE_SIZE/128))
    ```

    (On Linux 2.4, the default value is 128 kB, lowered 64 kB depending on low-memory systems.)

tcp_workaround_signed_windows (Boolean; default: disabled; since Linux 2.6.26)
: If enabled, assume that no receipt of a window-scaling option means that the remote TCP is broken and treats the window as a signed quantity. If disabled, assume that the remote TCP is not broken even if we do not receive a window scaling option from it.

Socket options

To set or get a TCP socket option, call *getsockopt*(2) to read or *setsockopt*(2) to write the option with the option level argument set to **IPPROTO_TCP**. Unless otherwise noted, *optval* is a pointer to an *int*. In addition, most **IPPROTO_IP** socket options are valid on TCP sockets. For more information see *ip*(7).

Following is a list of TCP-specific socket options. For details of some other socket options that are also applicable for TCP sockets, see *socket*(7).

TCP_CONGESTION (since Linux 2.6.13)
: The argument for this option is a string. This option allows the caller to set the TCP congestion control algorithm to be used, on a per-socket basis. Unprivileged processes are restricted to choosing one of the algorithms in *tcp_allowed_congestion_control* (described above). Privileged processes (**CAP_NET_ADMIN**) can choose from any of the available congestion-control algorithms (see the description of *tcp_available_congestion_control* above).

TCP_CORK (since Linux 2.2)
: If set, don't send out partial frames. All queued partial frames are sent when the option is cleared again. This is useful for prepending headers before calling *sendfile*(2), or for throughput optimization. As currently implemented, there is a 200 millisecond ceiling on the time for which output is corked by **TCP_CORK**. If this ceiling is reached, then queued data is automatically transmitted. This option can be combined with **TCP_NODELAY** only since Linux 2.5.71. This option should not be used in code intended to be portable.

TCP_DEFER_ACCEPT (since Linux 2.4)
Allow a listener to be awakened only when data arrives on the socket. Takes an integer value (seconds), this can bound the maximum number of attempts TCP will make to complete the connection. This option should not be used in code intended to be portable.

TCP_INFO (since Linux 2.4)
Used to collect information about this socket. The kernel returns a *struct tcp_info* as defined in the file */usr/include/linux/tcp.h*. This option should not be used in code intended to be portable.

TCP_KEEPCNT (since Linux 2.4)
The maximum number of keepalive probes TCP should send before dropping the connection. This option should not be used in code intended to be portable.

TCP_KEEPIDLE (since Linux 2.4)
The time (in seconds) the connection needs to remain idle before TCP starts sending keepalive probes, if the socket option **SO_KEEPALIVE** has been set on this socket. This option should not be used in code intended to be portable.

TCP_KEEPINTVL (since Linux 2.4)
The time (in seconds) between individual keepalive probes. This option should not be used in code intended to be portable.

TCP_LINGER2 (since Linux 2.4)
The lifetime of orphaned FIN_WAIT2 state sockets. This option can be used to override the system-wide setting in the file */proc/sys/net/ipv4/tcp_fin_timeout* for this socket. This is not to be confused with the *socket*(7) level option **SO_LINGER**. This option should not be used in code intended to be portable.

TCP_MAXSEG
The maximum segment size for outgoing TCP packets. In Linux 2.2 and earlier, and in Linux 2.6.28 and later, if this option is set before connection establishment, it also changes the MSS value announced to the other end in the initial packet. Values greater than the (eventual) interface MTU have no effect. TCP will also impose its minimum and maximum bounds over the value provided.

TCP_NODELAY
If set, disable the Nagle algorithm. This means that segments are always sent as soon as possible, even if there is only a small amount of data. When not set, data is buffered until there is a sufficient amount to send out, thereby avoiding the frequent sending of small packets, which results in poor utilization of the network. This option is overridden by **TCP_CORK**; however, setting this option forces an explicit flush of pending output, even if **TCP_CORK** is currently set.

TCP_QUICKACK (since Linux 2.4.4)
Enable quickack mode if set or disable quickack mode if cleared. In quickack mode, acks are sent immediately, rather than delayed if needed in accordance to normal TCP operation. This flag is not permanent, it only enables a switch to or from quickack mode. Subsequent operation of the TCP protocol will once again enter/leave quickack mode depending on internal protocol processing and factors such as delayed ack timeouts occurring and data transfer. This option should not be used in code intended to be portable.

TCP_SYNCNT (since Linux 2.4)
Set the number of SYN retransmits that TCP should send before aborting the attempt to connect. It cannot exceed 255. This option should not be used in code intended to be portable.

TCP_USER_TIMEOUT (since Linux 2.6.37)
This option takes an *unsigned int* as an argument. When the value is greater than 0, it specifies the maximum amount of time in milliseconds that transmitted data may remain unacknowledged, or buffered data may remain untransmitted (due to zero window size) before TCP will forcibly close the corresponding connection and return **ETIMEDOUT** to the application. If the option value is specified as 0, TCP will use the system default.

Increasing user timeouts allows a TCP connection to survive extended periods without end-to-end connectivity. Decreasing user timeouts allows applications to "fail fast", if so desired.

Otherwise, failure may take up to 20 minutes with the current system defaults in a normal WAN environment.

This option can be set during any state of a TCP connection, but is effective only during the synchronized states of a connection (ESTABLISHED, FIN-WAIT-1, FIN-WAIT-2, CLOSE-WAIT, CLOSING, and LAST-ACK). Moreover, when used with the TCP keepalive (**SO_KEEPALIVE**) option, **TCP_USER_TIMEOUT** will override keepalive to determine when to close a connection due to keepalive failure.

The option has no effect on when TCP retransmits a packet, nor when a keepalive probe is sent.

This option, like many others, will be inherited by the socket returned by *accept*(2), if it was set on the listening socket.

Further details on the user timeout feature can be found in RFC 793 and RFC 5482 ("TCP User Timeout Option").

TCP_WINDOW_CLAMP (since Linux 2.4)
Bound the size of the advertised window to this value. The kernel imposes a minimum size of SOCK_MIN_RCVBUF/2. This option should not be used in code intended to be portable.

TCP_FASTOPEN (since Linux 3.6)
This option enables Fast Open (RFC 7413) on the listener socket. The value specifies the maximum length of pending SYNs (similar to the backlog argument in *listen*(2)). Once enabled, the listener socket grants the TCP Fast Open cookie on incoming SYN with TCP Fast Open option.

More importantly it accepts the data in SYN with a valid Fast Open cookie and responds SYN-ACK acknowledging both the data and the SYN sequence. *accept*(2) returns a socket that is available for read and write when the handshake has not completed yet. Thus the data exchange can commence before the handshake completes. This option requires enabling the server-side support on sysctl *net.ipv4.tcp_fastopen* (see above). For TCP Fast Open client-side support, see *send*(2) **MSG_FASTOPEN** or **TCP_FASTOPEN_CONNECT** below.

TCP_FASTOPEN_CONNECT (since Linux 4.11)
This option enables an alternative way to perform Fast Open on the active side (client). When this option is enabled, *connect*(2) would behave differently depending on if a Fast Open cookie is available for the destination.

If a cookie is not available (i.e. first contact to the destination), *connect*(2) behaves as usual by sending a SYN immediately, except the SYN would include an empty Fast Open cookie option to solicit a cookie.

If a cookie is available, *connect*(2) would return 0 immediately but the SYN transmission is deferred. A subsequent *write*(2) or *sendmsg*(2) would trigger a SYN with data plus cookie in the Fast Open option. In other words, the actual connect operation is deferred until data is supplied.

Note: While this option is designed for convenience, enabling it does change the behaviors and certain system calls might set different *errno* values. With cookie present, *write*(2) or *sendmsg*(2) must be called right after *connect*(2) in order to send out SYN+data to complete 3WHS and establish connection. Calling *read*(2) right after *connect*(2) without *write*(2) will cause the blocking socket to be blocked forever.

The application should either set **TCP_FASTOPEN_CONNECT** socket option before *write*(2) or *sendmsg*(2), or call *write*(2) or *sendmsg*(2) with **MSG_FASTOPEN** flag directly, instead of both on the same connection.

Here is the typical call flow with this new option:

```
s = socket();
setsockopt(s, IPPROTO_TCP, TCP_FASTOPEN_CONNECT, 1, ...);
connect(s);
write(s); /* write() should always follow connect()
           * in order to trigger SYN to go out. */
read(s)/write(s);
```

```
/* ... */
close(s);
```

Sockets API

TCP provides limited support for out-of-band data, in the form of (a single byte of) urgent data. In Linux this means if the other end sends newer out-of-band data the older urgent data is inserted as normal data into the stream (even when **SO_OOBINLINE** is not set). This differs from BSD-based stacks.

Linux uses the BSD compatible interpretation of the urgent pointer field by default. This violates RFC 1122, but is required for interoperability with other stacks. It can be changed via */proc/sys/net/ipv4/tcp_stdurg*.

It is possible to peek at out-of-band data using the *recv*(2) **MSG_PEEK** flag.

Since Linux 2.4, Linux supports the use of **MSG_TRUNC** in the *flags* argument of *recv*(2) (and *recvmsg*(2)). This flag causes the received bytes of data to be discarded, rather than passed back in a caller-supplied buffer. Since Linux 2.4.4, **MSG_TRUNC** also has this effect when used in conjunction with **MSG_OOB** to receive out-of-band data.

Ioctls

The following *ioctl*(2) calls return information in *value*. The correct syntax is:

int *value***;**
error **= ioctl(***tcp_socket***,** *ioctl_type***, &***value***);**

ioctl_type is one of the following:

SIOCINQ

Returns the amount of queued unread data in the receive buffer. The socket must not be in LISTEN state, otherwise an error (**EINVAL**) is returned. **SIOCINQ** is defined in <*linux/sockios.h*>. Alternatively, you can use the synonymous **FIONREAD**, defined in <*sys/ioctl.h*>.

SIOCATMARK

Returns true (i.e., *value* is nonzero) if the inbound data stream is at the urgent mark.

If the **SO_OOBINLINE** socket option is set, and **SIOCATMARK** returns true, then the next read from the socket will return the urgent data. If the **SO_OOBINLINE** socket option is not set, and **SIOCATMARK** returns true, then the next read from the socket will return the bytes following the urgent data (to actually read the urgent data requires the **recv(MSG_OOB)** flag).

Note that a read never reads across the urgent mark. If an application is informed of the presence of urgent data via *select*(2) (using the *exceptfds* argument) or through delivery of a **SIGURG** signal, then it can advance up to the mark using a loop which repeatedly tests **SIOCATMARK** and performs a read (requesting any number of bytes) as long as **SIOCATMARK** returns false.

SIOCOUTQ

Returns the amount of unsent data in the socket send queue. The socket must not be in LISTEN state, otherwise an error (**EINVAL**) is returned. **SIOCOUTQ** is defined in <*linux/sockios.h*>. Alternatively, you can use the synonymous **TIOCOUTQ**, defined in <*sys/ioctl.h*>.

Error handling

When a network error occurs, TCP tries to resend the packet. If it doesn't succeed after some time, either **ETIMEDOUT** or the last received error on this connection is reported.

Some applications require a quicker error notification. This can be enabled with the **IPPROTO_IP** level **IP_RECVERR** socket option. When this option is enabled, all incoming errors are immediately passed to the user program. Use this option with care — it makes TCP less tolerant to routing changes and other normal network conditions.

ERRORS

EAFNOTSUPPORT

Passed socket address type in *sin_family* was not **AF_INET**.

EPIPE The other end closed the socket unexpectedly or a read is executed on a shut down socket.

ETIMEDOUT
The other end didn't acknowledge retransmitted data after some time.

Any errors defined for *ip*(7) or the generic socket layer may also be returned for TCP.

VERSIONS

Support for Explicit Congestion Notification, zero-copy *sendfile*(2), reordering support and some SACK extensions (DSACK) were introduced in Linux 2.4. Support for forward acknowledgement (FACK), TIME_WAIT recycling, and per-connection keepalive socket options were introduced in Linux 2.3.

BUGS

Not all errors are documented.

IPv6 is not described.

NAME

termio − System V terminal driver interface

DESCRIPTION

termio is the name of the old System V terminal driver interface. This interface defined a *termio* structure used to store terminal settings, and a range of *ioctl*(2) operations to get and set terminal attributes.

The **termio** interface is now obsolete: POSIX.1-1990 standardized a modified version of this interface, under the name **termios**. The POSIX.1 data structure differs slightly from the System V version, and POSIX.1 defined a suite of functions to replace the various *ioctl*(2) operations that existed in System V. (This was done because *ioctl*(2) was unstandardized, and its variadic third argument does not allow argument type checking.)

If you're looking for a page called "termio", then you can probably find most of the information that you seek in either *termios*(3) or *ioctl_tty*(2).

NAME

thread-keyring − per-thread keyring

DESCRIPTION

The thread keyring is a keyring used to anchor keys on behalf of a process. It is created only when a thread requests it. The thread keyring has the name (description) *_tid*.

A special serial number value, **KEY_SPEC_THREAD_KEYRING**, is defined that can be used in lieu of the actual serial number of the calling thread's thread keyring.

From the *keyctl*(1) utility, '**@t**' can be used instead of a numeric key ID in much the same way, but as *keyctl*(1) is a program run after forking, this is of no utility.

Thread keyrings are not inherited across *clone*(2) and *fork*(2) and are cleared by *execve*(2). A thread keyring is destroyed when the thread that refers to it terminates.

Initially, a thread does not have a thread keyring. If a thread doesn't have a thread keyring when it is accessed, then it will be created if it is to be modified; otherwise the operation fails with the error **ENOKEY**.

NAME

time − overview of time and timers

DESCRIPTION

Real time and process time

Real time is defined as time measured from some fixed point, either from a standard point in the past (see the description of the Epoch and calendar time below), or from some point (e.g., the start) in the life of a process (*elapsed time*).

Process time is defined as the amount of CPU time used by a process. This is sometimes divided into *user* and *system* components. User CPU time is the time spent executing code in user mode. System CPU time is the time spent by the kernel executing in system mode on behalf of the process (e.g., executing system calls). The *time*(1) command can be used to determine the amount of CPU time consumed during the execution of a program. A program can determine the amount of CPU time it has consumed using *times*(2), *getrusage*(2), or *clock*(3).

The hardware clock

Most computers have a (battery-powered) hardware clock which the kernel reads at boot time in order to initialize the software clock. For further details, see *rtc*(4) and *hwclock*(8)

The software clock, HZ, and jiffies

The accuracy of various system calls that set timeouts, (e.g., *select*(2), *sigtimedwait*(2)) and measure CPU time (e.g., *getrusage*(2)) is limited by the resolution of the *software clock*, a clock maintained by the kernel which measures time in *jiffies*. The size of a jiffy is determined by the value of the kernel constant *HZ*.

The value of *HZ* varies across kernel versions and hardware platforms. On i386 the situation is as follows: on kernels up to and including Linux 2.4.x, HZ was 100, giving a jiffy value of 0.01 seconds; starting with Linux 2.6.0, HZ was raised to 1000, giving a jiffy of 0.001 seconds. Since Linux 2.6.13, the HZ value is a kernel configuration parameter and can be 100, 250 (the default) or 1000, yielding a jiffies value of, respectively, 0.01, 0.004, or 0.001 seconds. Since Linux 2.6.20, a further frequency is available: 300, a number that divides evenly for the common video frame rates (PAL, 25 Hz; NTSC, 30 Hz).

The *times*(2) system call is a special case. It reports times with a granularity defined by the kernel constant *USER_HZ*. User-space applications can determine the value of this constant using *sysconf(_SC_CLK_TCK)*.

System and process clocks; time namespaces

The kernel supports a range of clocks that measure various kinds of elapsed and virtual (i.e., consumed CPU) time. These clocks are described in *clock_gettime*(2). A few of the clocks are settable using *clock_settime*(2). The values of certain clocks are virtualized by time namespaces; see *time_namespaces*(7).

High-resolution timers

Before Linux 2.6.21, the accuracy of timer and sleep system calls (see below) was also limited by the size of the jiffy.

Since Linux 2.6.21, Linux supports high-resolution timers (HRTs), optionally configurable via **CONFIG_HIGH_RES_TIMERS**. On a system that supports HRTs, the accuracy of sleep and timer system calls is no longer constrained by the jiffy, but instead can be as accurate as the hardware allows (microsecond accuracy is typical of modern hardware). You can determine whether high-resolution timers are supported by checking the resolution returned by a call to *clock_getres*(2) or looking at the "resolution" entries in */proc/timer_list*.

HRTs are not supported on all hardware architectures. (Support is provided on x86, ARM, and PowerPC, among others.)

The Epoch

UNIX systems represent time in seconds since the *Epoch*, 1970-01-01 00:00:00 +0000 (UTC).

A program can determine the *calendar time* via the *clock_gettime*(2) **CLOCK_REALTIME** clock, which returns time (in seconds and nanoseconds) that have elapsed since the Epoch; *time*(2) provides similar information, but only with accuracy to the nearest second. The system time can be changed using *clock_settime*(2).

Broken-down time

Certain library functions use a structure of type *tm* to represent *broken-down time*, which stores time value separated out into distinct components (year, month, day, hour, minute, second, etc.). This structure is described in *tm*(3type), which also describes functions that convert between calendar time and broken-down time. Functions for converting between broken-down time and printable string representations of the time are described in *ctime*(3), *strftime*(3), and *strptime*(3).

Sleeping and setting timers

Various system calls and functions allow a program to sleep (suspend execution) for a specified period of time; see *nanosleep*(2), *clock_nanosleep*(2), and *sleep*(3).

Various system calls allow a process to set a timer that expires at some point in the future, and optionally at repeated intervals; see *alarm*(2), *getitimer*(2), *timerfd_create*(2), and *timer_create*(2).

Timer slack

Since Linux 2.6.28, it is possible to control the "timer slack" value for a thread. The timer slack is the length of time by which the kernel may delay the wake-up of certain system calls that block with a timeout. Permitting this delay allows the kernel to coalesce wake-up events, thus possibly reducing the number of system wake-ups and saving power. For more details, see the description of **PR_SET_TIMERSLACK** in *prctl*(2).

NAME

time_namespaces − overview of Linux time namespaces

DESCRIPTION

Time namespaces virtualize the values of two system clocks:

- **CLOCK_MONOTONIC** (and likewise **CLOCK_MONOTONIC_COARSE** and **CLOCK_MONOTONIC_RAW**), a nonsettable clock that represents monotonic time since—as described by POSIX—"some unspecified point in the past".
- **CLOCK_BOOTTIME** (and likewise **CLOCK_BOOTTIME_ALARM**), a nonsettable clock that is identical to **CLOCK_MONOTONIC**, except that it also includes any time that the system is suspended.

Thus, the processes in a time namespace share per-namespace values for these clocks. This affects various APIs that measure against these clocks, including: *clock_gettime*(2), *clock_nanosleep*(2), *nanosleep*(2), *timer_settime*(2), *timerfd_settime*(2), and */proc/uptime*.

Currently, the only way to create a time namespace is by calling *unshare*(2) with the **CLONE_NEWTIME** flag. This call creates a new time namespace but does *not* place the calling process in the new namespace. Instead, the calling process's subsequently created children are placed in the new namespace. This allows clock offsets (see below) for the new namespace to be set before the first process is placed in the namespace. The */proc/*pid*/ns/time_for_children* symbolic link shows the time namespace in which the children of a process will be created. (A process can use a file descriptor opened on this symbolic link in a call to *setns*(2) in order to move into the namespace.)

/proc/*pid*/timens_offsets

Associated with each time namespace are offsets, expressed with respect to the initial time namespace, that define the values of the monotonic and boot-time clocks in that namespace. These offsets are exposed via the file */proc/*pid*/timens_offsets*. Within this file, the offsets are expressed as lines consisting of three space-delimited fields:

```
<clock-id> <offset-secs> <offset-nanosecs>
```

The *clock-id* is a string that identifies the clock whose offsets are being shown. This field is either *monotonic*, for **CLOCK_MONOTONIC**, or *boottime*, for **CLOCK_BOOTTIME**. The remaining fields express the offset (seconds plus nanoseconds) for the clock in this time namespace. These offsets are expressed relative to the clock values in the initial time namespace. The *offset-secs* value can be negative, subject to restrictions noted below; *offset-nanosecs* is an unsigned value.

In the initial time namespace, the contents of the *timens_offsets* file are as follows:

```
$ cat /proc/self/timens_offsets
monotonic           0         0
boottime            0         0
```

In a new time namespace that has had no member processes, the clock offsets can be modified by writing newline-terminated records of the same form to the *timens_offsets* file. The file can be written to multiple times, but after the first process has been created in or has entered the namespace, *write*(2)s on this file fail with the error **EACCES**. In order to write to the *timens_offsets* file, a process must have the **CAP_SYS_TIME** capability in the user namespace that owns the time namespace.

Writes to the *timens_offsets* file can fail with the following errors:

EINVAL
An *offset-nanosecs* value is greater than 999,999,999.

EINVAL
A *clock-id* value is not valid.

EPERM
The caller does not have the **CAP_SYS_TIME** capability.

ERANGE
An *offset-secs* value is out of range. In particular;

- *offset-secs* can't be set to a value which would make the current time on the corresponding clock inside the namespace a negative value; and

- *offset-secs* can't be set to a value such that the time on the corresponding clock inside the namespace would exceed half of the value of the kernel constant **KTIME_SEC_MAX** (this limits the clock value to a maximum of approximately 146 years).

In a new time namespace created by *unshare*(2), the contents of the *timens_offsets* file are inherited from the time namespace of the creating process.

NOTES

Use of time namespaces requires a kernel that is configured with the **CONFIG_TIME_NS** option.

Note that time namespaces do not virtualize the **CLOCK_REALTIME** clock. Virtualization of this clock was avoided for reasons of complexity and overhead within the kernel.

For compatibility with the initial implementation, when writing a *clock-id* to the */proc/*pid*/timens_offsets* file, the numerical values of the IDs can be written instead of the symbolic names show above; i.e., 1 instead of *monotonic*, and 7 instead of *boottime*. For readability, the use of the symbolic names over the numbers is preferred.

The motivation for adding time namespaces was to allow the monotonic and boot-time clocks to maintain consistent values during container migration and checkpoint/restore.

EXAMPLES

The following shell session demonstrates the operation of time namespaces. We begin by displaying the inode number of the time namespace of a shell in the initial time namespace:

```
$ readlink /proc/$$/ns/time
time:[4026531834]
```

Continuing in the initial time namespace, we display the system uptime using *uptime*(1) and use the *clock_times* example program shown in *clock_getres*(2) to display the values of various clocks:

```
$ uptime --pretty
up 21 hours, 17 minutes
$ ./clock_times
CLOCK_REALTIME : 1585989401.971 (18356 days +  8h 36m 41s)
CLOCK_TAI      : 1585989438.972 (18356 days +  8h 37m 18s)
CLOCK_MONOTONIC:      56338.247 (15h 38m 58s)
CLOCK_BOOTTIME :      76633.544 (21h 17m 13s)
```

We then use *unshare*(1) to create a time namespace and execute a *bash*(1) shell. From the new shell, we use the built-in **echo** command to write records to the *timens_offsets* file adjusting the offset for the **CLOCK_MONOTONIC** clock forward 2 days and the offset for the **CLOCK_BOOTTIME** clock forward 7 days:

```
$ PS1="ns2# " sudo unshare -T -- bash --norc
ns2# echo "monotonic $((2*24*60*60)) 0" > /proc/$$/timens_offsets
ns2# echo "boottime  $((7*24*60*60)) 0" > /proc/$$/timens_offsets
```

Above, we started the *bash*(1) shell with the **--norc** option so that no start-up scripts were executed. This ensures that no child processes are created from the shell before we have a chance to update the *timens_offsets* file.

We then use *cat*(1) to display the contents of the *timens_offsets* file. The execution of *cat*(1) creates the first process in the new time namespace, after which further attempts to update the *timens_offsets* file produce an error.

```
ns2# cat /proc/$$/timens_offsets
monotonic      172800         0
boottime       604800         0
ns2# echo "boottime $((9*24*60*60)) 0" > /proc/$$/timens_offsets
bash: echo: write error: Permission denied
```

Continuing in the new namespace, we execute *uptime*(1) and the *clock_times* example program:

```
ns2# uptime --pretty
up 1 week, 21 hours, 18 minutes
ns2# ./clock_times
CLOCK_REALTIME : 1585989457.056 (18356 days +  8h 37m 37s)
```

```
CLOCK_TAI      : 1585989494.057 (18356 days +  8h 38m 14s)
CLOCK_MONOTONIC:     229193.332 (2 days + 15h 39m 53s)
CLOCK_BOOTTIME :     681488.629 (7 days + 21h 18m  8s)
```

From the above output, we can see that the monotonic and boot-time clocks have different values in the new time namespace.

Examining the */proc/*pid*/ns/time* and */proc/*pid*/ns/time_for_children* symbolic links, we see that the shell is a member of the initial time namespace, but its children are created in the new namespace.

```
ns2# readlink /proc/$$/ns/time
time:[4026531834]
ns2# readlink /proc/$$/ns/time_for_children
time:[4026532900]
ns2# readlink /proc/self/ns/time   # Creates a child process
time:[4026532900]
```

Returning to the shell in the initial time namespace, we see that the monotonic and boot-time clocks are unaffected by the *timens_offsets* changes that were made in the other time namespace:

```
$ uptime --pretty
up 21 hours, 19 minutes
$ ./clock_times
CLOCK_REALTIME : 1585989401.971 (18356 days +  8h 38m 51s)
CLOCK_TAI      : 1585989438.972 (18356 days +  8h 39m 28s)
CLOCK_MONOTONIC:      56338.247 (15h 41m  8s)
CLOCK_BOOTTIME :      76633.544 (21h 19m 23s)
```

NAME

udp − User Datagram Protocol for IPv4

SYNOPSIS

#include <sys/socket.h>
#include <netinet/in.h>
#include <netinet/udp.h>

udp_socket = **socket(AF_INET, SOCK_DGRAM, 0);**

DESCRIPTION

This is an implementation of the User Datagram Protocol described in RFC 768. It implements a connectionless, unreliable datagram packet service. Packets may be reordered or duplicated before they arrive. UDP generates and checks checksums to catch transmission errors.

When a UDP socket is created, its local and remote addresses are unspecified. Datagrams can be sent immediately using *sendto*(2) or *sendmsg*(2) with a valid destination address as an argument. When *connect*(2) is called on the socket, the default destination address is set and datagrams can now be sent using *send*(2) or *write*(2) without specifying a destination address. It is still possible to send to other destinations by passing an address to *sendto*(2) or *sendmsg*(2). In order to receive packets, the socket can be bound to a local address first by using *bind*(2). Otherwise, the socket layer will automatically assign a free local port out of the range defined by */proc/sys/net/ipv4/ip_local_port_range* and bind the socket to **INADDR_ANY**.

All receive operations return only one packet. When the packet is smaller than the passed buffer, only that much data is returned; when it is bigger, the packet is truncated and the **MSG_TRUNC** flag is set. **MSG_WAITALL** is not supported.

IP options may be sent or received using the socket options described in *ip*(7). They are processed by the kernel only when the appropriate */proc* parameter is enabled (but still passed to the user even when it is turned off). See *ip*(7).

When the **MSG_DONTROUTE** flag is set on sending, the destination address must refer to a local interface address and the packet is sent only to that interface.

By default, Linux UDP does path MTU (Maximum Transmission Unit) discovery. This means the kernel will keep track of the MTU to a specific target IP address and return **EMSGSIZE** when a UDP packet write exceeds it. When this happens, the application should decrease the packet size. Path MTU discovery can be also turned off using the **IP_MTU_DISCOVER** socket option or the */proc/sys/net/ipv4/ip_no_pmtu_disc* file; see *ip*(7) for details. When turned off, UDP will fragment outgoing UDP packets that exceed the interface MTU. However, disabling it is not recommended for performance and reliability reasons.

Address format

UDP uses the IPv4 *sockaddr_in* address format described in *ip*(7).

Error handling

All fatal errors will be passed to the user as an error return even when the socket is not connected. This includes asynchronous errors received from the network. You may get an error for an earlier packet that was sent on the same socket. This behavior differs from many other BSD socket implementations which don't pass any errors unless the socket is connected. Linux's behavior is mandated by **RFC 1122**.

For compatibility with legacy code, in Linux 2.0 and 2.2 it was possible to set the **SO_BSDCOMPAT SOL_SOCKET** option to receive remote errors only when the socket has been connected (except for **EPROTO** and **EMSGSIZE**). Locally generated errors are always passed. Support for this socket option was removed in later kernels; see *socket*(7) for further information.

When the **IP_RECVERR** option is enabled, all errors are stored in the socket error queue, and can be received by *recvmsg*(2) with the **MSG_ERRQUEUE** flag set.

/proc interfaces

System-wide UDP parameter settings can be accessed by files in the directory */proc/sys/net/ipv4/* .

udp_mem (since Linux 2.6.25)
: This is a vector of three integers governing the number of pages allowed for queueing by all UDP sockets.

min Below this number of pages, UDP is not bothered about its memory appetite. When the amount of memory allocated by UDP exceeds this number, UDP starts to moderate memory usage.

pressure
This value was introduced to follow the format of *tcp_mem* (see *tcp*(7)).

max Number of pages allowed for queueing by all UDP sockets.

Defaults values for these three items are calculated at boot time from the amount of available memory.

udp_rmem_min (integer; default value: PAGE_SIZE; since Linux 2.6.25)
Minimal size, in bytes, of receive buffers used by UDP sockets in moderation. Each UDP socket is able to use the size for receiving data, even if total pages of UDP sockets exceed *udp_mem* pressure.

udp_wmem_min (integer; default value: PAGE_SIZE; since Linux 2.6.25)
Minimal size, in bytes, of send buffer used by UDP sockets in moderation. Each UDP socket is able to use the size for sending data, even if total pages of UDP sockets exceed *udp_mem* pressure.

Socket options

To set or get a UDP socket option, call *getsockopt*(2) to read or *setsockopt*(2) to write the option with the option level argument set to **IPPROTO_UDP**. Unless otherwise noted, *optval* is a pointer to an *int*.

Following is a list of UDP-specific socket options. For details of some other socket options that are also applicable for UDP sockets, see *socket*(7).

UDP_CORK (since Linux 2.5.44)
If this option is enabled, then all data output on this socket is accumulated into a single datagram that is transmitted when the option is disabled. This option should not be used in code intended to be portable.

UDP_SEGMENT (since Linux 4.18)
Enables UDP segmentation offload. Segmentation offload reduces *send*(2) cost by transferring multiple datagrams worth of data as a single large packet through the kernel transmit path, even when that exceeds MTU. As late as possible, the large packet is split by segment size into a series of datagrams. This segmentation offload step is deferred to hardware if supported, else performed in software. This option takes a value in the range [**0**, **USHRT_MAX**] that sets the segment size: the size of datagram payload, excluding the UDP header. The segment size must be chosen such that at most 64 datagrams are sent in a single call and that the datagrams after segmentation meet the same MTU rules that apply to datagrams sent without this option. Segmentation offload depends on checksum offload, as datagram checksums are computed after segmentation. The option may also be set for individual *sendmsg*(2) calls by passing it as a *cmsg*(3). A value of zero disables the feature. This option should not be used in code intended to be portable.

UDP_GRO (since Linux 5.0)
Enables UDP receive offload. If enabled, the socket may receive multiple datagrams worth of data as a single large buffer, together with a *cmsg*(3) that holds the segment size. This option is the inverse of segmentation offload. It reduces receive cost by handling multiple datagrams worth of data as a single large packet in the kernel receive path, even when that exceeds MTU. This option should not be used in code intended to be portable.

Ioctls

These ioctls can be accessed using *ioctl*(2). The correct syntax is:

int *value***;**
error **= ioctl(***udp_socket***,** *ioctl_type***, &***value***);**

FIONREAD (**SIOCINQ**)
Gets a pointer to an integer as argument. Returns the size of the next pending datagram in the integer in bytes, or 0 when no datagram is pending. **Warning:** Using **FIONREAD**, it is impossible to distinguish the case where no datagram is pending from the case where the next

pending datagram contains zero bytes of data. It is safer to use *select*(2), *poll*(2), or *epoll*(7) to distinguish these cases.

TIOCOUTQ (**SIOCOUTQ**)
Returns the number of data bytes in the local send queue. Supported only with Linux 2.4 and above.

In addition, all ioctls documented in *ip*(7) and *socket*(7) are supported.

ERRORS

All errors documented for *socket*(7) or *ip*(7) may be returned by a send or receive on a UDP socket.

ECONNREFUSED
No receiver was associated with the destination address. This might be caused by a previous packet sent over the socket.

VERSIONS

IP_RECVERR is a new feature in Linux 2.2.

NAME

udplite − Lightweight User Datagram Protocol

SYNOPSIS

#include <sys/socket.h>

sockfd = socket(AF_INET, SOCK_DGRAM, IPPROTO_UDPLITE);

DESCRIPTION

This is an implementation of the Lightweight User Datagram Protocol (UDP-Lite), as described in RFC 3828.

UDP-Lite is an extension of UDP (RFC 768) to support variable-length checksums. This has advantages for some types of multimedia transport that may be able to make use of slightly damaged datagrams, rather than having them discarded by lower-layer protocols.

The variable-length checksum coverage is set via a *setsockopt*(2) option. If this option is not set, the only difference from UDP is in using a different IP protocol identifier (IANA number 136).

The UDP-Lite implementation is a full extension of *udp*(7)—that is, it shares the same API and API behavior, and in addition offers two socket options to control the checksum coverage.

Address format

UDP-Litev4 uses the *sockaddr_in* address format described in *ip*(7). UDP-Litev6 uses the *sockaddr_in6* address format described in *ipv6*(7).

Socket options

To set or get a UDP-Lite socket option, call *getsockopt*(2) to read or *setsockopt*(2) to write the option with the option level argument set to **IPPROTO_UDPLITE**. In addition, all **IPPROTO_UDP** socket options are valid on a UDP-Lite socket. See *udp*(7) for more information.

The following two options are specific to UDP-Lite.

UDPLITE_SEND_CSCOV

This option sets the sender checksum coverage and takes an *int* as argument, with a checksum coverage value in the range 0..2^16-1.

A value of 0 means that the entire datagram is always covered. Values from 1−7 are illegal (RFC 3828, 3.1) and are rounded up to the minimum coverage of 8.

With regard to IPv6 jumbograms (RFC 2675), the UDP-Litev6 checksum coverage is limited to the first 2^16-1 octets, as per RFC 3828, 3.5. Higher values are therefore silently truncated to 2^16-1. If in doubt, the current coverage value can always be queried using *getsockopt*(2).

UDPLITE_RECV_CSCOV

This is the receiver-side analogue and uses the same argument format and value range as **UDPLITE_SEND_CSCOV**. This option is not required to enable traffic with partial checksum coverage. Its function is that of a traffic filter: when enabled, it instructs the kernel to drop all packets which have a coverage *less* than the specified coverage value.

When the value of **UDPLITE_RECV_CSCOV** exceeds the actual packet coverage, incoming packets are silently dropped, but may generate a warning message in the system log.

ERRORS

All errors documented for *udp*(7) may be returned. UDP-Lite does not add further errors.

FILES

/proc/net/snmp

Basic UDP-Litev4 statistics counters.

/proc/net/snmp6

Basic UDP-Litev6 statistics counters.

VERSIONS

UDP-Litev4/v6 first appeared in Linux 2.6.20.

BUGS

Where glibc support is missing, the following definitions are needed:

```
#define IPPROTO_UDPLITE     136
#define UDPLITE_SEND_CSCOV  10
```

```
#define UDPLITE_RECV_CSCOV  11
```

NAME

unicode − universal character set

DESCRIPTION

The international standard ISO/IEC 10646 defines the Universal Character Set (UCS). UCS contains all characters of all other character set standards. It also guarantees "round-trip compatibility"; in other words, conversion tables can be built such that no information is lost when a string is converted from any other encoding to UCS and back.

UCS contains the characters required to represent practically all known languages. This includes not only the Latin, Greek, Cyrillic, Hebrew, Arabic, Armenian, and Georgian scripts, but also Chinese, Japanese and Korean Han ideographs as well as scripts such as Hiragana, Katakana, Hangul, Devanagari, Bengali, Gurmukhi, Gujarati, Oriya, Tamil, Telugu, Kannada, Malayalam, Thai, Lao, Khmer, Bopomofo, Tibetan, Runic, Ethiopic, Canadian Syllabics, Cherokee, Mongolian, Ogham, Myanmar, Sinhala, Thaana, Yi, and others. For scripts not yet covered, research on how to best encode them for computer usage is still going on and they will be added eventually. This might eventually include not only Hieroglyphs and various historic Indo-European languages, but even some selected artistic scripts such as Tengwar, Cirth, and Klingon. UCS also covers a large number of graphical, typographical, mathematical, and scientific symbols, including those provided by TeX, Postscript, APL, MS-DOS, MS-Windows, Macintosh, OCR fonts, as well as many word processing and publishing systems, and more are being added.

The UCS standard (ISO/IEC 10646) describes a 31-bit character set architecture consisting of 128 24-bit *groups*, each divided into 256 16-bit *planes* made up of 256 8-bit *rows* with 256 *column* positions, one for each character. Part 1 of the standard (ISO/IEC 10646-1) defines the first 65534 code positions (0x0000 to 0xfffd), which form the *Basic Multilingual Plane* (BMP), that is plane 0 in group 0. Part 2 of the standard (ISO/IEC 10646-2) adds characters to group 0 outside the BMP in several *supplementary planes* in the range 0x10000 to 0x10ffff. There are no plans to add characters beyond 0x10ffff to the standard, therefore of the entire code space, only a small fraction of group 0 will ever be actually used in the foreseeable future. The BMP contains all characters found in the commonly used other character sets. The supplemental planes added by ISO/IEC 10646-2 cover only more exotic characters for special scientific, dictionary printing, publishing industry, higher-level protocol and enthusiast needs.

The representation of each UCS character as a 2-byte word is referred to as the UCS-2 form (only for BMP characters), whereas UCS-4 is the representation of each character by a 4-byte word. In addition, there exist two encoding forms UTF-8 for backward compatibility with ASCII processing software and UTF-16 for the backward-compatible handling of non-BMP characters up to 0x10ffff by UCS-2 software.

The UCS characters 0x0000 to 0x007f are identical to those of the classic US-ASCII character set and the characters in the range 0x0000 to 0x00ff are identical to those in ISO/IEC 8859-1 (Latin-1).

Combining characters

Some code points in UCS have been assigned to *combining characters*. These are similar to the nonspacing accent keys on a typewriter. A combining character just adds an accent to the previous character. The most important accented characters have codes of their own in UCS, however, the combining character mechanism allows us to add accents and other diacritical marks to any character. The combining characters always follow the character which they modify. For example, the German character Umlaut-A ("Latin capital letter A with diaeresis") can either be represented by the precomposed UCS code 0x00c4, or alternatively as the combination of a normal "Latin capital letter A" followed by a "combining diaeresis": 0x0041 0x0308.

Combining characters are essential for instance for encoding the Thai script or for mathematical typesetting and users of the International Phonetic Alphabet.

Implementation levels

As not all systems are expected to support advanced mechanisms like combining characters, ISO/IEC 10646-1 specifies the following three *implementation levels* of UCS:

Level 1 Combining characters and Hangul Jamo (a variant encoding of the Korean script, where a Hangul syllable glyph is coded as a triplet or pair of vowel/consonant codes) are not supported.

Level 2 In addition to level 1, combining characters are now allowed for some languages where they are essential (e.g., Thai, Lao, Hebrew, Arabic, Devanagari, Malayalam).

Level 3 All UCS characters are supported.

The Unicode 3.0 Standard published by the Unicode Consortium contains exactly the UCS Basic Multilingual Plane at implementation level 3, as described in ISO/IEC 10646-1:2000. Unicode 3.1 added the supplemental planes of ISO/IEC 10646-2. The Unicode standard and technical reports published by the Unicode Consortium provide much additional information on the semantics and recommended usages of various characters. They provide guidelines and algorithms for editing, sorting, comparing, normalizing, converting, and displaying Unicode strings.

Unicode under Linux

Under GNU/Linux, the C type *wchar_t* is a signed 32-bit integer type. Its values are always interpreted by the C library as UCS code values (in all locales), a convention that is signaled by the GNU C library to applications by defining the constant **__STDC_ISO_10646__** as specified in the ISO C99 standard.

UCS/Unicode can be used just like ASCII in input/output streams, terminal communication, plaintext files, filenames, and environment variables in the ASCII compatible UTF-8 multibyte encoding. To signal the use of UTF-8 as the character encoding to all applications, a suitable *locale* has to be selected via environment variables (e.g., "LANG=en_GB.UTF-8").

The **nl_langinfo(CODESET)** function returns the name of the selected encoding. Library functions such as *wctomb*(3) and *mbsrtowcs*(3) can be used to transform the internal *wchar_t* characters and strings into the system character encoding and back and *wcwidth*(3) tells how many positions (0–2) the cursor is advanced by the output of a character.

Private Use Areas (PUA)

In the Basic Multilingual Plane, the range 0xe000 to 0xf8ff will never be assigned to any characters by the standard and is reserved for private usage. For the Linux community, this private area has been subdivided further into the range 0xe000 to 0xefff which can be used individually by any end-user and the Linux zone in the range 0xf000 to 0xf8ff where extensions are coordinated among all Linux users. The registry of the characters assigned to the Linux zone is maintained by LANANA and the registry itself is *Documentation/admin−guide/unicode.rst* in the Linux kernel sources (or *Documentation/unicode.txt* before Linux 4.10).

Two other planes are reserved for private usage, plane 15 (Supplementary Private Use Area-A, range 0xf0000 to 0xffffd) and plane 16 (Supplementary Private Use Area-B, range 0x100000 to 0x10fffd).

NAME

units − decimal and binary prefixes

DESCRIPTION

Decimal prefixes

The SI system of units uses prefixes that indicate powers of ten. A kilometer is 1000 meter, and a megawatt is 1000000 watt. Below the standard prefixes.

Prefix	Name	Value
q	quecto	10^−30 = 0.000000000000000000000000000001
r	ronto	10^−27 = 0.000000000000000000000000001
y	yocto	10^−24 = 0.000000000000000000000001
z	zepto	10^−21 = 0.000000000000000000001
a	atto	10^−18 = 0.000000000000000001
f	femto	10^−15 = 0.000000000000001
p	pico	10^−12 = 0.000000000001
n	nano	10^−9 = 0.000000001
µ	micro	10^−6 = 0.000001
m	milli	10^−3 = 0.001
c	centi	10^−2 = 0.01
d	deci	10^−1 = 0.1
da	deka	10^ 1 = 10
h	hecto	10^ 2 = 100
k	kilo	10^ 3 = 1000
M	mega	10^ 6 = 1000000
G	giga	10^ 9 = 1000000000
T	tera	10^12 = 1000000000000
P	peta	10^15 = 1000000000000000
E	exa	10^18 = 1000000000000000000
Z	zetta	10^21 = 1000000000000000000000
Y	yotta	10^24 = 1000000000000000000000000
R	ronna	10^27 = 1000000000000000000000000000
Q	quetta	10^30 = 1000000000000000000000000000000

The symbol for micro is the Greek letter mu, often written u in an ASCII context where this Greek letter is not available.

Binary prefixes

The binary prefixes resemble the decimal ones, but have an additional 'i' (and "Ki" starts with a capital 'K'). The names are formed by taking the first syllable of the names of the decimal prefix with roughly the same size, followed by "bi" for "binary".

Prefix	Name	Value
Ki	kibi	2^10 = 1024
Mi	mebi	2^20 = 1048576
Gi	gibi	2^30 = 1073741824
Ti	tebi	2^40 = 1099511627776
Pi	pebi	2^50 = 1125899906842624
Ei	exbi	2^60 = 1152921504606846976
Zi	zebi	2^70 = 1180591620717411303424
Yi	yobi	2^80 = 1208925819614629174706176

Discussion

Before these binary prefixes were introduced, it was fairly common to use k=1000 and K=1024, just like b=bit, B=byte. Unfortunately, the M is capital already, and cannot be capitalized to indicate binary-ness.

At first that didn’t matter too much, since memory modules and disks came in sizes that were powers of two, so everyone knew that in such contexts "kilobyte" and "megabyte" meant 1024 and 1048576 bytes, respectively. What originally was a sloppy use of the prefixes "kilo" and "mega" started to become regarded as the "real true meaning" when computers were involved. But then disk technology changed, and disk sizes became arbitrary numbers. After a period of uncertainty all disk manufacturers settled on the standard, namely k=1000, M=1000 k, G=1000 M.

The situation was messy: in the 14k4 modems, k=1000; in the 1.44 MB diskettes, M=1024000; and so on. In 1998 the IEC approved the standard that defines the binary prefixes given above, enabling people to be precise and unambiguous.

Thus, today, MB = 1000000 B and MiB = 1048576 B.

In the free software world programs are slowly being changed to conform. When the Linux kernel boots and says

```
hda: 120064896 sectors (61473 MB) w/2048KiB Cache
```

the MB are megabytes and the KiB are kibibytes.

NAME

unix − sockets for local interprocess communication

SYNOPSIS

#include <sys/socket.h>
#include <sys/un.h>

unix_socket = **socket(AF_UNIX, type, 0);**
error = **socketpair(AF_UNIX, type, 0, int ****sv***);**

DESCRIPTION

The **AF_UNIX** (also known as **AF_LOCAL**) socket family is used to communicate between processes on the same machine efficiently. Traditionally, UNIX domain sockets can be either unnamed, or bound to a filesystem pathname (marked as being of type socket). Linux also supports an abstract namespace which is independent of the filesystem.

Valid socket types in the UNIX domain are: **SOCK_STREAM**, for a stream-oriented socket; **SOCK_DGRAM**, for a datagram-oriented socket that preserves message boundaries (as on most UNIX implementations, UNIX domain datagram sockets are always reliable and don't reorder datagrams); and (since Linux 2.6.4) **SOCK_SEQPACKET**, for a sequenced-packet socket that is connection-oriented, preserves message boundaries, and delivers messages in the order that they were sent.

UNIX domain sockets support passing file descriptors or process credentials to other processes using ancillary data.

Address format

A UNIX domain socket address is represented in the following structure:

```
struct sockaddr_un {
    sa_family_t sun_family;               /* AF_UNIX */
    char        sun_path[108];            /* Pathname */
};
```

The *sun_family* field always contains **AF_UNIX**. On Linux, *sun_path* is 108 bytes in size; see also BUGS, below.

Various system calls (for example, *bind*(2), *connect*(2), and *sendto*(2)) take a *sockaddr_un* argument as input. Some other system calls (for example, *getsockname*(2), *getpeername*(2), *recvfrom*(2), and *accept*(2)) return an argument of this type.

Three types of address are distinguished in the *sockaddr_un* structure:

pathname
: a UNIX domain socket can be bound to a null-terminated filesystem pathname using *bind*(2). When the address of a pathname socket is returned (by one of the system calls noted above), its length is

  ```
  offsetof(struct sockaddr_un, sun_path) + strlen(sun_path) + 1
  ```

  and *sun_path* contains the null-terminated pathname. (On Linux, the above **offsetof**() expression equates to the same value as *sizeof(sa_family_t)*, but some other implementations include other fields before *sun_path*, so the **offsetof**() expression more portably describes the size of the address structure.)

  For further details of pathname sockets, see below.

unnamed
: A stream socket that has not been bound to a pathname using *bind*(2) has no name. Likewise, the two sockets created by *socketpair*(2) are unnamed. When the address of an unnamed socket is returned, its length is *sizeof(sa_family_t)*, and *sun_path* should not be inspected.

abstract
: an abstract socket address is distinguished (from a pathname socket) by the fact that *sun_path[0]* is a null byte ('\0'). The socket's address in this namespace is given by the additional bytes in *sun_path* that are covered by the specified length of the address structure. (Null bytes in the name have no special significance.) The name has no connection with filesystem pathnames. When the address of an abstract socket is returned, the returned *addrlen* is greater than *sizeof(sa_family_t)* (i.e., greater than 2), and the name of the socket is

contained in the first *(addrlen − sizeof(sa_family_t))* bytes of *sun_path*.

Pathname sockets

When binding a socket to a pathname, a few rules should be observed for maximum portability and ease of coding:

- The pathname in *sun_path* should be null-terminated.
- The length of the pathname, including the terminating null byte, should not exceed the size of *sun_path*.
- The *addrlen* argument that describes the enclosing *sockaddr_un* structure should have a value of at least:

```
offsetof(struct sockaddr_un, sun_path)+strlen(addr.sun_path)+1
```

  or, more simply, *addrlen* can be specified as *sizeof(struct sockaddr_un)*.

There is some variation in how implementations handle UNIX domain socket addresses that do not follow the above rules. For example, some (but not all) implementations append a null terminator if none is present in the supplied *sun_path*.

When coding portable applications, keep in mind that some implementations have *sun_path* as short as 92 bytes.

Various system calls (**accept**(2), *recvfrom*(2), *getsockname*(2), *getpeername*(2)) return socket address structures. When applied to UNIX domain sockets, the value-result *addrlen* argument supplied to the call should be initialized as above. Upon return, the argument is set to indicate the *actual* size of the address structure. The caller should check the value returned in this argument: if the output value exceeds the input value, then there is no guarantee that a null terminator is present in *sun_path*. (See BUGS.)

Pathname socket ownership and permissions

In the Linux implementation, pathname sockets honor the permissions of the directory they are in. Creation of a new socket fails if the process does not have write and search (execute) permission on the directory in which the socket is created.

On Linux, connecting to a stream socket object requires write permission on that socket; sending a datagram to a datagram socket likewise requires write permission on that socket. POSIX does not make any statement about the effect of the permissions on a socket file, and on some systems (e.g., older BSDs), the socket permissions are ignored. Portable programs should not rely on this feature for security.

When creating a new socket, the owner and group of the socket file are set according to the usual rules. The socket file has all permissions enabled, other than those that are turned off by the process *umask*(2).

The owner, group, and permissions of a pathname socket can be changed (using *chown*(2) and *chmod*(2)).

Abstract sockets

Socket permissions have no meaning for abstract sockets: the process *umask*(2) has no effect when binding an abstract socket, and changing the ownership and permissions of the object (via *fchown*(2) and *fchmod*(2)) has no effect on the accessibility of the socket.

Abstract sockets automatically disappear when all open references to the socket are closed.

The abstract socket namespace is a nonportable Linux extension.

Socket options

For historical reasons, these socket options are specified with a **SOL_SOCKET** type even though they are **AF_UNIX** specific. They can be set with *setsockopt*(2) and read with *getsockopt*(2) by specifying **SOL_SOCKET** as the socket family.

SO_PASSCRED

Enabling this socket option causes receipt of the credentials of the sending process in an **SCM_CREDENTIALS ancillary** message in each subsequently received message. The returned credentials are those specified by the sender using **SCM_CREDENTIALS**, or a default that includes the sender's PID, real user ID, and real group ID, if the sender did not

specify **SCM_CREDENTIALS** ancillary data.

When this option is set and the socket is not yet connected, a unique name in the abstract namespace will be generated automatically.

The value given as an argument to *setsockopt*(2) and returned as the result of *getsockopt*(2) is an integer boolean flag.

SO_PASSSEC
Enables receiving of the SELinux security label of the peer socket in an ancillary message of type **SCM_SECURITY** (see below).

The value given as an argument to *setsockopt*(2) and returned as the result of *getsockopt*(2) is an integer boolean flag.

The **SO_PASSSEC** option is supported for UNIX domain datagram sockets since Linux 2.6.18; support for UNIX domain stream sockets was added in Linux 4.2.

SO_PEEK_OFF
See *socket*(7).

SO_PEERCRED
This read-only socket option returns the credentials of the peer process connected to this socket. The returned credentials are those that were in effect at the time of the call to *connect*(2), *listen*(2), or *socketpair*(2).

The argument to *getsockopt*(2) is a pointer to a *ucred* structure; define the **_GNU_SOURCE** feature test macro to obtain the definition of that structure from <*sys/socket.h*>.

The use of this option is possible only for connected **AF_UNIX** stream sockets and for **AF_UNIX** stream and datagram socket pairs created using *socketpair*(2).

SO_PEERSEC
This read-only socket option returns the security context of the peer socket connected to this socket. By default, this will be the same as the security context of the process that created the peer socket unless overridden by the policy or by a process with the required permissions.

The argument to *getsockopt*(2) is a pointer to a buffer of the specified length in bytes into which the security context string will be copied. If the buffer length is less than the length of the security context string, then *getsockopt*(2) returns −1, sets *errno* to **ERANGE**, and returns the required length via *optlen*. The caller should allocate at least **NAME_MAX** bytes for the buffer initially, although this is not guaranteed to be sufficient. Resizing the buffer to the returned length and retrying may be necessary.

The security context string may include a terminating null character in the returned length, but is not guaranteed to do so: a security context "foo" might be represented as either {'f','o','o'} of length 3 or {'f','o','o','\0'} of length 4, which are considered to be interchangeable. The string is printable, does not contain non-terminating null characters, and is in an unspecified encoding (in particular, it is not guaranteed to be ASCII or UTF-8).

The use of this option for sockets in the **AF_UNIX** address family is supported since Linux 2.6.2 for connected stream sockets, and since Linux 4.18 also for stream and datagram socket pairs created using *socketpair*(2).

Autobind feature
If a *bind*(2) call specifies *addrlen* as *sizeof(sa_family_t)*, or the **SO_PASSCRED** socket option was specified for a socket that was not explicitly bound to an address, then the socket is autobound to an abstract address. The address consists of a null byte followed by 5 bytes in the character set *[0−9a−f]*. Thus, there is a limit of 2^20 autobind addresses. (From Linux 2.1.15, when the autobind feature was added, 8 bytes were used, and the limit was thus 2^32 autobind addresses. The change to 5 bytes came in Linux 2.3.15.)

Sockets API
The following paragraphs describe domain-specific details and unsupported features of the sockets API for UNIX domain sockets on Linux.

UNIX domain sockets do not support the transmission of out-of-band data (the **MSG_OOB** flag for *send*(2) and *recv*(2)).

The *send*(2) **MSG_MORE** flag is not supported by UNIX domain sockets.

Before Linux 3.4, the use of **MSG_TRUNC** in the *flags* argument of *recv*(2) was not supported by UNIX domain sockets.

The **SO_SNDBUF** socket option does have an effect for UNIX domain sockets, but the **SO_RCVBUF** option does not. For datagram sockets, the **SO_SNDBUF** value imposes an upper limit on the size of outgoing datagrams. This limit is calculated as the doubled (see *socket*(7)) option value less 32 bytes used for overhead.

Ancillary messages

Ancillary data is sent and received using *sendmsg*(2) and *recvmsg*(2). For historical reasons, the ancillary message types listed below are specified with a **SOL_SOCKET** type even though they are **AF_UNIX** specific. To send them, set the *cmsg_level* field of the struct *cmsghdr* to **SOL_SOCKET** and the *cmsg_type* field to the type. For more information, see *cmsg*(3).

SCM_RIGHTS

Send or receive a set of open file descriptors from another process. The data portion contains an integer array of the file descriptors.

Commonly, this operation is referred to as "passing a file descriptor" to another process. However, more accurately, what is being passed is a reference to an open file description (see *open*(2)), and in the receiving process it is likely that a different file descriptor number will be used. Semantically, this operation is equivalent to duplicating (**dup**(2)) a file descriptor into the file descriptor table of another process.

If the buffer used to receive the ancillary data containing file descriptors is too small (or is absent), then the ancillary data is truncated (or discarded) and the excess file descriptors are automatically closed in the receiving process.

If the number of file descriptors received in the ancillary data would cause the process to exceed its **RLIMIT_NOFILE** resource limit (see *getrlimit*(2)), the excess file descriptors are automatically closed in the receiving process.

The kernel constant **SCM_MAX_FD** defines a limit on the number of file descriptors in the array. Attempting to send an array larger than this limit causes *sendmsg*(2) to fail with the error **EINVAL**. **SCM_MAX_FD** has the value 253 (or 255 before Linux 2.6.38).

SCM_CREDENTIALS

Send or receive UNIX credentials. This can be used for authentication. The credentials are passed as a *struct ucred* ancillary message. This structure is defined in *<sys/socket.h>* as follows:

```
struct ucred {
    pid_t pid;    /* Process ID of the sending process */
    uid_t uid;    /* User ID of the sending process */
    gid_t gid;    /* Group ID of the sending process */
};
```

Since glibc 2.8, the **_GNU_SOURCE** feature test macro must be defined (before including *any* header files) in order to obtain the definition of this structure.

The credentials which the sender specifies are checked by the kernel. A privileged process is allowed to specify values that do not match its own. The sender must specify its own process ID (unless it has the capability **CAP_SYS_ADMIN**, in which case the PID of any existing process may be specified), its real user ID, effective user ID, or saved set-user-ID (unless it has **CAP_SETUID**), and its real group ID, effective group ID, or saved set-group-ID (unless it has **CAP_SETGID**).

To receive a *struct ucred* message, the **SO_PASSCRED** option must be enabled on the socket.

SCM_SECURITY

Receive the SELinux security context (the security label) of the peer socket. The received ancillary data is a null-terminated string containing the security context. The receiver should allocate at least **NAME_MAX** bytes in the data portion of the ancillary message for this data.

To receive the security context, the **SO_PASSSEC** option must be enabled on the socket (see above).

When sending ancillary data with *sendmsg*(2), only one item of each of the above types may be included in the sent message.

At least one byte of real data should be sent when sending ancillary data. On Linux, this is required to successfully send ancillary data over a UNIX domain stream socket. When sending ancillary data over a UNIX domain datagram socket, it is not necessary on Linux to send any accompanying real data. However, portable applications should also include at least one byte of real data when sending ancillary data over a datagram socket.

When receiving from a stream socket, ancillary data forms a kind of barrier for the received data. For example, suppose that the sender transmits as follows:

(1) *sendmsg*(2) of four bytes, with no ancillary data.
(2) *sendmsg*(2) of one byte, with ancillary data.
(3) *sendmsg*(2) of four bytes, with no ancillary data.

Suppose that the receiver now performs *recvmsg*(2) calls each with a buffer size of 20 bytes. The first call will receive five bytes of data, along with the ancillary data sent by the second *sendmsg*(2) call. The next call will receive the remaining four bytes of data.

If the space allocated for receiving incoming ancillary data is too small then the ancillary data is truncated to the number of headers that will fit in the supplied buffer (or, in the case of an **SCM_RIGHTS** file descriptor list, the list of file descriptors may be truncated). If no buffer is provided for incoming ancillary data (i.e., the *msg_control* field of the *msghdr* structure supplied to *recvmsg*(2) is NULL), then the incoming ancillary data is discarded. In both of these cases, the **MSG_CTRUNC** flag will be set in the *msg.msg_flags* value returned by *recvmsg*(2).

Ioctls

The following *ioctl*(2) calls return information in *value*. The correct syntax is:

int *value***;**
error **= ioctl(***unix_socket***,** *ioctl_type***, &***value***);**

ioctl_type can be:

SIOCINQ
For **SOCK_STREAM** sockets, this call returns the number of unread bytes in the receive buffer. The socket must not be in LISTEN state, otherwise an error (**EINVAL**) is returned. **SIOCINQ** is defined in <*linux/sockios.h*>. Alternatively, you can use the synonymous **FIONREAD**, defined in <*sys/ioctl.h*>. For **SOCK_DGRAM** sockets, the returned value is the same as for Internet domain datagram sockets; see *udp*(7).

ERRORS

EADDRINUSE
The specified local address is already in use or the filesystem socket object already exists.

EBADF
This error can occur for *sendmsg*(2) when sending a file descriptor as ancillary data over a UNIX domain socket (see the description of **SCM_RIGHTS**, above), and indicates that the file descriptor number that is being sent is not valid (e.g., it is not an open file descriptor).

ECONNREFUSED
The remote address specified by *connect*(2) was not a listening socket. This error can also occur if the target pathname is not a socket.

ECONNRESET
Remote socket was unexpectedly closed.

EFAULT
User memory address was not valid.

EINVAL
Invalid argument passed. A common cause is that the value **AF_UNIX** was not specified in the *sun_type* field of passed addresses, or the socket was in an invalid state for the applied operation.

EISCONN
connect(2) called on an already connected socket or a target address was specified on a connected socket.

ENFILE
The system-wide limit on the total number of open files has been reached.

ENOENT
The pathname in the remote address specified to *connect*(2) did not exist.

ENOMEM
Out of memory.

ENOTCONN
Socket operation needs a target address, but the socket is not connected.

EOPNOTSUPP
Stream operation called on non-stream oriented socket or tried to use the out-of-band data option.

EPERM
The sender passed invalid credentials in the *struct ucred*.

EPIPE Remote socket was closed on a stream socket. If enabled, a **SIGPIPE** is sent as well. This can be avoided by passing the **MSG_NOSIGNAL** flag to *send*(2) or *sendmsg*(2).

EPROTONOSUPPORT
Passed protocol is not **AF_UNIX**.

EPROTOTYPE
Remote socket does not match the local socket type (**SOCK_DGRAM** versus **SOCK_STREAM**).

ESOCKTNOSUPPORT
Unknown socket type.

ESRCH
While sending an ancillary message containing credentials (**SCM_CREDENTIALS**), the caller specified a PID that does not match any existing process.

ETOOMANYREFS
This error can occur for *sendmsg*(2) when sending a file descriptor as ancillary data over a UNIX domain socket (see the description of **SCM_RIGHTS**, above). It occurs if the number of "in-flight" file descriptors exceeds the **RLIMIT_NOFILE** resource limit and the caller does not have the **CAP_SYS_RESOURCE** capability. An in-flight file descriptor is one that has been sent using *sendmsg*(2) but has not yet been accepted in the recipient process using *recvmsg*(2).

This error is diagnosed since mainline Linux 4.5 (and in some earlier kernel versions where the fix has been backported). In earlier kernel versions, it was possible to place an unlimited number of file descriptors in flight, by sending each file descriptor with *sendmsg*(2) and then closing the file descriptor so that it was not accounted against the **RLIMIT_NOFILE** resource limit.

Other errors can be generated by the generic socket layer or by the filesystem while generating a filesystem socket object. See the appropriate manual pages for more information.

VERSIONS

SCM_CREDENTIALS and the abstract namespace were introduced with Linux 2.2 and should not be used in portable programs. (Some BSD-derived systems also support credential passing, but the implementation details differ.)

NOTES

Binding to a socket with a filename creates a socket in the filesystem that must be deleted by the caller when it is no longer needed (using *unlink*(2)). The usual UNIX close-behind semantics apply; the socket can be unlinked at any time and will be finally removed from the filesystem when the last reference to it is closed.

To pass file descriptors or credentials over a **SOCK_STREAM** socket, you must send or receive at

least one byte of nonancillary data in the same *sendmsg*(2) or *recvmsg*(2) call.

UNIX domain stream sockets do not support the notion of out-of-band data.

BUGS

When binding a socket to an address, Linux is one of the implementations that append a null terminator if none is supplied in *sun_path*. In most cases this is unproblematic: when the socket address is retrieved, it will be one byte longer than that supplied when the socket was bound. However, there is one case where confusing behavior can result: if 108 non-null bytes are supplied when a socket is bound, then the addition of the null terminator takes the length of the pathname beyond *sizeof(sun_path)*. Consequently, when retrieving the socket address (for example, via *accept*(2)), if the input *addrlen* argument for the retrieving call is specified as *sizeof(struct sockaddr_un)*, then the returned address structure *won't* have a null terminator in *sun_path*.

In addition, some implementations don't require a null terminator when binding a socket (the *addrlen* argument is used to determine the length of *sun_path*) and when the socket address is retrieved on these implementations, there is no null terminator in *sun_path*.

Applications that retrieve socket addresses can (portably) code to handle the possibility that there is no null terminator in *sun_path* by respecting the fact that the number of valid bytes in the pathname is:

```
strnlen(addr.sun_path, addrlen - offsetof(sockaddr_un, sun_path))
```

Alternatively, an application can retrieve the socket address by allocating a buffer of size *sizeof(struct sockaddr_un)+1* that is zeroed out before the retrieval. The retrieving call can specify *addrlen* as *sizeof(struct sockaddr_un)*, and the extra zero byte ensures that there will be a null terminator for the string returned in *sun_path*:

```
void *addrp;

addrlen = sizeof(struct sockaddr_un);
addrp = malloc(addrlen + 1);
if (addrp == NULL)
    /* Handle error */ ;
memset(addrp, 0, addrlen + 1);

if (getsockname(sfd, (struct sockaddr *) addrp, &addrlen)) == -1)
    /* handle error */ ;

printf("sun_path = %s\n", ((struct sockaddr_un *) addrp)->sun_path);
```

This sort of messiness can be avoided if it is guaranteed that the applications that *create* pathname sockets follow the rules outlined above under *Pathname sockets*.

EXAMPLES

The following code demonstrates the use of sequenced-packet sockets for local interprocess communication. It consists of two programs. The server program waits for a connection from the client program. The client sends each of its command-line arguments in separate messages. The server treats the incoming messages as integers and adds them up. The client sends the command string "END". The server sends back a message containing the sum of the client's integers. The client prints the sum and exits. The server waits for the next client to connect. To stop the server, the client is called with the command-line argument "DOWN".

The following output was recorded while running the server in the background and repeatedly executing the client. Execution of the server program ends when it receives the "DOWN" command.

Example output

```
$ ./server &
[1] 25887
$ ./client 3 4
Result = 7
$ ./client 11 -5
Result = 6
$ ./client DOWN
Result = 0
```

```
[1]+  Done                    ./server
$
```

NAME

uri, url, urn − uniform resource identifier (URI), including a URL or URN

SYNOPSIS

URI = [*absoluteURI* | *relativeURI*] ["**#**" *fragment*]

absoluteURI = *scheme* "**:**" (*hierarchical_part* | *opaque_part*)

relativeURI = (*net_path* | *absolute_path* | *relative_path*) ["**?**" *query*]

scheme = "**http**" | "**ftp**" | "**gopher**" | "**mailto**" | "**news**" | "**telnet**" | "**file**" | "**ftp**" | "**man**" | "**info**" | "**whatis**" | "**ldap**" | "**wais**" | ...

hierarchical_part = (*net_path* | *absolute_path*) ["**?**" *query*]

net_path = "//" *authority* [*absolute_path*]

absolute_path = "/" *path_segments*

relative_path = *relative_segment* [*absolute_path*]

DESCRIPTION

A Uniform Resource Identifier (URI) is a short string of characters identifying an abstract or physical resource (for example, a web page). A Uniform Resource Locator (URL) is a URI that identifies a resource through its primary access mechanism (e.g., its network "location"), rather than by name or some other attribute of that resource. A Uniform Resource Name (URN) is a URI that must remain globally unique and persistent even when the resource ceases to exist or becomes unavailable.

URIs are the standard way to name hypertext link destinations for tools such as web browsers. The string "http://www.kernel.org" is a URL (and thus it is also a URI). Many people use the term URL loosely as a synonym for URI (though technically URLs are a subset of URIs).

URIs can be absolute or relative. An absolute identifier refers to a resource independent of context, while a relative identifier refers to a resource by describing the difference from the current context. Within a relative path reference, the complete path segments "." and ".." have special meanings: "the current hierarchy level" and "the level above this hierarchy level", respectively, just like they do in UNIX-like systems. A path segment which contains a colon character can't be used as the first segment of a relative URI path (e.g., "this:that"), because it would be mistaken for a scheme name; precede such segments with ./ (e.g., "./this:that"). Note that descendants of MS-DOS (e.g., Microsoft Windows) replace devicename colons with the vertical bar ("|") in URIs, so "C:" becomes "C|".

A fragment identifier, if included, refers to a particular named portion (fragment) of a resource; text after a '#' identifies the fragment. A URI beginning with '#' refers to that fragment in the current resource.

Usage

There are many different URI schemes, each with specific additional rules and meanings, but they are intentionally made to be as similar as possible. For example, many URL schemes permit the authority to be the following format, called here an *ip_server* (square brackets show what's optional):

ip_server = [*user* [: *password*] @] *host* [: *port*]

This format allows you to optionally insert a username, a user plus password, and/or a port number. The *host* is the name of the host computer, either its name as determined by DNS or an IP address (numbers separated by periods). Thus the URI <http://fred:fredpassword@example.com:8080/> logs into a web server on host example.com as fred (using fredpassword) using port 8080. Avoid including a password in a URI if possible because of the many security risks of having a password written down. If the URL supplies a username but no password, and the remote server requests a password, the program interpreting the URL should request one from the user.

Here are some of the most common schemes in use on UNIX-like systems that are understood by many tools. Note that many tools using URIs also have internal schemes or specialized schemes; see those tools' documentation for information on those schemes.

http − Web (HTTP) server

http://*ip_server*/*path*
http://*ip_server*/*path*?*query*

This is a URL accessing a web (HTTP) server. The default port is 80. If the path refers to a directory,

the web server will choose what to return; usually if there is a file named "index.html" or "index.htm" its content is returned, otherwise, a list of the files in the current directory (with appropriate links) is generated and returned. An example is <http://lwn.net>.

A query can be given in the archaic "isindex" format, consisting of a word or phrase and not including an equal sign (=). A query can also be in the longer "GET" format, which has one or more query entries of the form *key=value* separated by the ampersand character (&). Note that *key* can be repeated more than once, though it's up to the web server and its application programs to determine if there's any meaning to that. There is an unfortunate interaction with HTML/XML/SGML and the GET query format; when such URIs with more than one key are embedded in SGML/XML documents (including HTML), the ampersand (&) has to be rewritten as &. Note that not all queries use this format; larger forms may be too long to store as a URI, so they use a different interaction mechanism (called POST) which does not include the data in the URI. See the Common Gateway Interface specification at for more information.

ftp − File Transfer Protocol (FTP)

ftp://*ip_server*/*path*

This is a URL accessing a file through the file transfer protocol (FTP). The default port (for control) is 21. If no username is included, the username "anonymous" is supplied, and in that case many clients provide as the password the requestor's Internet email address. An example is <ftp://ftp.is.co.za/rfc/rfc1808.txt>.

gopher − Gopher server

gopher://*ip_server*/*gophertype selector*
gopher://*ip_server*/*gophertype selector*%09*search*
gopher://*ip_server*/*gophertype selector*%09*search*%09*gopher+_string*

The default gopher port is 70. *gophertype* is a single-character field to denote the Gopher type of the resource to which the URL refers. The entire path may also be empty, in which case the delimiting "/" is also optional and the gophertype defaults to "1".

selector is the Gopher selector string. In the Gopher protocol, Gopher selector strings are a sequence of octets which may contain any octets except 09 hexadecimal (US-ASCII HT or tab), 0A hexadecimal (US-ASCII character LF), and 0D (US-ASCII character CR).

mailto − Email address

mailto:*email-address*

This is an email address, usually of the form *name@hostname*. See *mailaddr*(7) for more information on the correct format of an email address. Note that any % character must be rewritten as %25. An example is <mailto:dwheeler@dwheeler.com>.

news − Newsgroup or News message

news:*newsgroup-name*
news:*message-id*

A *newsgroup-name* is a period-delimited hierarchical name, such as "comp.infosystems.www.misc". If <newsgroup-name> is "*" (as in <news:*>), it is used to refer to "all available news groups". An example is <news:comp.lang.ada>.

A *message-id* corresponds to the Message-ID of IETF RFC 1036, without the enclosing "<" and ">"; it takes the form *unique@ full_domain_name*. A message identifier may be distinguished from a news group name by the presence of the "@" character.

telnet − Telnet login

telnet://*ip_server*/

The Telnet URL scheme is used to designate interactive text services that may be accessed by the Telnet protocol. The final "/" character may be omitted. The default port is 23. An example is <telnet://melvyl.ucop.edu/>.

file − Normal file

file://*ip_server*/*path_segments*
file:*path_segments*

This represents a file or directory accessible locally. As a special case, *ip_server* can be the string "localhost" or the empty string; this is interpreted as "the machine from which the URL is being interpreted". If the path is to a directory, the viewer should display the directory's contents with links to each containee; not all viewers currently do this. KDE supports generated files through the URL <file:/cgi-bin>. If the given file isn't found, browser writers may want to try to expand the filename via filename globbing (see *glob*(7) and *glob*(3)).

The second format (e.g., <file:/etc/passwd>) is a correct format for referring to a local file. However, older standards did not permit this format, and some programs don't recognize this as a URI. A more portable syntax is to use an empty string as the server name, for example, <file:///etc/passwd>; this form does the same thing and is easily recognized by pattern matchers and older programs as a URI. Note that if you really mean to say "start from the current location", don't specify the scheme at all; use a relative address like <../test.txt>, which has the side-effect of being scheme-independent. An example of this scheme is <file:///etc/passwd>.

man − Man page documentation

man:*command-name*
man:*command-name*(*section*)

This refers to local online manual (man) reference pages. The command name can optionally be followed by a parenthesis and section number; see *man*(7) for more information on the meaning of the section numbers. This URI scheme is unique to UNIX-like systems (such as Linux) and is not currently registered by the IETF. An example is <man:ls(1)>.

info − Info page documentation

info:*virtual-filename*
info:*virtual-filename#nodename*
info:(*virtual-filename*)
info:(*virtual-filename*)*nodename*

This scheme refers to online info reference pages (generated from texinfo files), a documentation format used by programs such as the GNU tools. This URI scheme is unique to UNIX-like systems (such as Linux) and is not currently registered by the IETF. As of this writing, GNOME and KDE differ in their URI syntax and do not accept the other's syntax. The first two formats are the GNOME format; in nodenames all spaces are written as underscores. The second two formats are the KDE format; spaces in nodenames must be written as spaces, even though this is forbidden by the URI standards. It's hoped that in the future most tools will understand all of these formats and will always accept underscores for spaces in nodenames. In both GNOME and KDE, if the form without the nodename is used the nodename is assumed to be "Top". Examples of the GNOME format are <info:gcc> and <info:gcc#G++_and_GCC>. Examples of the KDE format are <info:(gcc)> and <info:(gcc)G++ and GCC>.

whatis − Documentation search

whatis:*string*

This scheme searches the database of short (one-line) descriptions of commands and returns a list of descriptions containing that string. Only complete word matches are returned. See *whatis*(1)This URI scheme is unique to UNIX-like systems (such as Linux) and is not currently registered by the IETF.

ghelp − GNOME help documentation

ghelp:*name-of-application*

This loads GNOME help for the given application. Note that not much documentation currently exists in this format.

ldap − Lightweight Directory Access Protocol

ldap://*hostport*
ldap://*hostport*/
ldap://*hostport*/*dn*
ldap://*hostport*/*dn*?*attributes*
ldap://*hostport*/*dn*?*attributes*?*scope*
ldap://*hostport*/*dn*?*attributes*?*scope*?*filter*
ldap://*hostport*/*dn*?*attributes*?*scope*?*filter*?*extensions*

This scheme supports queries to the Lightweight Directory Access Protocol (LDAP), a protocol for querying a set of servers for hierarchically organized information (such as people and computing resources). See RFC 2255 for more information on the LDAP URL scheme. The components of this URL are:

hostport
: the LDAP server to query, written as a hostname optionally followed by a colon and the port number. The default LDAP port is TCP port 389. If empty, the client determines which the LDAP server to use.

dn
: the LDAP Distinguished Name, which identifies the base object of the LDAP search (see RFC 2253 section 3).

attributes
: a comma-separated list of attributes to be returned; see RFC 2251 section 4.1.5. If omitted, all attributes should be returned.

scope
: specifies the scope of the search, which can be one of "base" (for a base object search), "one" (for a one-level search), or "sub" (for a subtree search). If scope is omitted, "base" is assumed.

filter
: specifies the search filter (subset of entries to return). If omitted, all entries should be returned. See RFC 2254 section 4.

extensions
: a comma-separated list of type=value pairs, where the =value portion may be omitted for options not requiring it. An extension prefixed with a '!' is critical (must be supported to be valid), otherwise it is noncritical (optional).

LDAP queries are easiest to explain by example. Here's a query that asks ldap.itd.umich.edu for information about the University of Michigan in the U.S.:

ldap://ldap.itd.umich.edu/o=University%20of%20Michigan,c=US

To just get its postal address attribute, request:

ldap://ldap.itd.umich.edu/o=University%20of%20Michigan,c=US?postalAddress

To ask a host.com at port 6666 for information about the person with common name (cn) "Babs Jensen" at University of Michigan, request:

ldap://host.com:6666/o=University%20of%20Michigan,c=US??sub?(cn=Babs%20Jensen)

wais − Wide Area Information Servers

wais://*hostport*/*database*
wais://*hostport*/*database*?*search*
wais://*hostport*/*database*/*wtype*/*wpath*

This scheme designates a WAIS database, search, or document (see IETF RFC 1625 for more information on WAIS). Hostport is the hostname, optionally followed by a colon and port number (the default port number is 210).

The first form designates a WAIS database for searching. The second form designates a particular search of the WAIS database *database*. The third form designates a particular document within a WAIS database to be retrieved. *wtype* is the WAIS designation of the type of the object and *wpath* is the WAIS document-id.

other schemes

There are many other URI schemes. Most tools that accept URIs support a set of internal URIs (e.g., Mozilla has the about: scheme for internal information, and the GNOME help browser has the toc: scheme for various starting locations). There are many schemes that have been defined but are not as widely used at the current time (e.g., prospero). The nntp: scheme is deprecated in favor of the news: scheme. URNs are to be supported by the urn: scheme, with a hierarchical name space (e.g., urn:ietf:... would identify IETF documents); at this time URNs are not widely implemented. Not all tools support all schemes.

Character encoding

URIs use a limited number of characters so that they can be typed in and used in a variety of situations.

The following characters are reserved, that is, they may appear in a URI but their use is limited to their

reserved purpose (conflicting data must be escaped before forming the URI):

```
; / ? : @ & = + $ ,
```

Unreserved characters may be included in a URI. Unreserved characters include uppercase and lowercase Latin letters, decimal digits, and the following limited set of punctuation marks and symbols:

```
- _ . ! ~ * ' ( )
```

All other characters must be escaped. An escaped octet is encoded as a character triplet, consisting of the percent character "%" followed by the two hexadecimal digits representing the octet code (you can use uppercase or lowercase letters for the hexadecimal digits). For example, a blank space must be escaped as "%20", a tab character as "%09", and the "&" as "%26". Because the percent "%" character always has the reserved purpose of being the escape indicator, it must be escaped as "%25". It is common practice to escape space characters as the plus symbol (+) in query text; this practice isn't uniformly defined in the relevant RFCs (which recommend %20 instead) but any tool accepting URIs with query text should be prepared for them. A URI is always shown in its "escaped" form.

Unreserved characters can be escaped without changing the semantics of the URI, but this should not be done unless the URI is being used in a context that does not allow the unescaped character to appear. For example, "%7e" is sometimes used instead of "~" in an HTTP URL path, but the two are equivalent for an HTTP URL.

For URIs which must handle characters outside the US ASCII character set, the HTML 4.01 specification (section B.2) and IETF RFC 3986 (last paragraph of section 2.5) recommend the following approach:

(1) translate the character sequences into UTF-8 (IETF RFC 3629)—see *utf-8*(7)—and then

(2) use the URI escaping mechanism, that is, use the %HH encoding for unsafe octets.

Writing a URI

When written, URIs should be placed inside double quotes (e.g., "http://www.kernel.org"), enclosed in angle brackets (e.g., <http://lwn.net>), or placed on a line by themselves. A warning for those who use double-quotes: **never** move extraneous punctuation (such as the period ending a sentence or the comma in a list) inside a URI, since this will change the value of the URI. Instead, use angle brackets instead, or switch to a quoting system that never includes extraneous characters inside quotation marks. This latter system, called the 'new' or 'logical' quoting system by "Hart's Rules" and the "Oxford Dictionary for Writers and Editors", is preferred practice in Great Britain and in various European languages. Older documents suggested inserting the prefix "URL:" just before the URI, but this form has never caught on.

The URI syntax was designed to be unambiguous. However, as URIs have become commonplace, traditional media (television, radio, newspapers, billboards, etc.) have increasingly used abbreviated URI references consisting of only the authority and path portions of the identified resource (e.g., <www.w3.org/Addressing>). Such references are primarily intended for human interpretation rather than machine, with the assumption that context-based heuristics are sufficient to complete the URI (e.g., hostnames beginning with "www" are likely to have a URI prefix of "http://" and hostnames beginning with "ftp" likely to have a prefix of "ftp://"). Many client implementations heuristically resolve these references. Such heuristics may change over time, particularly when new schemes are introduced. Since an abbreviated URI has the same syntax as a relative URL path, abbreviated URI references cannot be used where relative URIs are permitted, and can be used only when there is no defined base (such as in dialog boxes). Don't use abbreviated URIs as hypertext links inside a document; use the standard format as described here.

STANDARDS

(IETF RFC 2396), (HTML 4.0).

NOTES

Any tool accepting URIs (e.g., a web browser) on a Linux system should be able to handle (directly or indirectly) all of the schemes described here, including the man: and info: schemes. Handling them by invoking some other program is fine and in fact encouraged.

Technically the fragment isn't part of the URI.

For information on how to embed URIs (including URLs) in a data format, see documentation on that format. HTML uses the format <A HREF="*uri*"> *text* </A>. Texinfo files use the format @uref{*uri*}.

Man and mdoc have the recently added UR macro, or just include the URI in the text (viewers should be able to detect :// as part of a URI).

The GNOME and KDE desktop environments currently vary in the URIs they accept, in particular in their respective help browsers. To list man pages, GNOME uses <toc:man> while KDE uses <man:(index)>, and to list info pages, GNOME uses <toc:info> while KDE uses <info:(dir)> (the author of this man page prefers the KDE approach here, though a more regular format would be even better). In general, KDE uses <file:/cgi-bin/> as a prefix to a set of generated files. KDE prefers documentation in HTML, accessed via the <file:/cgi-bin/helpindex>. GNOME prefers the ghelp scheme to store and find documentation. Neither browser handles file: references to directories at the time of this writing, making it difficult to refer to an entire directory with a browsable URI. As noted above, these environments differ in how they handle the info: scheme, probably the most important variation. It is expected that GNOME and KDE will converge to common URI formats, and a future version of this man page will describe the converged result. Efforts to aid this convergence are encouraged.

Security

A URI does not in itself pose a security threat. There is no general guarantee that a URL, which at one time located a given resource, will continue to do so. Nor is there any guarantee that a URL will not locate a different resource at some later point in time; such a guarantee can be obtained only from the person(s) controlling that namespace and the resource in question.

It is sometimes possible to construct a URL such that an attempt to perform a seemingly harmless operation, such as the retrieval of an entity associated with the resource, will in fact cause a possibly damaging remote operation to occur. The unsafe URL is typically constructed by specifying a port number other than that reserved for the network protocol in question. The client unwittingly contacts a site that is in fact running a different protocol. The content of the URL contains instructions that, when interpreted according to this other protocol, cause an unexpected operation. An example has been the use of a gopher URL to cause an unintended or impersonating message to be sent via a SMTP server.

Caution should be used when using any URL that specifies a port number other than the default for the protocol, especially when it is a number within the reserved space.

Care should be taken when a URI contains escaped delimiters for a given protocol (for example, CR and LF characters for telnet protocols) that these are not unescaped before transmission. This might violate the protocol, but avoids the potential for such characters to be used to simulate an extra operation or parameter in that protocol, which might lead to an unexpected and possibly harmful remote operation to be performed.

It is clearly unwise to use a URI that contains a password which is intended to be secret. In particular, the use of a password within the "userinfo" component of a URI is strongly recommended against except in those rare cases where the "password" parameter is intended to be public.

BUGS

Documentation may be placed in a variety of locations, so there currently isn't a good URI scheme for general online documentation in arbitrary formats. References of the form <file:///usr/doc/ZZZ> don't work because different distributions and local installation requirements may place the files in different directories (it may be in /usr/doc, or /usr/local/doc, or /usr/share, or somewhere else). Also, the directory ZZZ usually changes when a version changes (though filename globbing could partially overcome this). Finally, using the file: scheme doesn't easily support people who dynamically load documentation from the Internet (instead of loading the files onto a local filesystem). A future URI scheme may be added (e.g., "userdoc:") to permit programs to include cross-references to more detailed documentation without having to know the exact location of that documentation. Alternatively, a future version of the filesystem specification may specify file locations sufficiently so that the file: scheme will be able to locate documentation.

Many programs and file formats don't include a way to incorporate or implement links using URIs.

Many programs can't handle all of these different URI formats; there should be a standard mechanism to load an arbitrary URI that automatically detects the users' environment (e.g., text or graphics, desktop environment, local user preferences, and currently executing tools) and invokes the right tool for any URI.

IETF RFC 2255

NAME

user-keyring − per-user keyring

DESCRIPTION

The user keyring is a keyring used to anchor keys on behalf of a user. Each UID the kernel deals with has its own user keyring that is shared by all processes with that UID. The user keyring has a name (description) of the form *_uid.*<*UID*> where <*UID*> is the user ID of the corresponding user.

The user keyring is associated with the record that the kernel maintains for the UID. It comes into existence upon the first attempt to access either the user keyring, the *user-session-keyring*(7), or the *session-keyring*(7). The keyring remains pinned in existence so long as there are processes running with that real UID or files opened by those processes remain open. (The keyring can also be pinned indefinitely by linking it into another keyring.)

Typically, the user keyring is created by *pam_keyinit*(8) when a user logs in.

The user keyring is not searched by default by *request_key*(2). When *pam_keyinit*(8) creates a session keyring, it adds to it a link to the user keyring so that the user keyring will be searched when the session keyring is.

A special serial number value, **KEY_SPEC_USER_KEYRING**, is defined that can be used in lieu of the actual serial number of the calling process's user keyring.

From the *keyctl*(1) utility, '**@u**' can be used instead of a numeric key ID in much the same way.

User keyrings are independent of *clone*(2), *fork*(2), *vfork*(2), *execve*(2), and *_exit*(2) excepting that the keyring is destroyed when the UID record is destroyed when the last process pinning it exits.

If it is necessary for a key associated with a user to exist beyond the UID record being garbage collected—for example, for use by a *cron*(8) script—then the *persistent-keyring*(7) should be used instead.

If a user keyring does not exist when it is accessed, it will be created.

keyctl(1), *keyctl*(3), *keyrings*(7), *persistent-keyring*(7), *process-keyring*(7), *session-keyring*(7), *thread-keyring*(7), *user-session-keyring*(7), *pam_keyinit*(8)

NAME

user-session-keyring − per-user default session keyring

DESCRIPTION

The user session keyring is a keyring used to anchor keys on behalf of a user. Each UID the kernel deals with has its own user session keyring that is shared by all processes with that UID. The user session keyring has a name (description) of the form *_uid_ses.<UID>* where *<UID>* is the user ID of the corresponding user.

The user session keyring is associated with the record that the kernel maintains for the UID. It comes into existence upon the first attempt to access either the user session keyring, the *user-keyring*(7), or the *session-keyring*(7). The keyring remains pinned in existence so long as there are processes running with that real UID or files opened by those processes remain open. (The keyring can also be pinned indefinitely by linking it into another keyring.)

The user session keyring is created on demand when a thread requests it or when a thread asks for its *session-keyring*(7) and that keyring doesn't exist. In the latter case, a user session keyring will be created and, if the session keyring wasn't to be created, the user session keyring will be set as the process's actual session keyring.

The user session keyring is searched by *request_key*(2) if the actual session keyring does not exist and is ignored otherwise.

A special serial number value, **KEY_SPEC_USER_SESSION_KEYRING**, is defined that can be used in lieu of the actual serial number of the calling process's user session keyring.

From the *keyctl*(1) utility, '**@us**' can be used instead of a numeric key ID in much the same way.

User session keyrings are independent of *clone*(2), *fork*(2), *vfork*(2), *execve*(2), and *_exit*(2) excepting that the keyring is destroyed when the UID record is destroyed when the last process pinning it exits.

If a user session keyring does not exist when it is accessed, it will be created.

Rather than relying on the user session keyring, it is strongly recommended—especially if the process is running as root—that a *session-keyring*(7) be set explicitly, for example by *pam_keyinit*(8)

NOTES

The user session keyring was added to support situations where a process doesn't have a session keyring, perhaps because it was created via a pathway that didn't involve PAM (e.g., perhaps it was a daemon started by *inetd*(8)). In such a scenario, the user session keyring acts as a substitute for the *session-keyring*(7).

NAME

user_namespaces − overview of Linux user namespaces

DESCRIPTION

For an overview of namespaces, see *namespaces*(7).

User namespaces isolate security-related identifiers and attributes, in particular, user IDs and group IDs (see *credentials*(7)), the root directory, keys (see *keyrings*(7)), and capabilities (see *capabilities*(7)). A process's user and group IDs can be different inside and outside a user namespace. In particular, a process can have a normal unprivileged user ID outside a user namespace while at the same time having a user ID of 0 inside the namespace; in other words, the process has full privileges for operations inside the user namespace, but is unprivileged for operations outside the namespace.

Nested namespaces, namespace membership

User namespaces can be nested; that is, each user namespace—except the initial ("root") namespace—has a parent user namespace, and can have zero or more child user namespaces. The parent user namespace is the user namespace of the process that creates the user namespace via a call to *unshare*(2) or *clone*(2) with the **CLONE_NEWUSER** flag.

The kernel imposes (since Linux 3.11) a limit of 32 nested levels of user namespaces. Calls to *unshare*(2) or *clone*(2) that would cause this limit to be exceeded fail with the error **EUSERS**.

Each process is a member of exactly one user namespace. A process created via *fork*(2) or *clone*(2) without the **CLONE_NEWUSER** flag is a member of the same user namespace as its parent. A single-threaded process can join another user namespace with *setns*(2) if it has the **CAP_SYS_ADMIN** in that namespace; upon doing so, it gains a full set of capabilities in that namespace.

A call to *clone*(2) or *unshare*(2) with the **CLONE_NEWUSER** flag makes the new child process (for *clone*(2)) or the caller (for *unshare*(2)) a member of the new user namespace created by the call.

The **NS_GET_PARENT** *ioctl*(2) operation can be used to discover the parental relationship between user namespaces; see *ioctl_ns*(2).

A task that changes one of its effective IDs will have its dumpability reset to the value in */proc/sys/fs/suid_dumpable*. This may affect the ownership of proc files of child processes and may thus cause the parent to lack the permissions to write to mapping files of child processes running in a new user namespace. In such cases making the parent process dumpable, using **PR_SET_DUMPABLE** in a call to *prctl*(2), before creating a child process in a new user namespace may rectify this problem. See *prctl*(2) and *proc*(5) for details on how ownership is affected.

Capabilities

The child process created by *clone*(2) with the **CLONE_NEWUSER** flag starts out with a complete set of capabilities in the new user namespace. Likewise, a process that creates a new user namespace using *unshare*(2) or joins an existing user namespace using *setns*(2) gains a full set of capabilities in that namespace. On the other hand, that process has no capabilities in the parent (in the case of *clone*(2)) or previous (in the case of *unshare*(2) and *setns*(2)) user namespace, even if the new namespace is created or joined by the root user (i.e., a process with user ID 0 in the root namespace).

Note that a call to *execve*(2) will cause a process's capabilities to be recalculated in the usual way (see *capabilities*(7)). Consequently, unless the process has a user ID of 0 within the namespace, or the executable file has a nonempty inheritable capabilities mask, the process will lose all capabilities. See the discussion of user and group ID mappings, below.

A call to *clone*(2) or *unshare*(2) using the **CLONE_NEWUSER** flag or a call to *setns*(2) that moves the caller into another user namespace sets the "securebits" flags (see *capabilities*(7)) to their default values (all flags disabled) in the child (for *clone*(2)) or caller (for *unshare*(2) or *setns*(2)). Note that because the caller no longer has capabilities in its original user namespace after a call to *setns*(2), it is not possible for a process to reset its "securebits" flags while retaining its user namespace membership by using a pair of *setns*(2) calls to move to another user namespace and then return to its original user namespace.

The rules for determining whether or not a process has a capability in a particular user namespace are as follows:

- A process has a capability inside a user namespace if it is a member of that namespace and it has the capability in its effective capability set. A process can gain capabilities in its effective capability set in various ways. For example, it may execute a set-user-ID program or an executable with associated file capabilities. In addition, a process may gain capabilities via the effect of *clone*(2), *unshare*(2), or *setns*(2), as already described.
- If a process has a capability in a user namespace, then it has that capability in all child (and further removed descendant) namespaces as well.
- When a user namespace is created, the kernel records the effective user ID of the creating process as being the "owner" of the namespace. A process that resides in the parent of the user namespace and whose effective user ID matches the owner of the namespace has all capabilities in the namespace. By virtue of the previous rule, this means that the process has all capabilities in all further removed descendant user namespaces as well. The **NS_GET_OWNER_UID** *ioctl*(2) operation can be used to discover the user ID of the owner of the namespace; see *ioctl_ns*(2).

Effect of capabilities within a user namespace

Having a capability inside a user namespace permits a process to perform operations (that require privilege) only on resources governed by that namespace. In other words, having a capability in a user namespace permits a process to perform privileged operations on resources that are governed by (nonuser) namespaces owned by (associated with) the user namespace (see the next subsection).

On the other hand, there are many privileged operations that affect resources that are not associated with any namespace type, for example, changing the system (i.e., calendar) time (governed by **CAP_SYS_TIME**), loading a kernel module (governed by **CAP_SYS_MODULE**), and creating a device (governed by **CAP_MKNOD**). Only a process with privileges in the *initial* user namespace can perform such operations.

Holding **CAP_SYS_ADMIN** within the user namespace that owns a process's mount namespace allows that process to create bind mounts and mount the following types of filesystems:

- */proc* (since Linux 3.8)
- */sys* (since Linux 3.8)
- *devpts* (since Linux 3.9)
- *tmpfs*(5) (since Linux 3.9)
- *ramfs* (since Linux 3.9)
- *mqueue* (since Linux 3.9)
- *bpf* (since Linux 4.4)
- *overlayfs* (since Linux 5.11)

Holding **CAP_SYS_ADMIN** within the user namespace that owns a process's cgroup namespace allows (since Linux 4.6) that process to the mount the cgroup version 2 filesystem and cgroup version 1 named hierarchies (i.e., cgroup filesystems mounted with the *"none,name="* option).

Holding **CAP_SYS_ADMIN** within the user namespace that owns a process's PID namespace allows (since Linux 3.8) that process to mount */proc* filesystems.

Note, however, that mounting block-based filesystems can be done only by a process that holds **CAP_SYS_ADMIN** in the initial user namespace.

Interaction of user namespaces and other types of namespaces

Starting in Linux 3.8, unprivileged processes can create user namespaces, and the other types of namespaces can be created with just the **CAP_SYS_ADMIN** capability in the caller's user namespace.

When a nonuser namespace is created, it is owned by the user namespace in which the creating process was a member at the time of the creation of the namespace. Privileged operations on resources governed by the nonuser namespace require that the process has the necessary capabilities in the user namespace that owns the nonuser namespace.

If **CLONE_NEWUSER** is specified along with other **CLONE_NEW*** flags in a single *clone*(2) or *unshare*(2) call, the user namespace is guaranteed to be created first, giving the child (**clone**(2)) or caller (**unshare**(2)) privileges over the remaining namespaces created by the call. Thus, it is possible for an unprivileged caller to specify this combination of flags.

When a new namespace (other than a user namespace) is created via *clone*(2) or *unshare*(2), the kernel records the user namespace of the creating process as the owner of the new namespace. (This

association can't be changed.) When a process in the new namespace subsequently performs privileged operations that operate on global resources isolated by the namespace, the permission checks are performed according to the process's capabilities in the user namespace that the kernel associated with the new namespace. For example, suppose that a process attempts to change the hostname (**sethostname**(2)), a resource governed by the UTS namespace. In this case, the kernel will determine which user namespace owns the process's UTS namespace, and check whether the process has the required capability (**CAP_SYS_ADMIN**) in that user namespace.

The **NS_GET_USERNS** *ioctl*(2) operation can be used to discover the user namespace that owns a nonuser namespace; see *ioctl_ns*(2).

User and group ID mappings: uid_map and gid_map

When a user namespace is created, it starts out without a mapping of user IDs (group IDs) to the parent user namespace. The */proc/*pid*/uid_map* and */proc/*pid*/gid_map* files (available since Linux 3.5) expose the mappings for user and group IDs inside the user namespace for the process *pid*. These files can be read to view the mappings in a user namespace and written to (once) to define the mappings.

The description in the following paragraphs explains the details for *uid_map*; *gid_map* is exactly the same, but each instance of "user ID" is replaced by "group ID".

The *uid_map* file exposes the mapping of user IDs from the user namespace of the process *pid* to the user namespace of the process that opened *uid_map* (but see a qualification to this point below). In other words, processes that are in different user namespaces will potentially see different values when reading from a particular *uid_map* file, depending on the user ID mappings for the user namespaces of the reading processes.

Each line in the *uid_map* file specifies a 1-to-1 mapping of a range of contiguous user IDs between two user namespaces. (When a user namespace is first created, this file is empty.) The specification in each line takes the form of three numbers delimited by white space. The first two numbers specify the starting user ID in each of the two user namespaces. The third number specifies the length of the mapped range. In detail, the fields are interpreted as follows:

(1) The start of the range of user IDs in the user namespace of the process *pid*.

(2) The start of the range of user IDs to which the user IDs specified by field one map. How field two is interpreted depends on whether the process that opened *uid_map* and the process *pid* are in the same user namespace, as follows:

  (a) If the two processes are in different user namespaces: field two is the start of a range of user IDs in the user namespace of the process that opened *uid_map*.

  (b) If the two processes are in the same user namespace: field two is the start of the range of user IDs in the parent user namespace of the process *pid*. This case enables the opener of *uid_map* (the common case here is opening */proc/self/uid_map*) to see the mapping of user IDs into the user namespace of the process that created this user namespace.

(3) The length of the range of user IDs that is mapped between the two user namespaces.

System calls that return user IDs (group IDs)—for example, *getuid*(2), *getgid*(2), and the credential fields in the structure returned by *stat*(2)—return the user ID (group ID) mapped into the caller's user namespace.

When a process accesses a file, its user and group IDs are mapped into the initial user namespace for the purpose of permission checking and assigning IDs when creating a file. When a process retrieves file user and group IDs via *stat*(2), the IDs are mapped in the opposite direction, to produce values relative to the process user and group ID mappings.

The initial user namespace has no parent namespace, but, for consistency, the kernel provides dummy user and group ID mapping files for this namespace. Looking at the *uid_map* file (*gid_map* is the same) from a shell in the initial namespace shows:

```
$ cat /proc/$$/uid_map
         0          0 4294967295
```

This mapping tells us that the range starting at user ID 0 in this namespace maps to a range starting at 0 in the (nonexistent) parent namespace, and the length of the range is the largest 32-bit unsigned integer. This leaves 4294967295 (the 32-bit signed −1 value) unmapped. This is deliberate: *(uid_t) −1* is used in several interfaces (e.g., *setreuid*(2)) as a way to specify "no user ID". Leaving *(uid_t) −1* unmapped

and unusable guarantees that there will be no confusion when using these interfaces.

Defining user and group ID mappings: writing to uid_map and gid_map

After the creation of a new user namespace, the *uid_map* file of *one* of the processes in the namespace may be written to *once* to define the mapping of user IDs in the new user namespace. An attempt to write more than once to a *uid_map* file in a user namespace fails with the error **EPERM**. Similar rules apply for *gid_map* files.

The lines written to *uid_map* (*gid_map*) must conform to the following validity rules:

- The three fields must be valid numbers, and the last field must be greater than 0.
- Lines are terminated by newline characters.
- There is a limit on the number of lines in the file. In Linux 4.14 and earlier, this limit was (arbitrarily) set at 5 lines. Since Linux 4.15, the limit is 340 lines. In addition, the number of bytes written to the file must be less than the system page size, and the write must be performed at the start of the file (i.e., *lseek*(2) and *pwrite*(2) can't be used to write to nonzero offsets in the file).
- The range of user IDs (group IDs) specified in each line cannot overlap with the ranges in any other lines. In the initial implementation (Linux 3.8), this requirement was satisfied by a simplistic implementation that imposed the further requirement that the values in both field 1 and field 2 of successive lines must be in ascending numerical order, which prevented some otherwise valid maps from being created. Linux 3.9 and later fix this limitation, allowing any valid set of nonoverlapping maps.
- At least one line must be written to the file.

Writes that violate the above rules fail with the error **EINVAL**.

In order for a process to write to the */proc/*pid*/uid_map* (*/proc/*pid*/gid_map*) file, all of the following permission requirements must be met:

- The writing process must have the **CAP_SETUID** (**CAP_SETGID**) capability in the user namespace of the process *pid*.
- The writing process must either be in the user namespace of the process *pid* or be in the parent user namespace of the process *pid*.
- The mapped user IDs (group IDs) must in turn have a mapping in the parent user namespace.
- If updating */proc/*pid*/uid_map* to create a mapping that maps UID 0 in the parent namespace, then one of the following must be true:

  (a) if writing process is in the parent user namespace, then it must have the **CAP_SETFCAP** capability in that user namespace; or

  (b) if the writing process is in the child user namespace, then the process that created the user namespace must have had the **CAP_SETFCAP** capability when the namespace was created.

  This rule has been in place since Linux 5.12. It eliminates an earlier security bug whereby a UID 0 process that lacks the **CAP_SETFCAP** capability, which is needed to create a binary with namespaced file capabilities (as described in *capabilities*(7)), could nevertheless create such a binary, by the following steps:

  (1) Create a new user namespace with the identity mapping (i.e., UID 0 in the new user namespace maps to UID 0 in the parent namespace), so that UID 0 in both namespaces is equivalent to the same root user ID.

  (2) Since the child process has the **CAP_SETFCAP** capability, it could create a binary with namespaced file capabilities that would then be effective in the parent user namespace (because the root user IDs are the same in the two namespaces).
- One of the following two cases applies:

  (a) *Either* the writing process has the **CAP_SETUID** (**CAP_SETGID**) capability in the *parent* user namespace.

  - No further restrictions apply: the process can make mappings to arbitrary user IDs (group IDs) in the parent user namespace.

(b) *Or* otherwise all of the following restrictions apply:

- The data written to *uid_map* (*gid_map*) must consist of a single line that maps the writing process's effective user ID (group ID) in the parent user namespace to a user ID (group ID) in the user namespace.
- The writing process must have the same effective user ID as the process that created the user namespace.
- In the case of *gid_map*, use of the *setgroups*(2) system call must first be denied by writing "*deny*" to the */proc/*pid*/setgroups* file (see below) before writing to *gid_map*.

Writes that violate the above rules fail with the error **EPERM**.

Project ID mappings: projid_map

Similarly to user and group ID mappings, it is possible to create project ID mappings for a user namespace. (Project IDs are used for disk quotas; see *setquota*(8) and *quotactl*(2).)

Project ID mappings are defined by writing to the */proc/*pid*/projid_map* file (present since Linux 3.7).

The validity rules for writing to the */proc/*pid*/projid_map* file are as for writing to the *uid_map* file; violation of these rules causes *write*(2) to fail with the error **EINVAL**.

The permission rules for writing to the */proc/*pid*/projid_map* file are as follows:

- The writing process must either be in the user namespace of the process *pid* or be in the parent user namespace of the process *pid*.
- The mapped project IDs must in turn have a mapping in the parent user namespace.

Violation of these rules causes *write*(2) to fail with the error **EPERM**.

Interaction with system calls that change process UIDs or GIDs

In a user namespace where the *uid_map* file has not been written, the system calls that change user IDs will fail. Similarly, if the *gid_map* file has not been written, the system calls that change group IDs will fail. After the *uid_map* and *gid_map* files have been written, only the mapped values may be used in system calls that change user and group IDs.

For user IDs, the relevant system calls include *setuid*(2), *setfsuid*(2), *setreuid*(2), and *setresuid*(2). For group IDs, the relevant system calls include *setgid*(2), *setfsgid*(2), *setregid*(2), *setresgid*(2), and *setgroups*(2).

Writing "*deny*" to the */proc/*pid*/setgroups* file before writing to */proc/*pid*/gid_map* will permanently disable *setgroups*(2) in a user namespace and allow writing to */proc/*pid*/gid_map* without having the **CAP_SETGID** capability in the parent user namespace.

The */proc/*pid*/setgroups* file

The */proc/*pid*/setgroups* file displays the string "*allow*" if processes in the user namespace that contains the process *pid* are permitted to employ the *setgroups*(2) system call; it displays "*deny*" if *setgroups*(2) is not permitted in that user namespace. Note that regardless of the value in the */proc/*pid*/setgroups* file (and regardless of the process's capabilities), calls to *setgroups*(2) are also not permitted if */proc/*pid*/gid_map* has not yet been set.

A privileged process (one with the **CAP_SYS_ADMIN** capability in the namespace) may write either of the strings "*allow*" or "*deny*" to this file *before* writing a group ID mapping for this user namespace to the file */proc/*pid*/gid_map*. Writing the string "*deny*" prevents any process in the user namespace from employing *setgroups*(2).

The essence of the restrictions described in the preceding paragraph is that it is permitted to write to */proc/*pid*/setgroups* only so long as calling *setgroups*(2) is disallowed because */proc/*pid*/gid_map* has not been set. This ensures that a process cannot transition from a state where *setgroups*(2) is allowed to a state where *setgroups*(2) is denied; a process can transition only from *setgroups*(2) being disallowed to *setgroups*(2) being allowed.

The default value of this file in the initial user namespace is "*allow*".

Once */proc/*pid*/gid_map* has been written to (which has the effect of enabling *setgroups*(2) in the user namespace), it is no longer possible to disallow *setgroups*(2) by writing "*deny*" to */proc/*pid*/setgroups* (the write fails with the error **EPERM**).

A child user namespace inherits the */proc/*pid*/setgroups* setting from its parent.

If the *setgroups* file has the value "*deny*", then the *setgroups*(2) system call can't subsequently be reenabled (by writing "*allow*" to the file) in this user namespace. (Attempts to do so fail with the error **EPERM**.) This restriction also propagates down to all child user namespaces of this user namespace.

The */proc/*pid*/setgroups* file was added in Linux 3.19, but was backported to many earlier stable kernel series, because it addresses a security issue. The issue concerned files with permissions such as "rwx−−−rwx". Such files give fewer permissions to "group" than they do to "other". This means that dropping groups using *setgroups*(2) might allow a process file access that it did not formerly have. Before the existence of user namespaces this was not a concern, since only a privileged process (one with the **CAP_SETGID** capability) could call *setgroups*(2). However, with the introduction of user namespaces, it became possible for an unprivileged process to create a new namespace in which the user had all privileges. This then allowed formerly unprivileged users to drop groups and thus gain file access that they did not previously have. The */proc/*pid*/setgroups* file was added to address this security issue, by denying any pathway for an unprivileged process to drop groups with *setgroups*(2).

Unmapped user and group IDs

There are various places where an unmapped user ID (group ID) may be exposed to user space. For example, the first process in a new user namespace may call *getuid*(2) before a user ID mapping has been defined for the namespace. In most such cases, an unmapped user ID is converted to the overflow user ID (group ID); the default value for the overflow user ID (group ID) is 65534. See the descriptions of */proc/sys/kernel/overflowuid* and */proc/sys/kernel/overflowgid* in *proc*(5).

The cases where unmapped IDs are mapped in this fashion include system calls that return user IDs (**getuid**(2), *getgid*(2), and similar), credentials passed over a UNIX domain socket, credentials returned by *stat*(2), *waitid*(2), and the System V IPC "ctl" **IPC_STAT** operations, credentials exposed by */proc/*pid*/status* and the files in */proc/sysvipc/**, credentials returned via the *si_uid* field in the *siginfo_t* received with a signal (see *sigaction*(2)), credentials written to the process accounting file (see *acct*(5)), and credentials returned with POSIX message queue notifications (see *mq_notify*(3)).

There is one notable case where unmapped user and group IDs are *not* converted to the corresponding overflow ID value. When viewing a *uid_map* or *gid_map* file in which there is no mapping for the second field, that field is displayed as 4294967295 (−1 as an unsigned integer).

Accessing files

In order to determine permissions when an unprivileged process accesses a file, the process credentials (UID, GID) and the file credentials are in effect mapped back to what they would be in the initial user namespace and then compared to determine the permissions that the process has on the file. The same is also true of other objects that employ the credentials plus permissions mask accessibility model, such as System V IPC objects.

Operation of file-related capabilities

Certain capabilities allow a process to bypass various kernel-enforced restrictions when performing operations on files owned by other users or groups. These capabilities are: **CAP_CHOWN**, **CAP_DAC_OVERRIDE**, **CAP_DAC_READ_SEARCH**, **CAP_FOWNER**, and **CAP_FSETID**.

Within a user namespace, these capabilities allow a process to bypass the rules if the process has the relevant capability over the file, meaning that:

- the process has the relevant effective capability in its user namespace; and
- the file's user ID and group ID both have valid mappings in the user namespace.

The **CAP_FOWNER** capability is treated somewhat exceptionally: it allows a process to bypass the corresponding rules so long as at least the file's user ID has a mapping in the user namespace (i.e., the file's group ID does not need to have a valid mapping).

Set-user-ID and set-group-ID programs

When a process inside a user namespace executes a set-user-ID (set-group-ID) program, the process's effective user (group) ID inside the namespace is changed to whatever value is mapped for the user (group) ID of the file. However, if either the user *or* the group ID of the file has no mapping inside the namespace, the set-user-ID (set-group-ID) bit is silently ignored: the new program is executed, but the process's effective user (group) ID is left unchanged. (This mirrors the semantics of executing a set-user-ID or set-group-ID program that resides on a filesystem that was mounted with the **MS_NOSUID** flag, as described in *mount*(2).)

Miscellaneous

When a process's user and group IDs are passed over a UNIX domain socket to a process in a different user namespace (see the description of **SCM_CREDENTIALS** in *unix*(7)), they are translated into the corresponding values as per the receiving process's user and group ID mappings.

STANDARDS

Linux.

NOTES

Over the years, there have been a lot of features that have been added to the Linux kernel that have been made available only to privileged users because of their potential to confuse set-user-ID-root applications. In general, it becomes safe to allow the root user in a user namespace to use those features because it is impossible, while in a user namespace, to gain more privilege than the root user of a user namespace has.

Global root

The term "global root" is sometimes used as a shorthand for user ID 0 in the initial user namespace.

Availability

Use of user namespaces requires a kernel that is configured with the **CONFIG_USER_NS** option. User namespaces require support in a range of subsystems across the kernel. When an unsupported subsystem is configured into the kernel, it is not possible to configure user namespaces support.

As at Linux 3.8, most relevant subsystems supported user namespaces, but a number of filesystems did not have the infrastructure needed to map user and group IDs between user namespaces. Linux 3.9 added the required infrastructure support for many of the remaining unsupported filesystems (Plan 9 (9P), Andrew File System (AFS), Ceph, CIFS, CODA, NFS, and OCFS2). Linux 3.12 added support for the last of the unsupported major filesystems, XFS.

EXAMPLES

The program below is designed to allow experimenting with user namespaces, as well as other types of namespaces. It creates namespaces as specified by command-line options and then executes a command inside those namespaces. The comments and *usage*() function inside the program provide a full explanation of the program. The following shell session demonstrates its use.

First, we look at the run-time environment:

```
$ uname -rs     # Need Linux 3.8 or later
Linux 3.8.0
$ id -u         # Running as unprivileged user
1000
$ id -g
1000
```

Now start a new shell in new user (*-U*), mount (*-m*), and PID (*-p*) namespaces, with user ID (*-M*) and group ID (*-G*) 1000 mapped to 0 inside the user namespace:

```
$ ./userns_child_exec -p -m -U -M '0 1000 1' -G '0 1000 1' bash
```

The shell has PID 1, because it is the first process in the new PID namespace:

```
bash$ echo $$
1
```

Mounting a new */proc* filesystem and listing all of the processes visible in the new PID namespace shows that the shell can't see any processes outside the PID namespace:

```
bash$ mount -t proc proc /proc
bash$ ps ax
  PID TTY      STAT   TIME COMMAND
    1 pts/3    S      0:00 bash
   22 pts/3    R+     0:00 ps ax
```

Inside the user namespace, the shell has user and group ID 0, and a full set of permitted and effective capabilities:

```
bash$ cat /proc/$$/status | egrep '^[UG]id'
Uid:  0     0     0     0
```

```
    Gid:  0     0     0     0
    bash$ cat /proc/$$/status | egrep '^Cap(Prm|Inh|Eff)'
    CapInh:     0000000000000000
    CapPrm:     0000001fffffffff
    CapEff:     0000001fffffffff
```

    /* Linux 3.19 made a change in the handling of setgroups(2) and
       the 'gid_map' file to address a security issue.  The issue
       allowed *unprivileged* users to employ user namespaces in
       order to drop groups.  The upshot of the 3.19 changes is that
```

```
       in order to update the 'gid_maps' file, use of the setgroups()
       system call in this user namespace must first be disabled by
       writing "deny" to one of the /proc/PID/setgroups files for
       this namespace.  That is the purpose of the following function.  */

   static void
   proc_setgroups_write(pid_t child_pid, char *str)
   {
       char setgroups_path[PATH_MAX];
       int fd;

       snprintf(setgroups_path, PATH_MAX, "/proc/%jd/setgroups",
               (intmax_t) child_pid);

       fd = open(setgroups_path, O_RDWR);
       if (fd == -1) {

           /* We may be on a system that doesn't support
              /proc/PID/setgroups. In that case, the file won't exist,
              and the system won't impose the restrictions that Linux 3.19
              added. That's fine: we don't need to do anything in order
              to permit 'gid_map' to be updated.

              However, if the error from open() was something other than
              the ENOENT error that is expected for that case,  let the
              user know. */

NAME

UTF-8 − an ASCII compatible multibyte Unicode encoding

DESCRIPTION

The Unicode 3.0 character set occupies a 16-bit code space. The most obvious Unicode encoding (known as UCS-2) consists of a sequence of 16-bit words. Such strings can contain—as part of many 16-bit characters—bytes such as '\0' or '/', which have a special meaning in filenames and other C library function arguments. In addition, the majority of UNIX tools expect ASCII files and can't read 16-bit words as characters without major modifications. For these reasons, UCS-2 is not a suitable external encoding of Unicode in filenames, text files, environment variables, and so on. The ISO/IEC 10646 Universal Character Set (UCS), a superset of Unicode, occupies an even larger code space—31 bits—and the obvious UCS-4 encoding for it (a sequence of 32-bit words) has the same problems.

The UTF-8 encoding of Unicode and UCS does not have these problems and is the common way in which Unicode is used on UNIX-style operating systems.

Properties

The UTF-8 encoding has the following nice properties:

- UCS characters 0x00000000 to 0x0000007f (the classic US-ASCII characters) are encoded simply as bytes 0x00 to 0x7f (ASCII compatibility). This means that files and strings which contain only 7-bit ASCII characters have the same encoding under both ASCII and UTF-8.
- All UCS characters greater than 0x7f are encoded as a multibyte sequence consisting only of bytes in the range 0x80 to 0xfd, so no ASCII byte can appear as part of another character and there are no problems with, for example, '\0' or '/'.
- The lexicographic sorting order of UCS-4 strings is preserved.
- All possible 2^31 UCS codes can be encoded using UTF-8.
- The bytes 0xc0, 0xc1, 0xfe, and 0xff are never used in the UTF-8 encoding.
- The first byte of a multibyte sequence which represents a single non-ASCII UCS character is always in the range 0xc2 to 0xfd and indicates how long this multibyte sequence is. All further bytes in a multibyte sequence are in the range 0x80 to 0xbf. This allows easy resynchronization and makes the encoding stateless and robust against missing bytes.
- UTF-8 encoded UCS characters may be up to six bytes long, however the Unicode standard specifies no characters above 0x10ffff, so Unicode characters can be only up to four bytes long in UTF-8.

Encoding

The following byte sequences are used to represent a character. The sequence to be used depends on the UCS code number of the character:

0x00000000 − 0x0000007F:
0*xxxxxxx*

0x00000080 − 0x000007FF:
110*xxxxx* 10*xxxxxx*

0x00000800 − 0x0000FFFF:
1110*xxxx* 10*xxxxxx* 10*xxxxxx*

0x00010000 − 0x001FFFFF:
11110*xxx* 10*xxxxxx* 10*xxxxxx* 10*xxxxxx*

0x00200000 − 0x03FFFFFF:
111110*xx* 10*xxxxxx* 10*xxxxxx* 10*xxxxxx* 10*xxxxxx*

0x04000000 − 0x7FFFFFFF:
1111110*x* 10*xxxxxx* 10*xxxxxx* 10*xxxxxx* 10*xxxxxx* 10*xxxxxx*

The *xxx* bit positions are filled with the bits of the character code number in binary representation, most significant bit first (big-endian). Only the shortest possible multibyte sequence which can represent the code number of the character can be used.

The UCS code values 0xd800–0xdfff (UTF-16 surrogates) as well as 0xfffe and 0xffff (UCS

noncharacters) should not appear in conforming UTF-8 streams. According to RFC 3629 no point above U+10FFFF should be used, which limits characters to four bytes.

Example

The Unicode character 0xa9 = 1010 1001 (the copyright sign) is encoded in UTF-8 as

11000010 10101001 = 0xc2 0xa9

and character 0x2260 = 0010 0010 0110 0000 (the "not equal" symbol) is encoded as:

11100010 10001001 10100000 = 0xe2 0x89 0xa0

Application notes

Users have to select a UTF-8 locale, for example with

export LANG=en_GB.UTF-8

in order to activate the UTF-8 support in applications.

Application software that has to be aware of the used character encoding should always set the locale with for example

setlocale(LC_CTYPE, "")

and programmers can then test the expression

strcmp(nl_langinfo(CODESET), "UTF-8") == 0

to determine whether a UTF-8 locale has been selected and whether therefore all plaintext standard input and output, terminal communication, plaintext file content, filenames, and environment variables are encoded in UTF-8.

Programmers accustomed to single-byte encodings such as US-ASCII or ISO/IEC 8859 have to be aware that two assumptions made so far are no longer valid in UTF-8 locales. Firstly, a single byte does not necessarily correspond any more to a single character. Secondly, since modern terminal emulators in UTF-8 mode also support Chinese, Japanese, and Korean double-width characters as well as nonspacing combining characters, outputting a single character does not necessarily advance the cursor by one position as it did in ASCII. Library functions such as *mbsrtowcs*(3) and *wcswidth*(3) should be used today to count characters and cursor positions.

The official ESC sequence to switch from an ISO/IEC 2022 encoding scheme (as used for instance by VT100 terminals) to UTF-8 is ESC % G ("\x1b%G"). The corresponding return sequence from UTF-8 to ISO/IEC 2022 is ESC % @ ("\x1b%@"). Other ISO/IEC 2022 sequences (such as for switching the G0 and G1 sets) are not applicable in UTF-8 mode.

Security

The Unicode and UCS standards require that producers of UTF-8 shall use the shortest form possible, for example, producing a two-byte sequence with first byte 0xc0 is nonconforming. Unicode 3.1 has added the requirement that conforming programs must not accept non-shortest forms in their input. This is for security reasons: if user input is checked for possible security violations, a program might check only for the ASCII version of "/../" or ";" or NUL and overlook that there are many non-ASCII ways to represent these things in a non-shortest UTF-8 encoding.

Standards

ISO/IEC 10646-1:2000, Unicode 3.1, RFC 3629, Plan 9.

NAME

uts_namespaces − overview of Linux UTS namespaces

DESCRIPTION

UTS namespaces provide isolation of two system identifiers: the hostname and the NIS domain name. These identifiers are set using *sethostname*(2) and *setdomainname*(2), and can be retrieved using *uname*(2), *gethostname*(2), and *getdomainname*(2). Changes made to these identifiers are visible to all other processes in the same UTS namespace, but are not visible to processes in other UTS namespaces.

When a process creates a new UTS namespace using *clone*(2) or *unshare*(2) with the **CLONE_NEWUTS** flag, the hostname and domain name of the new UTS namespace are copied from the corresponding values in the caller's UTS namespace.

Use of UTS namespaces requires a kernel that is configured with the **CONFIG_UTS_NS** option.

NAME

vdso − overview of the virtual ELF dynamic shared object

SYNOPSIS

#include <sys/auxv.h>

void *vdso = (uintptr_t) getauxval(AT_SYSINFO_EHDR);

DESCRIPTION

The "vDSO" (virtual dynamic shared object) is a small shared library that the kernel automatically maps into the address space of all user-space applications. Applications usually do not need to concern themselves with these details as the vDSO is most commonly called by the C library. This way you can code in the normal way using standard functions and the C library will take care of using any functionality that is available via the vDSO.

Why does the vDSO exist at all? There are some system calls the kernel provides that user-space code ends up using frequently, to the point that such calls can dominate overall performance. This is due both to the frequency of the call as well as the context-switch overhead that results from exiting user space and entering the kernel.

The rest of this documentation is geared toward the curious and/or C library writers rather than general developers. If you're trying to call the vDSO in your own application rather than using the C library, you're most likely doing it wrong.

Example background

Making system calls can be slow. In x86 32-bit systems, you can trigger a software interrupt (*int $0x80*) to tell the kernel you wish to make a system call. However, this instruction is expensive: it goes through the full interrupt-handling paths in the processor's microcode as well as in the kernel. Newer processors have faster (but backward incompatible) instructions to initiate system calls. Rather than require the C library to figure out if this functionality is available at run time, the C library can use functions provided by the kernel in the vDSO.

Note that the terminology can be confusing. On x86 systems, the vDSO function used to determine the preferred method of making a system call is named "__kernel_vsyscall", but on x86-64, the term "vsyscall" also refers to an obsolete way to ask the kernel what time it is or what CPU the caller is on.

One frequently used system call is *gettimeofday*(2). This system call is called both directly by user-space applications as well as indirectly by the C library. Think timestamps or timing loops or polling—all of these frequently need to know what time it is right now. This information is also not secret—any application in any privilege mode (root or any unprivileged user) will get the same answer. Thus the kernel arranges for the information required to answer this question to be placed in memory the process can access. Now a call to *gettimeofday*(2) changes from a system call to a normal function call and a few memory accesses.

Finding the vDSO

The base address of the vDSO (if one exists) is passed by the kernel to each program in the initial auxiliary vector (see *getauxval*(3)), via the **AT_SYSINFO_EHDR** tag.

You must not assume the vDSO is mapped at any particular location in the user's memory map. The base address will usually be randomized at run time every time a new process image is created (at *execve*(2) time). This is done for security reasons, to prevent "return-to-libc" attacks.

For some architectures, there is also an **AT_SYSINFO** tag. This is used only for locating the vsyscall entry point and is frequently omitted or set to 0 (meaning it's not available). This tag is a throwback to the initial vDSO work (see *History* below) and its use should be avoided.

File format

Since the vDSO is a fully formed ELF image, you can do symbol lookups on it. This allows new symbols to be added with newer kernel releases, and allows the C library to detect available functionality at run time when running under different kernel versions. Oftentimes the C library will do detection with the first call and then cache the result for subsequent calls.

All symbols are also versioned (using the GNU version format). This allows the kernel to update the function signature without breaking backward compatibility. This means changing the arguments that the function accepts as well as the return value. Thus, when looking up a symbol in the vDSO, you must always include the version to match the ABI you expect.

Typically the vDSO follows the naming convention of prefixing all symbols with "__vdso_" or "__kernel_" so as to distinguish them from other standard symbols. For example, the "gettimeofday" function is named "__vdso_gettimeofday".

You use the standard C calling conventions when calling any of these functions. No need to worry about weird register or stack behavior.

NOTES

Source

When you compile the kernel, it will automatically compile and link the vDSO code for you. You will frequently find it under the architecture-specific directory:

```
find arch/$ARCH/ -name '*vdso*.so*' -o -name '*gate*.so*'
```

vDSO names

The name of the vDSO varies across architectures. It will often show up in things like glibc's *ldd*(1) output. The exact name should not matter to any code, so do not hardcode it.

user ABI	vDSO name
aarch64	linux-vdso.so.1
arm	linux-vdso.so.1
ia64	linux-gate.so.1
mips	linux-vdso.so.1
ppc/32	linux-vdso32.so.1
ppc/64	linux-vdso64.so.1
riscv	linux-vdso.so.1
s390	linux-vdso32.so.1
s390x	linux-vdso64.so.1
sh	linux-gate.so.1
i386	linux-gate.so.1
x86-64	linux-vdso.so.1
x86/x32	linux-vdso.so.1

strace(1), seccomp(2), and the vDSO

When tracing system calls with *strace*(1), symbols (system calls) that are exported by the vDSO will *not* appear in the trace output. Those system calls will likewise not be visible to *seccomp*(2) filters.

ARCHITECTURE-SPECIFIC NOTES

The subsections below provide architecture-specific notes on the vDSO.

Note that the vDSO that is used is based on the ABI of your user-space code and not the ABI of the kernel. Thus, for example, when you run an i386 32-bit ELF binary, you'll get the same vDSO regardless of whether you run it under an i386 32-bit kernel or under an x86-64 64-bit kernel. Therefore, the name of the user-space ABI should be used to determine which of the sections below is relevant.

ARM functions

The table below lists the symbols exported by the vDSO.

symbol	version
__vdso_gettimeofday	LINUX_2.6 (exported since Linux 4.1)
__vdso_clock_gettime	LINUX_2.6 (exported since Linux 4.1)

Additionally, the ARM port has a code page full of utility functions. Since it's just a raw page of code, there is no ELF information for doing symbol lookups or versioning. It does provide support for different versions though.

For information on this code page, it's best to refer to the kernel documentation as it's extremely detailed and covers everything you need to know: *Documentation/arm/kernel_user_helpers.rst*.

aarch64 functions

The table below lists the symbols exported by the vDSO.

symbol	version
__kernel_rt_sigreturn	LINUX_2.6.39
__kernel_gettimeofday	LINUX_2.6.39

__kernel_clock_gettime	LINUX_2.6.39
__kernel_clock_getres	LINUX_2.6.39

bfin (Blackfin) functions (port removed in Linux 4.17)

As this CPU lacks a memory management unit (MMU), it doesn't set up a vDSO in the normal sense. Instead, it maps at boot time a few raw functions into a fixed location in memory. User-space applications then call directly into that region. There is no provision for backward compatibility beyond sniffing raw opcodes, but as this is an embedded CPU, it can get away with things—some of the object formats it runs aren't even ELF based (they're bFLT/FLAT).

For information on this code page, it's best to refer to the public documentation:
http://docs.blackfin.uclinux.org/doku.php?id=linux−kernel:fixed−code

mips functions

The table below lists the symbols exported by the vDSO.

symbol	version
__kernel_gettimeofday	LINUX_2.6 (exported since Linux 4.4)
__kernel_clock_gettime	LINUX_2.6 (exported since Linux 4.4)

ia64 (Itanium) functions

The table below lists the symbols exported by the vDSO.

symbol	version
__kernel_sigtramp	LINUX_2.5
__kernel_syscall_via_break	LINUX_2.5
__kernel_syscall_via_epc	LINUX_2.5

The Itanium port is somewhat tricky. In addition to the vDSO above, it also has "light-weight system calls" (also known as "fast syscalls" or "fsys"). You can invoke these via the *__kernel_syscall_via_epc* vDSO helper. The system calls listed here have the same semantics as if you called them directly via *syscall*(2), so refer to the relevant documentation for each. The table below lists the functions available via this mechanism.

function
clock_gettime
getcpu
getpid
getppid
gettimeofday
set_tid_address

parisc (hppa) functions

The parisc port has a code page with utility functions called a gateway page. Rather than use the normal ELF auxiliary vector approach, it passes the address of the page to the process via the SR2 register. The permissions on the page are such that merely executing those addresses automatically executes with kernel privileges and not in user space. This is done to match the way HP-UX works.

Since it's just a raw page of code, there is no ELF information for doing symbol lookups or versioning. Simply call into the appropriate offset via the branch instruction, for example:

```
ble <offset>(%sr2, %r0)
```

offset	function
00b0	lws_entry (CAS operations)
00e0	set_thread_pointer (used by glibc)
0100	linux_gateway_entry (syscall)

ppc/32 functions

The table below lists the symbols exported by the vDSO. The functions marked with a * are available only when the kernel is a PowerPC64 (64-bit) kernel.

symbol	version
__kernel_clock_getres	LINUX_2.6.15
__kernel_clock_gettime	LINUX_2.6.15
__kernel_clock_gettime64	LINUX_5.11
__kernel_datapage_offset	LINUX_2.6.15
__kernel_get_syscall_map	LINUX_2.6.15
__kernel_get_tbfreq	LINUX_2.6.15
__kernel_getcpu *	LINUX_2.6.15
__kernel_gettimeofday	LINUX_2.6.15
__kernel_sigtramp_rt32	LINUX_2.6.15
__kernel_sigtramp32	LINUX_2.6.15
__kernel_sync_dicache	LINUX_2.6.15
__kernel_sync_dicache_p5	LINUX_2.6.15

Before Linux 5.6, the **CLOCK_REALTIME_COARSE** and **CLOCK_MONOTONIC_COARSE** clocks are *not* supported by the *__kernel_clock_getres* and *__kernel_clock_gettime* interfaces; the kernel falls back to the real system call.

ppc/64 functions

The table below lists the symbols exported by the vDSO.

symbol	version
__kernel_clock_getres	LINUX_2.6.15
__kernel_clock_gettime	LINUX_2.6.15
__kernel_datapage_offset	LINUX_2.6.15
__kernel_get_syscall_map	LINUX_2.6.15
__kernel_get_tbfreq	LINUX_2.6.15
__kernel_getcpu	LINUX_2.6.15
__kernel_gettimeofday	LINUX_2.6.15
__kernel_sigtramp_rt64	LINUX_2.6.15
__kernel_sync_dicache	LINUX_2.6.15
__kernel_sync_dicache_p5	LINUX_2.6.15

Before Linux 4.16, the **CLOCK_REALTIME_COARSE** and **CLOCK_MONOTONIC_COARSE** clocks are *not* supported by the *__kernel_clock_getres* and *__kernel_clock_gettime* interfaces; the kernel falls back to the real system call.

riscv functions

The table below lists the symbols exported by the vDSO.

symbol	version
__vdso_rt_sigreturn	LINUX_4.15
__vdso_gettimeofday	LINUX_4.15
__vdso_clock_gettime	LINUX_4.15
__vdso_clock_getres	LINUX_4.15
__vdso_getcpu	LINUX_4.15
__vdso_flush_icache	LINUX_4.15

s390 functions

The table below lists the symbols exported by the vDSO.

symbol	version
__kernel_clock_getres	LINUX_2.6.29
__kernel_clock_gettime	LINUX_2.6.29
__kernel_gettimeofday	LINUX_2.6.29

s390x functions

The table below lists the symbols exported by the vDSO.

symbol	version

__kernel_clock_getres	LINUX_2.6.29
__kernel_clock_gettime	LINUX_2.6.29
__kernel_gettimeofday	LINUX_2.6.29

sh (SuperH) functions

The table below lists the symbols exported by the vDSO.

symbol	version
__kernel_rt_sigreturn	LINUX_2.6
__kernel_sigreturn	LINUX_2.6
__kernel_vsyscall	LINUX_2.6

i386 functions

The table below lists the symbols exported by the vDSO.

symbol	version
__kernel_sigreturn	LINUX_2.5
__kernel_rt_sigreturn	LINUX_2.5
__kernel_vsyscall	LINUX_2.5
__vdso_clock_gettime	LINUX_2.6 (exported since Linux 3.15)
__vdso_gettimeofday	LINUX_2.6 (exported since Linux 3.15)
__vdso_time	LINUX_2.6 (exported since Linux 3.15)

x86-64 functions

The table below lists the symbols exported by the vDSO. All of these symbols are also available without the "__vdso_" prefix, but you should ignore those and stick to the names below.

symbol	version
__vdso_clock_gettime	LINUX_2.6
__vdso_getcpu	LINUX_2.6
__vdso_gettimeofday	LINUX_2.6
__vdso_time	LINUX_2.6

x86/x32 functions

The table below lists the symbols exported by the vDSO.

symbol	version
__vdso_clock_gettime	LINUX_2.6
__vdso_getcpu	LINUX_2.6
__vdso_gettimeofday	LINUX_2.6
__vdso_time	LINUX_2.6

History

The vDSO was originally just a single function—the vsyscall. In older kernels, you might see that name in a process's memory map rather than "vdso". Over time, people realized that this mechanism was a great way to pass more functionality to user space, so it was reconceived as a vDSO in the current format.

```

NAME

vsock − Linux VSOCK address family

SYNOPSIS

#include <sys/socket.h>
#include <linux/vm_sockets.h>

stream_socket = **socket(AF_VSOCK, SOCK_STREAM, 0);**
datagram_socket = **socket(AF_VSOCK, SOCK_DGRAM, 0);**

DESCRIPTION

The VSOCK address family facilitates communication between virtual machines and the host they are running on. This address family is used by guest agents and hypervisor services that need a communications channel that is independent of virtual machine network configuration.

Valid socket types are **SOCK_STREAM** and **SOCK_DGRAM**. **SOCK_STREAM** provides connection-oriented byte streams with guaranteed, in-order delivery. **SOCK_DGRAM** provides a connectionless datagram packet service with best-effort delivery and best-effort ordering. Availability of these socket types is dependent on the underlying hypervisor.

A new socket is created with

```
socket(AF_VSOCK, socket_type, 0);
```

When a process wants to establish a connection, it calls *connect*(2) with a given destination socket address. The socket is automatically bound to a free port if unbound.

A process can listen for incoming connections by first binding to a socket address using *bind*(2) and then calling *listen*(2).

Data is transmitted using the *send*(2) or *write*(2) families of system calls and data is received using the *recv*(2) or *read*(2) families of system calls.

Address format

A socket address is defined as a combination of a 32-bit Context Identifier (CID) and a 32-bit port number. The CID identifies the source or destination, which is either a virtual machine or the host. The port number differentiates between multiple services running on a single machine.

```
struct sockaddr_vm {
    sa_family_t    svm_family;    /* Address family: AF_VSOCK */
    unsigned short svm_reserved1;
    unsigned int   svm_port;      /* Port # in host byte order */
    unsigned int   svm_cid;       /* Address in host byte order */
    unsigned char  svm_zero[sizeof(struct sockaddr) −
                            sizeof(sa_family_t) −
                            sizeof(unsigned short) −
                            sizeof(unsigned int) −
                            sizeof(unsigned int)];
};
```

svm_family is always set to **AF_VSOCK**. *svm_reserved1* is always set to 0. *svm_port* contains the port number in host byte order. The port numbers below 1024 are called *privileged ports*. Only a process with the **CAP_NET_BIND_SERVICE** capability may *bind*(2) to these port numbers. *svm_zero* must be zero-filled.

There are several special addresses: **VMADDR_CID_ANY** (−1U) means any address for binding; **VMADDR_CID_HYPERVISOR** (0) is reserved for services built into the hypervisor; **VMADDR_CID_LOCAL** (1) is the well-known address for local communication (loopback); **VMADDR_CID_HOST** (2) is the well-known address of the host.

The special constant **VMADDR_PORT_ANY** (−1U) means any port number for binding.

Live migration

Sockets are affected by live migration of virtual machines. Connected **SOCK_STREAM** sockets become disconnected when the virtual machine migrates to a new host. Applications must reconnect when this happens.

The local CID may change across live migration if the old CID is not available on the new host. Bound

sockets are automatically updated to the new CID.

Ioctls

The following ioctls are available on the */dev/vsock* device.

IOCTL_VM_SOCKETS_GET_LOCAL_CID
Get the CID of the local machine. The argument is a pointer to an *unsigned int*.

```
ioctl(fd, IOCTL_VM_SOCKETS_GET_LOCAL_CID, &cid);
```

Consider using **VMADDR_CID_ANY** when binding instead of getting the local CID with **IOCTL_VM_SOCKETS_GET_LOCAL_CID**.

Local communication

VMADDR_CID_LOCAL (1) directs packets to the same host that generated them. This is useful for testing applications on a single host and for debugging.

The local CID obtained with **IOCTL_VM_SOCKETS_GET_LOCAL_CID** can be used for the same purpose, but it is preferable to use **VMADDR_CID_LOCAL**.

ERRORS

EACCES
Unable to bind to a privileged port without the **CAP_NET_BIND_SERVICE** capability.

EADDRINUSE
Unable to bind to a port that is already in use.

EADDRNOTAVAIL
Unable to find a free port for binding or unable to bind to a nonlocal CID.

EINVAL
Invalid parameters. This includes: attempting to bind a socket that is already bound, providing an invalid struct *sockaddr_vm*, and other input validation errors.

ENOPROTOOPT
Invalid socket option in *setsockopt*(2) or *getsockopt*(2).

ENOTCONN
Unable to perform operation on an unconnected socket.

EOPNOTSUPP
Operation not supported. This includes: the **MSG_OOB** flag that is not implemented for the *send*(2) family of syscalls and **MSG_PEEK** for the *recv*(2) family of syscalls.

EPROTONOSUPPORT
Invalid socket protocol number. The protocol should always be 0.

ESOCKTNOSUPPORT
Unsupported socket type in *socket*(2). Only **SOCK_STREAM** and **SOCK_DGRAM** are valid.

VERSIONS

Support for VMware (VMCI) has been available since Linux 3.9. KVM (virtio) is supported since Linux 4.8. Hyper-V is supported since Linux 4.14.

VMADDR_CID_LOCAL is supported since Linux 5.6. Local communication in the guest and on the host is available since Linux 5.6. Previous versions supported only local communication within a guest (not on the host), and with only some transports (VMCI and virtio).

NAME

x25 − ITU-T X.25 / ISO/IEC 8208 protocol interface

SYNOPSIS

#include <sys/socket.h>
#include <linux/x25.h>

x25_socket = **socket(AF_X25, SOCK_SEQPACKET, 0);**

DESCRIPTION

X25 sockets provide an interface to the X.25 packet layer protocol. This allows applications to communicate over a public X.25 data network as standardized by International Telecommunication Union's recommendation X.25 (X.25 DTE-DCE mode). X25 sockets can also be used for communication without an intermediate X.25 network (X.25 DTE-DTE mode) as described in ISO/IEC 8208.

Message boundaries are preserved — a *read*(2) from a socket will retrieve the same chunk of data as output with the corresponding *write*(2) to the peer socket. When necessary, the kernel takes care of segmenting and reassembling long messages by means of the X.25 M-bit. There is no hard-coded upper limit for the message size. However, reassembling of a long message might fail if there is a temporary lack of system resources or when other constraints (such as socket memory or buffer size limits) become effective. If that occurs, the X.25 connection will be reset.

Socket addresses

The **AF_X25** socket address family uses the *struct sockaddr_x25* for representing network addresses as defined in ITU-T recommendation X.121.

```
struct sockaddr_x25 {
    sa_family_t sx25_family;    /* must be AF_X25 */
    x25_address sx25_addr;      /* X.121 Address */
};
```

sx25_addr contains a char array *x25_addr[]* to be interpreted as a null-terminated string. *sx25_addr.x25_addr[]* consists of up to 15 (not counting the terminating null byte) ASCII characters forming the X.121 address. Only the decimal digit characters from '0' to '9' are allowed.

Socket options

The following X.25-specific socket options can be set by using *setsockopt*(2) and read with *getsockopt*(2) with the *level* argument set to **SOL_X25**.

X25_QBITINCL

Controls whether the X.25 Q-bit (Qualified Data Bit) is accessible by the user. It expects an integer argument. If set to 0 (default), the Q-bit is never set for outgoing packets and the Q-bit of incoming packets is ignored. If set to 1, an additional first byte is prepended to each message read from or written to the socket. For data read from the socket, a 0 first byte indicates that the Q-bits of the corresponding incoming data packets were not set. A first byte with value 1 indicates that the Q-bit of the corresponding incoming data packets was set. If the first byte of the data written to the socket is 1, the Q-bit of the corresponding outgoing data packets will be set. If the first byte is 0, the Q-bit will not be set.

VERSIONS

The AF_X25 protocol family is a new feature of Linux 2.2.

BUGS

Plenty, as the X.25 PLP implementation is **CONFIG_EXPERIMENTAL**.

This man page is incomplete.

There is no dedicated application programmer's header file yet; you need to include the kernel header file *<linux/x25.h>*. **CONFIG_EXPERIMENTAL** might also imply that future versions of the interface are not binary compatible.

X.25 N-Reset events are not propagated to the user process yet. Thus, if a reset occurred, data might be lost without notice.

NAME

xattr − Extended attributes

DESCRIPTION

Extended attributes are name:value pairs associated permanently with files and directories, similar to the environment strings associated with a process. An attribute may be defined or undefined. If it is defined, its value may be empty or non-empty.

Extended attributes are extensions to the normal attributes which are associated with all inodes in the system (i.e., the *stat*(2) data). They are often used to provide additional functionality to a filesystem—for example, additional security features such as Access Control Lists (ACLs) may be implemented using extended attributes.

Users with search access to a file or directory may use *listxattr*(2) to retrieve a list of attribute names defined for that file or directory.

Extended attributes are accessed as atomic objects. Reading (**getxattr**(2)) retrieves the whole value of an attribute and stores it in a buffer. Writing (**setxattr**(2)) replaces any previous value with the new value.

Space consumed for extended attributes may be counted towards the disk quotas of the file owner and file group.

Extended attribute namespaces

Attribute names are null-terminated strings. The attribute name is always specified in the fully qualified *namespace.attribute* form, for example, *user.mime_type*, *trusted.md5sum*, *system.posix_acl_access*, or *security.selinux*.

The namespace mechanism is used to define different classes of extended attributes. These different classes exist for several reasons; for example, the permissions and capabilities required for manipulating extended attributes of one namespace may differ to another.

Currently, the *security*, *system*, *trusted*, and *user* extended attribute classes are defined as described below. Additional classes may be added in the future.

Extended security attributes

The security attribute namespace is used by kernel security modules, such as Security Enhanced Linux, and also to implement file capabilities (see *capabilities*(7)). Read and write access permissions to security attributes depend on the policy implemented for each security attribute by the security module. When no security module is loaded, all processes have read access to extended security attributes, and write access is limited to processes that have the **CAP_SYS_ADMIN** capability.

System extended attributes

System extended attributes are used by the kernel to store system objects such as Access Control Lists. Read and write access permissions to system attributes depend on the policy implemented for each system attribute implemented by filesystems in the kernel.

Trusted extended attributes

Trusted extended attributes are visible and accessible only to processes that have the **CAP_SYS_ADMIN** capability. Attributes in this class are used to implement mechanisms in user space (i.e., outside the kernel) which keep information in extended attributes to which ordinary processes should not have access.

User extended attributes

User extended attributes may be assigned to files and directories for storing arbitrary additional information such as the mime type, character set or encoding of a file. The access permissions for user attributes are defined by the file permission bits: read permission is required to retrieve the attribute value, and writer permission is required to change it.

The file permission bits of regular files and directories are interpreted differently from the file permission bits of special files and symbolic links. For regular files and directories the file permission bits define access to the file's contents, while for device special files they define access to the device described by the special file. The file permissions of symbolic links are not used in access checks. These differences would allow users to consume filesystem resources in a way not controllable by disk quotas for group or world writable special files and directories.

For this reason, user extended attributes are allowed only for regular files and directories, and access to

user extended attributes is restricted to the owner and to users with appropriate capabilities for directories with the sticky bit set (see the *chmod*(1) manual page for an explanation of the sticky bit).

Filesystem differences

The kernel and the filesystem may place limits on the maximum number and size of extended attributes that can be associated with a file. The VFS-imposed limits on attribute names and values are 255 bytes and 64 kB, respectively. The list of attribute names that can be returned is also limited to 64 kB (see BUGS in *listxattr*(2)).

Some filesystems, such as Reiserfs (and, historically, ext2 and ext3), require the filesystem to be mounted with the **user_xattr** mount option in order for user extended attributes to be used.

In the current ext2, ext3, and ext4 filesystem implementations, the total bytes used by the names and values of all of a file's extended attributes must fit in a single filesystem block (1024, 2048 or 4096 bytes, depending on the block size specified when the filesystem was created).

In the Btrfs, XFS, and Reiserfs filesystem implementations, there is no practical limit on the number of extended attributes associated with a file, and the algorithms used to store extended attribute information on disk are scalable.

In the JFS, XFS, and Reiserfs filesystem implementations, the limit on bytes used in an EA value is the ceiling imposed by the VFS.

In the Btrfs filesystem implementation, the total bytes used for the name, value, and implementation overhead bytes is limited to the filesystem *nodesize* value (16 kB by default).

STANDARDS

Extended attributes are not specified in POSIX.1, but some other systems (e.g., the BSDs and Solaris) provide a similar feature.

NOTES

Since the filesystems on which extended attributes are stored might also be used on architectures with a different byte order and machine word size, care should be taken to store attribute values in an architecture-independent format.

NAME

intro − introduction to administration and privileged commands

DESCRIPTION

Section 8 of the manual describes commands which either can be or are used only by the superuser, like system-administration commands, daemons, and hardware-related commands.

As with the commands described in Section 1, the commands described in this section terminate with an exit status that indicates whether the command succeeded or failed. See *intro*(1) for more information.

NOTES

Authors and copyright conditions

Look at the header of the manual page source for the author(s) and copyright conditions. Note that these can be different from page to page!

NAME

iconvconfig − create iconv module configuration cache

SYNOPSIS

iconvconfig [*options*] [*directory*]...

DESCRIPTION

The *iconv*(3) function internally uses *gconv* modules to convert to and from a character set. A configuration file is used to determine the needed modules for a conversion. Loading and parsing such a configuration file would slow down programs that use *iconv*(3), so a caching mechanism is employed.

The **iconvconfig** program reads iconv module configuration files and writes a fast-loading gconv module configuration cache file.

In addition to the system provided gconv modules, the user can specify custom gconv module directories with the environment variable **GCONV_PATH**. However, iconv module configuration caching is used only when the environment variable **GCONV_PATH** is not set.

OPTIONS

−−nostdlib
: Do not search the system default gconv directory, only the directories provided on the command line.

−−output=*outputfile*
−o *outputfile*
: Use *outputfile* for output instead of the system default cache location.

−−prefix=*pathname*
: Set the prefix to be prepended to the system pathnames. See FILES, below. By default, the prefix is empty. Setting the prefix to *foo*, the gconv module configuration would be read from *foo/usr/lib/gconv/gconv−modules* and the cache would be written to *foo/usr/lib/gconv/gconv−modules.cache*.

−−help
−? Print a usage summary and exit.

−−usage
: Print a short usage summary and exit.

−−version
−V Print the version number, license, and disclaimer of warranty for **iconv**.

EXIT STATUS

Zero on success, nonzero on errors.

FILES

/usr/lib/gconv
: Usual default gconv module path.

/usr/lib/gconv/gconv−modules
: Usual system default gconv module configuration file.

/usr/lib/gconv/gconv−modules.cache
: Usual system gconv module configuration cache.

Depending on the architecture, the above files may instead be located at directories with the path prefix */usr/lib64*.

NAME

ld.so, ld−linux.so − dynamic linker/loader

SYNOPSIS

The dynamic linker can be run either indirectly by running some dynamically linked program or shared object (in which case no command-line options to the dynamic linker can be passed and, in the ELF case, the dynamic linker which is stored in the **.interp** section of the program is executed) or directly by running:

*/lib/ld−linux.so.** [OPTIONS] [PROGRAM [ARGUMENTS]]

DESCRIPTION

The programs **ld.so** and **ld−linux.so*** find and load the shared objects (shared libraries) needed by a program, prepare the program to run, and then run it.

Linux binaries require dynamic linking (linking at run time) unless the **−static** option was given to *ld*(1) during compilation.

The program **ld.so** handles a.out binaries, a binary format used long ago. The program **ld−linux.so*** (*/lib/ld−linux.so.1* for libc5, */lib/ld−linux.so.2* for glibc2) handles binaries that are in the more modern ELF format. Both programs have the same behavior, and use the same support files and programs (**ldd**(1), *ldconfig*(8), and */etc/ld.so.conf*).

When resolving shared object dependencies, the dynamic linker first inspects each dependency string to see if it contains a slash (this can occur if a shared object pathname containing slashes was specified at link time). If a slash is found, then the dependency string is interpreted as a (relative or absolute) pathname, and the shared object is loaded using that pathname.

If a shared object dependency does not contain a slash, then it is searched for in the following order:

(1) Using the directories specified in the DT_RPATH dynamic section attribute of the binary if present and DT_RUNPATH attribute does not exist. Use of DT_RPATH is deprecated.

(2) Using the environment variable **LD_LIBRARY_PATH**, unless the executable is being run in secure-execution mode (see below), in which case this variable is ignored.

(3) Using the directories specified in the DT_RUNPATH dynamic section attribute of the binary if present. Such directories are searched only to find those objects required by DT_NEEDED (direct dependencies) entries and do not apply to those objects' children, which must themselves have their own DT_RUNPATH entries. This is unlike DT_RPATH, which is applied to searches for all children in the dependency tree.

(4) From the cache file */etc/ld.so.cache*, which contains a compiled list of candidate shared objects previously found in the augmented library path. If, however, the binary was linked with the **−z nodefaultlib** linker option, shared objects in the default paths are skipped. Shared objects installed in hardware capability directories (see below) are preferred to other shared objects.

(5) In the default path */lib*, and then */usr/lib*. (On some 64-bit architectures, the default paths for 64-bit shared objects are */lib64*, and then */usr/lib64*.) If the binary was linked with the **−z nodefaultlib** linker option, this step is skipped.

Dynamic string tokens

In several places, the dynamic linker expands dynamic string tokens:

- In the environment variables **LD_LIBRARY_PATH**, **LD_PRELOAD**, and **LD_AUDIT**,
- inside the values of the dynamic section tags **DT_NEEDED**, **DT_RPATH**, **DT_RUNPATH**, **DT_AUDIT**, and **DT_DEPAUDIT** of ELF binaries,
- in the arguments to the **ld.so** command line options **--audit**, **--library-path**, and **−−preload** (see below), and
- in the filename arguments to the *dlopen*(3) and *dlmopen*(3) functions.

The substituted tokens are as follows:

$ORIGIN (or equivalently *${ORIGIN}*)

This expands to the directory containing the program or shared object. Thus, an application located in *somedir/app* could be compiled with

```
gcc -Wl,-rpath,'$ORIGIN/../lib'
```

so that it finds an associated shared object in *somedir/lib* no matter where *somedir* is located in the directory hierarchy. This facilitates the creation of "turn-key" applications that do not need to be installed into special directories, but can instead be unpacked into any directory and still find their own shared objects.

$LIB (or equivalently *${LIB}*)
This expands to *lib* or *lib64* depending on the architecture (e.g., on x86-64, it expands to *lib64* and on x86-32, it expands to *lib*).

$PLATFORM (or equivalently *${PLATFORM}*)
This expands to a string corresponding to the processor type of the host system (e.g., "x86_64"). On some architectures, the Linux kernel doesn't provide a platform string to the dynamic linker. The value of this string is taken from the **AT_PLATFORM** value in the auxiliary vector (see *getauxval*(3)).

Note that the dynamic string tokens have to be quoted properly when set from a shell, to prevent their expansion as shell or environment variables.

OPTIONS

--argv0 *string* (since glibc 2.33)
Set *argv[0]* to the value *string* before running the program.

−−audit *list*
Use objects named in *list* as auditors. The objects in *list* are delimited by colons.

−−glibc-hwcaps-mask *list*
only search built-in subdirectories if in *list*.

−−glibc-hwcaps-prepend *list*
Search glibc-hwcaps subdirectories in *list*.

−−inhibit−cache
Do not use */etc/ld.so.cache*.

−−library−path *path*
Use *path* instead of **LD_LIBRARY_PATH** environment variable setting (see below). The names *ORIGIN*, *LIB*, and *PLATFORM* are interpreted as for the **LD_LIBRARY_PATH** environment variable.

−−inhibit−rpath *list*
Ignore RPATH and RUNPATH information in object names in *list*. This option is ignored when running in secure-execution mode (see below). The objects in *list* are delimited by colons or spaces.

−−list List all dependencies and how they are resolved.

--list-diagnostics (since glibc 2.33)
Print system diagnostic information in a machine-readable format, such as some internal loader variables, the auxiliary vector (see *getauxval*(3)), and the environment variables. On some architectures, the command might print additional information (like the cpu features used in GNU indirect function selection on x86). **--list-tunables** (since glibc 2.33) Print the names and values of all tunables, along with the minimum and maximum allowed values.

--preload *list* (since glibc 2.30)
Preload the objects specified in *list*. The objects in *list* are delimited by colons or spaces. The objects are preloaded as explained in the description of the **LD_PRELOAD** environment variable below.

By contrast with **LD_PRELOAD**, the **−−preload** option provides a way to perform preloading for a single executable without affecting preloading performed in any child process that executes a new program.

−−verify
Verify that program is dynamically linked and this dynamic linker can handle it.

ENVIRONMENT

Various environment variables influence the operation of the dynamic linker.

Secure-execution mode

For security reasons, if the dynamic linker determines that a binary should be run in secure-execution mode, the effects of some environment variables are voided or modified, and furthermore those environment variables are stripped from the environment, so that the program does not even see the definitions. Some of these environment variables affect the operation of the dynamic linker itself, and are described below. Other environment variables treated in this way include: **GCONV_PATH**, **GETCONF_DIR**, **HOSTALIASES**, **LOCALDOMAIN**, **LD_AUDIT**, **LD_DEBUG**, **LD_DEBUG_OUTPUT**, **LD_DYNAMIC_WEAK**, **LD_HWCAP_MASK**, **LD_LIBRARY_PATH**, **LD_ORIGIN_PATH**, **LD_PRELOAD**, **LD_PROFILE**, **LD_SHOW_AUXV**, **LOCALDOMAIN**, **LOCPATH**, **MALLOC_TRACE**, **NIS_PATH**, **NLSPATH**, **RESOLV_HOST_CONF**, **RES_OPTIONS**, **TMPDIR**, and **TZDIR**.

A binary is executed in secure-execution mode if the **AT_SECURE** entry in the auxiliary vector (see *getauxval*(3)) has a nonzero value. This entry may have a nonzero value for various reasons, including:

- The process's real and effective user IDs differ, or the real and effective group IDs differ. This typically occurs as a result of executing a set-user-ID or set-group-ID program.
- A process with a non-root user ID executed a binary that conferred capabilities to the process.
- A nonzero value may have been set by a Linux Security Module.

Environment variables

Among the more important environment variables are the following:

LD_ASSUME_KERNEL (from glibc 2.2.3 to glibc 2.36)

Each shared object can inform the dynamic linker of the minimum kernel ABI version that it requires. (This requirement is encoded in an ELF note section that is viewable via *readelf −n* as a section labeled **NT_GNU_ABI_TAG**.) At run time, the dynamic linker determines the ABI version of the running kernel and will reject loading shared objects that specify minimum ABI versions that exceed that ABI version.

LD_ASSUME_KERNEL can be used to cause the dynamic linker to assume that it is running on a system with a different kernel ABI version. For example, the following command line causes the dynamic linker to assume it is running on Linux 2.2.5 when loading the shared objects required by *myprog*:

```
$ LD_ASSUME_KERNEL=2.2.5 ./myprog
```

On systems that provide multiple versions of a shared object (in different directories in the search path) that have different minimum kernel ABI version requirements, **LD_ASSUME_KERNEL** can be used to select the version of the object that is used (dependent on the directory search order).

Historically, the most common use of the **LD_ASSUME_KERNEL** feature was to manually select the older LinuxThreads POSIX threads implementation on systems that provided both LinuxThreads and NPTL (which latter was typically the default on such systems); see *pthreads*(7).

LD_BIND_NOW (since glibc 2.1.1)

If set to a nonempty string, causes the dynamic linker to resolve all symbols at program startup instead of deferring function call resolution to the point when they are first referenced. This is useful when using a debugger.

LD_LIBRARY_PATH

A list of directories in which to search for ELF libraries at execution time. The items in the list are separated by either colons or semicolons, and there is no support for escaping either separator. A zero-length directory name indicates the current working directory.

This variable is ignored in secure-execution mode.

Within the pathnames specified in **LD_LIBRARY_PATH**, the dynamic linker expands the tokens *$ORIGIN*, *$LIB*, and *$PLATFORM* (or the versions using curly braces around the names) as described above in *Dynamic string tokens*. Thus, for example, the following would cause a library to be searched for in either the *lib* or *lib64* subdirectory below the directory

containing the program to be executed:

```
$ LD_LIBRARY_PATH='$ORIGIN/$LIB' prog
```

(Note the use of single quotes, which prevent expansion of *$ORIGIN* and *$LIB* as shell variables!)

LD_PRELOAD
A list of additional, user-specified, ELF shared objects to be loaded before all others. This feature can be used to selectively override functions in other shared objects.

The items of the list can be separated by spaces or colons, and there is no support for escaping either separator. The objects are searched for using the rules given under DESCRIPTION. Objects are searched for and added to the link map in the left-to-right order specified in the list.

In secure-execution mode, preload pathnames containing slashes are ignored. Furthermore, shared objects are preloaded only from the standard search directories and only if they have set-user-ID mode bit enabled (which is not typical).

Within the names specified in the **LD_PRELOAD** list, the dynamic linker understands the tokens *$ORIGIN*, *$LIB*, and *$PLATFORM* (or the versions using curly braces around the names) as described above in *Dynamic string tokens*. (See also the discussion of quoting under the description of **LD_LIBRARY_PATH**.)

There are various methods of specifying libraries to be preloaded, and these are handled in the following order:

(1) The **LD_PRELOAD** environment variable.

(2) The **--preload** command-line option when invoking the dynamic linker directly.

(3) The */etc/ld.so.preload* file (described below).

LD_TRACE_LOADED_OBJECTS
If set (to any value), causes the program to list its dynamic dependencies, as if run by *ldd*(1), instead of running normally.

Then there are lots of more or less obscure variables, many obsolete or only for internal use.

LD_AUDIT (since glibc 2.4)
A list of user-specified, ELF shared objects to be loaded before all others in a separate linker namespace (i.e., one that does not intrude upon the normal symbol bindings that would occur in the process) These objects can be used to audit the operation of the dynamic linker. The items in the list are colon-separated, and there is no support for escaping the separator.

LD_AUDIT is ignored in secure-execution mode.

The dynamic linker will notify the audit shared objects at so-called auditing checkpoints—for example, loading a new shared object, resolving a symbol, or calling a symbol from another shared object—by calling an appropriate function within the audit shared object. For details, see *rtld-audit*(7). The auditing interface is largely compatible with that provided on Solaris, as described in its *Linker and Libraries Guide*, in the chapter *Runtime Linker Auditing Interface*.

Within the names specified in the **LD_AUDIT** list, the dynamic linker understands the tokens *$ORIGIN*, *$LIB*, and *$PLATFORM* (or the versions using curly braces around the names) as described above in *Dynamic string tokens*. (See also the discussion of quoting under the description of **LD_LIBRARY_PATH**.)

Since glibc 2.13, in secure-execution mode, names in the audit list that contain slashes are ignored, and only shared objects in the standard search directories that have the set-user-ID mode bit enabled are loaded.

LD_BIND_NOT (since glibc 2.1.95)
If this environment variable is set to a nonempty string, do not update the GOT (global offset table) and PLT (procedure linkage table) after resolving a function symbol. By combining the use of this variable with **LD_DEBUG** (with the categories *bindings* and *symbols*), one can observe all run-time function bindings.

LD_DEBUG (since glibc 2.1)
Output verbose debugging information about operation of the dynamic linker. The content of this variable is one of more of the following categories, separated by colons, commas, or (if the value is quoted) spaces:

help	Specifying *help* in the value of this variable does not run the specified program, and displays a help message about which categories can be specified in this environment variable.
all	Print all debugging information (except *statistics* and *unused*; see below).
bindings	Display information about which definition each symbol is bound to.
files	Display progress for input file.
libs	Display library search paths.
reloc	Display relocation processing.
scopes	Display scope information.
statistics	Display relocation statistics.
symbols	Display search paths for each symbol look-up.
unused	Determine unused DSOs.
versions	Display version dependencies.

Since glibc 2.3.4, **LD_DEBUG** is ignored in secure-execution mode, unless the file */etc/suid−debug* exists (the content of the file is irrelevant).

LD_DEBUG_OUTPUT (since glibc 2.1)
By default, **LD_DEBUG** output is written to standard error. If **LD_DEBUG_OUTPUT** is defined, then output is written to the pathname specified by its value, with the suffix "." (dot) followed by the process ID appended to the pathname.

LD_DEBUG_OUTPUT is ignored in secure-execution mode.

LD_DYNAMIC_WEAK (since glibc 2.1.91)
By default, when searching shared libraries to resolve a symbol reference, the dynamic linker will resolve to the first definition it finds.

Old glibc versions (before glibc 2.2), provided a different behavior: if the linker found a symbol that was weak, it would remember that symbol and keep searching in the remaining shared libraries. If it subsequently found a strong definition of the same symbol, then it would instead use that definition. (If no further symbol was found, then the dynamic linker would use the weak symbol that it initially found.)

The old glibc behavior was nonstandard. (Standard practice is that the distinction between weak and strong symbols should have effect only at static link time.) In glibc 2.2, the dynamic linker was modified to provide the current behavior (which was the behavior that was provided by most other implementations at that time).

Defining the **LD_DYNAMIC_WEAK** environment variable (with any value) provides the old (nonstandard) glibc behavior, whereby a weak symbol in one shared library may be overridden by a strong symbol subsequently discovered in another shared library. (Note that even when this variable is set, a strong symbol in a shared library will not override a weak definition of the same symbol in the main program.)

Since glibc 2.3.4, **LD_DYNAMIC_WEAK** is ignored in secure-execution mode.

LD_HWCAP_MASK (from glibc 2.1 to glibc 2.38)
Mask for hardware capabilities. Since glibc 2.26, the option might be ignored if glibc does not support tunables.

LD_ORIGIN_PATH (since glibc 2.1)
Path where the binary is found.

Since glibc 2.4, **LD_ORIGIN_PATH** is ignored in secure-execution mode.

LD_POINTER_GUARD (from glibc 2.4 to glibc 2.22)
Set to 0 to disable pointer guarding. Any other value enables pointer guarding, which is also the default. Pointer guarding is a security mechanism whereby some pointers to code stored in writable program memory (return addresses saved by *setjmp*(3) or function pointers used by various glibc internals) are mangled semi-randomly to make it more difficult for an attacker to hijack the pointers for use in the event of a buffer overrun or stack-smashing attack. Since glibc 2.23, **LD_POINTER_GUARD** can no longer be used to disable pointer guarding, which is now always enabled.

LD_PROFILE (since glibc 2.1)
The name of a (single) shared object to be profiled, specified either as a pathname or a soname. Profiling output is appended to the file whose name is: $LD_PROFILE_OUTPUT/$LD_PROFILE.*profile*.

Since glibc 2.2.5, **LD_PROFILE** uses a different default path in secure-execution mode.

LD_PROFILE_OUTPUT (since glibc 2.1)
Directory where **LD_PROFILE** output should be written. If this variable is not defined, or is defined as an empty string, then the default is */var/tmp*.

LD_PROFILE_OUTPUT is ignored in secure-execution mode; instead */var/profile* is always used.

LD_SHOW_AUXV (since glibc 2.1)
If this environment variable is defined (with any value), show the auxiliary array passed up from the kernel (see also *getauxval*(3)).

Since glibc 2.3.4, **LD_SHOW_AUXV** is ignored in secure-execution mode.

LD_TRACE_PRELINKING (from glibc 2.4 to glibc 2.35)
If this environment variable is defined, trace prelinking of the object whose name is assigned to this environment variable. (Use *ldd*(1) to get a list of the objects that might be traced.) If the object name is not recognized, then all prelinking activity is traced.

LD_USE_LOAD_BIAS (from glibc 2.3.3 to glibc 2.35)
By default (i.e., if this variable is not defined), executables and prelinked shared objects will honor base addresses of their dependent shared objects and (nonprelinked) position-independent executables (PIEs) and other shared objects will not honor them. If **LD_USE_LOAD_BIAS** is defined with the value 1, both executables and PIEs will honor the base addresses. If **LD_USE_LOAD_BIAS** is defined with the value 0, neither executables nor PIEs will honor the base addresses.

Since glibc 2.3.3, this variable is ignored in secure-execution mode.

LD_VERBOSE (since glibc 2.1)
If set to a nonempty string, output symbol versioning information about the program if the **LD_TRACE_LOADED_OBJECTS** environment variable has been set.

LD_WARN (since glibc 2.1.3)
If set to a nonempty string, warn about unresolved symbols.

LD_PREFER_MAP_32BIT_EXEC (x86-64 only; since glibc 2.23)
According to the Intel Silvermont software optimization guide, for 64-bit applications, branch prediction performance can be negatively impacted when the target of a branch is more than 4 GB away from the branch. If this environment variable is set (to any value), the dynamic linker will first try to map executable pages using the *mmap*(2) **MAP_32BIT** flag, and fall back to mapping without that flag if that attempt fails. NB: MAP_32BIT will map to the low 2 GB (not 4 GB) of the address space.

Because **MAP_32BIT** reduces the address range available for address space layout randomization (ASLR), **LD_PREFER_MAP_32BIT_EXEC** is always disabled in secure-execution mode.

FILES

/lib/ld.so
a.out dynamic linker/loader

/lib/ld−linux.so.{1,2}
: ELF dynamic linker/loader

/etc/ld.so.cache
: File containing a compiled list of directories in which to search for shared objects and an ordered list of candidate shared objects. See *ldconfig*(8).

/etc/ld.so.preload
: File containing a whitespace-separated list of ELF shared objects to be loaded before the program. See the discussion of **LD_PRELOAD** above. If both **LD_PRELOAD** and */etc/ld.so.preload* are employed, the libraries specified by **LD_PRELOAD** are preloaded first. */etc/ld.so.preload* has a system-wide effect, causing the specified libraries to be preloaded for all programs that are executed on the system. (This is usually undesirable, and is typically employed only as an emergency remedy, for example, as a temporary workaround to a library misconfiguration issue.)

lib.so**
: shared objects

NOTES

Legacy Hardware capabilities (from glibc 2.5 to glibc 2.37)

Some shared objects are compiled using hardware-specific instructions which do not exist on every CPU. Such objects should be installed in directories whose names define the required hardware capabilities, such as */usr/lib/sse2/*. The dynamic linker checks these directories against the hardware of the machine and selects the most suitable version of a given shared object. Hardware capability directories can be cascaded to combine CPU features. The list of supported hardware capability names depends on the CPU. The following names are currently recognized:

Alpha ev4, ev5, ev56, ev6, ev67

MIPS loongson2e, loongson2f, octeon, octeon2

PowerPC
: 4xxmac, altivec, arch_2_05, arch_2_06, booke, cellbe, dfp, efpdouble, efpsingle, fpu, ic_snoop, mmu, notb, pa6t, power4, power5, power5+, power6x, ppc32, ppc601, ppc64, smt, spe, ucache, vsx

SPARC
: flush, muldiv, stbar, swap, ultra3, v9, v9v, v9v2

s390 dfp, eimm, esan3, etf3enh, g5, highgprs, hpage, ldisp, msa, stfle, z900, z990, z9-109, z10, zarch

x86 (32-bit only)
: acpi, apic, clflush, cmov, cx8, dts, fxsr, ht, i386, i486, i586, i686, mca, mmx, mtrr, pat, pbe, pge, pn, pse36, sep, ss, sse, sse2, tm

The legacy hardware capabilities support has the drawback that each new feature added grows the search path exponentially, because it has to be added to every combination of the other existing features.

For instance, on x86 32-bit, if the hardware supports **i686** and **sse2**, the resulting search path will be **i686/sse2:i686:sse2:.**. A new capability **newcap** will set the search path to **newcap/i686/sse2:newcap/i686:newcap/sse2:newcap:i686/sse2:i686:sse2:**.

glibc Hardware capabilities (from glibc 2.33)

glibc 2.33 added a new hardware capability scheme,
: where under each CPU architecture, certain levels can be defined, grouping support for certain features or special instructions. Each architecture level has a fixed set of paths that it adds to the dynamic linker search list, depending on the hardware of the machine. Since each new architecture level is not combined with previously existing ones, the new scheme does not have the drawback of growing the dynamic linker search list uncontrollably.

For instance, on x86 64-bit, if the hardware supports **x86_64-v3** (for instance Intel Haswell or AMD Excavator), the resulting search path will be **glibc-hwcaps/x86-64-v3:glibc-hwcaps/x86-64-v2:.** The following paths are currently supported, in priority order.

PowerPC (64-bit little-endian only)
power10, power9

s390 (64-bit only)
z16, z15, z14, z13

x86 (64-bit only)
x86-64-v4, x86-64-v3, x86-64-v2

glibc 2.37 removed support for the legacy hardware capabilities.

NAME

ldconfig − configure dynamic linker run-time bindings

SYNOPSIS

/sbin/ldconfig [**−nNvVX**] [**−C** *cache*] [**−f** *conf*] [**−r** *root*] *directory* . . .

/sbin/ldconfig −l [**−v**] *library* . . .

/sbin/ldconfig −p

DESCRIPTION

ldconfig creates the necessary links and cache to the most recent shared libraries found in the directories specified on the command line, in the file */etc/ld.so.conf* , and in the trusted directories, */lib* and */usr/lib*. On some 64-bit architectures such as x86-64, */lib* and */usr/lib* are the trusted directories for 32-bit libraries, while */lib64* and */usr/lib64* are used for 64-bit libraries.

The cache is used by the run-time linker, *ld.so* or *ld−linux.so*. **ldconfig** checks the header and filenames of the libraries it encounters when determining which versions should have their links updated. **ldconfig** should normally be run by the superuser as it may require write permission on some root owned directories and files.

ldconfig will look only at files that are named *lib**.so** (for regular shared objects) or *ld−**.so** (for the dynamic loader itself). Other files will be ignored. Also, **ldconfig** expects a certain pattern to how the symbolic links are set up, like this example, where the middle file (**libfoo.so.1** here) is the SONAME for the library:

```
libfoo.so −> libfoo.so.1 −> libfoo.so.1.12
```

Failure to follow this pattern may result in compatibility issues after an upgrade.

OPTIONS

−−format= *fmt*

−c *fmt* (Since glibc 2.2) Use cache format *fmt*, which is one of **old**, **new**, or **compat**. Since glibc 2.32, the default is **new**. Before that, it was **compat**.

−C *cache*
Use *cache* instead of */etc/ld.so.cache*.

−f *conf* Use *conf* instead of */etc/ld.so.conf* .

−−ignore−aux−cache

−i (Since glibc 2.7) Ignore auxiliary cache file.

−l (Since glibc 2.2) Interpret each operand as a library name and configure its links. Intended for use only by experts.

−n Process only the directories specified on the command line; don't process the trusted directories, nor those specified in */etc/ld.so.conf* . Implies **-N**.

−N Don't rebuild the cache. Unless **−X** is also specified, links are still updated.

−−print−cache

−p Print the lists of directories and candidate libraries stored in the current cache.

−r *root* Change to and use *root* as the root directory.

−−verbose

−v Verbose mode. Print current version number, the name of each directory as it is scanned, and any links that are created. Overrides quiet mode.

−−version

−V Print program version.

−X Don't update links. Unless **−N** is also specified, the cache is still rebuilt.

FILES

/lib/ld.so
is the run-time linker/loader.

/etc/ld.so.conf
: contains a list of directories, one per line, in which to search for libraries.

/etc/ld.so.cache
: contains an ordered list of libraries found in the directories specified in */etc/ld.so.conf*, as well as those found in the trusted directories.

NAME

nscd − name service cache daemon

DESCRIPTION

nscd is a daemon that provides a cache for the most common name service requests. The default configuration file, */etc/nscd.conf* , determines the behavior of the cache daemon. See *nscd.conf*(5).

nscd provides caching for accesses of the *passwd*(5), *group*(5), *hosts*(5) *services*(5) and *netgroup* databases through standard libc interfaces, such as *getpwnam*(3), *getpwuid*(3), *getgrnam*(3), *getgrgid*(3), *gethostbyname*(3), and others.

There are two caches for each database: a positive one for items found, and a negative one for items not found. Each cache has a separate TTL (time-to-live) period for its data. Note that the shadow file is specifically not cached. *getspnam*(3) calls remain uncached as a result.

OPTIONS

−−help will give you a list with all options and what they do.

NOTES

The daemon will try to watch for changes in configuration files appropriate for each database (e.g., */etc/passwd* for the *passwd* database or */etc/hosts* and */etc/resolv.conf* for the *hosts* database), and flush the cache when these are changed. However, this will happen only after a short delay (unless the *inotify*(7) mechanism is available and glibc 2.9 or later is available), and this auto-detection does not cover configuration files required by nonstandard NSS modules, if any are specified in */etc/nsswitch.conf* . In that case, you need to run the following command after changing the configuration file of the database so that **nscd** invalidates its cache:

```
$ nscd -i <database>
```

NAME

sln − create symbolic links

SYNOPSIS

sln *source dest*
sln *filelist*

DESCRIPTION

The **sln** program creates symbolic links. Unlike the *ln*(1) program, it is statically linked. This means that if for some reason the dynamic linker is not working, **sln** can be used to make symbolic links to dynamic libraries.

The command line has two forms. In the first form, it creates *dest* as a new symbolic link to *source*.

In the second form, *filelist* is a list of space-separated pathname pairs, and the effect is as if **sln** was executed once for each line of the file, with the two pathnames as the arguments.

The **sln** program supports no command-line options.

NAME

tzselect − select a timezone

SYNOPSIS

tzselect [**-c** *coord*] [**-n** *limit*] [**--help**] [**--version**]

DESCRIPTION

The **tzselect** program asks the user for information about the current location, and outputs the resulting timezone to standard output. The output is suitable as a value for the TZ environment variable.

All interaction with the user is done via standard input and standard error.

OPTIONS

-c *coord*

Instead of asking for continent and then country and then city, ask for selection from time zones whose largest cities are closest to the location with geographical coordinates *coord*. Use ISO 6709 notation for *coord*, that is, a latitude immediately followed by a longitude. The latitude and longitude should be signed integers followed by an optional decimal point and fraction: positive numbers represent north and east, negative south and west. Latitudes with two and longitudes with three integer digits are treated as degrees; latitudes with four or six and longitudes with five or seven integer digits are treated as *DDMM*, *DDDMM*, *DDMMSS*, or *DDDMMSS* representing *DD* or *DDD* degrees, *MM* minutes, and zero or *SS* seconds, with any trailing fractions represent fractional minutes or (if *SS* is present) seconds. The decimal point is that of the current locale. For example, in the (default) C locale, **-c +40.689-074.045** specifies 40.689° N, 74.045° W, **-c +4041.4-07402.7** specifies 40° 41.4′ N, 74° 2.7′ W, and **-c +404121-0740240** specifies 40° 41′ 21″ N, 74° 2′ 40″ W. If *coord* is not one of the documented forms, the resulting behavior is unspecified.

-n *limit*

When **-c** is used, display the closest *limit* locations (default 10).

--help Output help information and exit.

--version

Output version information and exit.

ENVIRONMENT VARIABLES

AWK Name of a POSIX-compliant **awk** program (default: **awk**).

TZDIR

Name of the directory containing timezone data files (default: **/usr/share/zoneinfo**).

FILES

TZDIR/**iso3166.tab**

Table of ISO 3166 2-letter country codes and country names.

TZDIR/**zone1970.tab**

Table of country codes, latitude and longitude, timezones, and descriptive comments.

TZDIR/*TZ*

Timezone data file for timezone *TZ*.

EXIT STATUS

The exit status is zero if a timezone was successfully obtained from the user, nonzero otherwise.

SEE ALSO

newctime(3), tzfile(5), zdump(8), zic(8)

NOTES

Applications should not assume that **tzselect**'s output matches the user's political preferences.

NAME

zdump − timezone dumper

SYNOPSIS

zdump [*option* ...] [*timezone* ...]

DESCRIPTION

The **zdump** program prints the current time in each *timezone* named on the command line.

OPTIONS

--version
: Output version information and exit.

--help Output short usage message and exit.

-i Output a description of time intervals. For each *timezone* on the command line, output an interval-format description of the timezone. See "INTERVAL FORMAT" below.

-v Output a verbose description of time intervals. For each *timezone* on the command line, print the times at the two extreme time values, the times (if present) at and just beyond the boundaries of years that *localtime*(3) and *gmtime*(3) can represent, and the times both one second before and exactly at each detected time discontinuity. Each line is followed by **isdst=***D* where *D* is positive, zero, or negative depending on whether the given time is daylight saving time, standard time, or an unknown time type, respectively. Each line is also followed by **gmtoff=***N* if the given local time is known to be *N* seconds east of Greenwich.

-V Like **-v**, except omit output concerning extreme time and year values. This generates output that is easier to compare to that of implementations with different time representations.

-c [*loyear***,**]*hiyear*
: Cut off interval output at the given year(s). Cutoff times are computed using the proleptic Gregorian calendar with year 0 and with Universal Time (UT) ignoring leap seconds. Cutoffs are at the start of each year, where the lower-bound timestamp is inclusive and the upper is exclusive; for example, **-c 1970,2070** selects transitions on or after 1970-01-01 00:00:00 UTC and before 2070-01-01 00:00:00 UTC. The default cutoff is **-500,2500**.

-t [*lotime***,**]*hitime*
: Cut off interval output at the given time(s), given in decimal seconds since 1970-01-01 00:00:00 Coordinated Universal Time (UTC). The *timezone* determines whether the count includes leap seconds. As with **-c**, the cutoff's lower bound is inclusive and its upper bound is exclusive.

INTERVAL FORMAT

The interval format is a compact text representation that is intended to be both human- and machine-readable. It consists of an empty line, then a line "TZ=*string*" where *string* is a double-quoted string giving the timezone, a second line "- - *interval*" describing the time interval before the first transition if any, and zero or more following lines "*date time interval*", one line for each transition time and following interval. Fields are separated by single tabs.

Dates are in *yyyy*-*mm*-*dd* format and times are in 24-hour *hh*:*mm*:*ss* format where *hh*<24. Times are in local time immediately after the transition. A time interval description consists of a UT offset in signed ±*hhmmss* format, a time zone abbreviation, and an isdst flag. An abbreviation that equals the UT offset is omitted; other abbreviations are double-quoted strings unless they consist of one or more alphabetic characters. An isdst flag is omitted for standard time, and otherwise is a decimal integer that is unsigned and positive (typically 1) for daylight saving time and negative for unknown.

In times and in UT offsets with absolute value less than 100 hours, the seconds are omitted if they are zero, and the minutes are also omitted if they are also zero. Positive UT offsets are east of Greenwich. The UT offset -00 denotes a UT placeholder in areas where the actual offset is unspecified; by convention, this occurs when the UT offset is zero and the time zone abbreviation begins with "-" or is "zzz".

In double-quoted strings, escape sequences represent unusual characters. The escape sequences are \s for space, and \", \\, \f, \n, \r, \t, and \v with their usual meaning in the C programming language. E.g., the double-quoted string ""CET\s\"\\"" represents the character sequence "CET "\".

Here is an example of the output, with the leading empty line omitted. (This example is shown with tab stops set far enough apart so that the tabbed columns line up.)

```
TZ="Pacific/Honolulu"
-           -         -103126  LMT
1896-01-13  12:01:26  -1030    HST
1933-04-30  03        -0930    HDT  1
1933-05-21  11        -1030    HST
1942-02-09  03        -0930    HWT  1
1945-08-14  13:30     -0930    HPT  1
1945-09-30  01        -1030    HST
1947-06-08  02:30     -10      HST
```

Here, local time begins 10 hours, 31 minutes and 26 seconds west of UT, and is a standard time abbreviated LMT. Immediately after the first transition, the date is 1896-01-13 and the time is 12:01:26, and the following time interval is 10.5 hours west of UT, a standard time abbreviated HST. Immediately after the second transition, the date is 1933-04-30 and the time is 03:00:00 and the following time interval is 9.5 hours west of UT, is abbreviated HDT, and is daylight saving time. Immediately after the last transition the date is 1947-06-08 and the time is 02:30:00, and the following time interval is 10 hours west of UT, a standard time abbreviated HST.

Here are excerpts from another example:

```
TZ="Europe/Astrakhan"
-           -         +031212  LMT
1924-04-30  23:47:48  +03
1930-06-21  01        +04
1981-04-01  01        +05           1
1981-09-30  23        +04
...
2014-10-26  01        +03
2016-03-27  03        +04
```

This time zone is east of UT, so its UT offsets are positive. Also, many of its time zone abbreviations are omitted since they duplicate the text of the UT offset.

LIMITATIONS

Time discontinuities are found by sampling the results returned by *localtime*(3) at twelve-hour intervals. This works in all real-world cases; one can construct artificial time zones for which this fails.

In the **-v** and **-V** output, "UT" denotes the value returned by *gmtime*(3), which uses UTC for modern timestamps and some other UT flavor for timestamps that predate the introduction of UTC. No attempt is currently made to have the output use "UTC" for newer and "UT" for older timestamps, partly because the exact date of the introduction of UTC is problematic.

SEE ALSO

tzfile(5), *zic*(8)

NAME

zic − timezone compiler

SYNOPSIS

zic [*option* ...] [*filename* ...]

DESCRIPTION

The **zic** program reads text from the file(s) named on the command line and creates the timezone information format (TZif) files specified in this input. If a *filename* is "**-**", standard input is read.

OPTIONS

--version

Output version information and exit.

--help Output short usage message and exit.

-b *bloat*

Output backward-compatibility data as specified by *bloat*. If *bloat* is **fat**, generate additional data entries that work around potential bugs or incompatibilities in older software, such as software that mishandles the 64-bit generated data. If *bloat* is **slim**, keep the output files small; this can help check for the bugs and incompatibilities. The default is **slim**, as software that mishandles 64-bit data typically mishandles timestamps after the year 2038 anyway. Also see the **-r** option for another way to alter output size.

-d *directory*

Create time conversion information files in the named directory rather than in the standard directory named below.

-l *timezone*

Use *timezone* as local time. **zic** will act as if the input contained a link line of the form

Link *timezone* localtime

If *timezone* is **-**, any already-existing link is removed.

-L *leapsecondfilename*

Read leap second information from the file with the given name. If this option is not used, no leap second information appears in output files.

-p *timezone*

Use *timezone*'s rules when handling nonstandard TZ strings like "EET-2EEST" that lack transition rules. **zic** will act as if the input contained a link line of the form

Link *timezone* posixrules

If *timezone* is "**-**" (the default), any already-existing link is removed.

Unless *timezone is* "**-**", this option is obsolete and poorly supported. Among other things it should not be used for timestamps after the year 2037, and it should not be combined with **-b slim** if *timezone*'s transitions are at standard time or Universal Time (UT) instead of local time.

-r [**@***lo*][/**@***hi*]

Limit the applicability of output files to timestamps in the range from *lo* (inclusive) to *hi* (exclusive), where *lo* and *hi* are possibly signed decimal counts of seconds since the Epoch (1970-01-01 00:00:00 UTC). Omitted counts default to extreme values. The output files use UT offset 0 and abbreviation "-00" in place of the omitted timestamp data. For example, "zic -r @0" omits data intended for negative timestamps (i.e., before the Epoch), and "zic -r @0/@2147483648" outputs data intended only for nonnegative timestamps that fit into 31-bit signed integers. On platforms with GNU **date**, "zic -r @$(date +%s)" omits data intended for past timestamps. Although this option typically reduces the output file's size, the size can increase due to the need to represent the timestamp range boundaries, particularly if *hi* causes a TZif file to contain explicit entries for pre-*hi* transitions rather than concisely representing them with an extended POSIX.1-2017 TZ string. Also see the **-b slim** option for another way to shrink output size.

-R @*hi*

Generate redundant trailing explicit transitions for timestamps that occur less than *hi* seconds since the Epoch, even though the transitions could be more concisely represented via the extended POSIX.1-2017 TZ string. This option does not affect the represented timestamps. Although it accommodates nonstandard TZif readers that ignore the extended POSIX.1-2017 TZ string, it increases the size of the altered output files.

-t *file* When creating local time information, put the configuration link in the named file rather than in the standard location.

-v Be more verbose, and complain about the following situations:

The input specifies a link to a link, something not supported by some older parsers, including **zic** itself through release 2022e.

A year that appears in a data file is outside the range of representable years.

A time of 24:00 or more appears in the input. Pre-1998 versions of **zic** prohibit 24:00, and pre-2007 versions prohibit times greater than 24:00.

A rule goes past the start or end of the month. Pre-2004 versions of **zic** prohibit this.

A time zone abbreviation uses a **%z** format. Pre-2015 versions of **zic** do not support this.

A timestamp contains fractional seconds. Pre-2018 versions of **zic** do not support this.

The input contains abbreviations that are mishandled by pre-2018 versions of **zic** due to a longstanding coding bug. These abbreviations include "L" for "Link", "mi" for "min", "Sa" for "Sat", and "Su" for "Sun".

The output file does not contain all the information about the long-term future of a timezone, because the future cannot be summarized as an extended POSIX.1-2017 TZ string. For example, as of 2023 this problem occurs for Morocco's daylight-saving rules, as these rules are based on predictions for when Ramadan will be observed, something that an extended POSIX.1-2017 TZ string cannot represent.

The output contains data that may not be handled properly by client code designed for older **zic** output formats. These compatibility issues affect only timestamps before 1970 or after the start of 2038.

The output contains a truncated leap second table, which can cause some older TZif readers to misbehave. This can occur if the **-L** option is used, and either an Expires line is present or the **-r** option is also used.

The output file contains more than 1200 transitions, which may be mishandled by some clients. The current reference client supports at most 2000 transitions; pre-2014 versions of the reference client support at most 1200 transitions.

A time zone abbreviation has fewer than 3 or more than 6 characters. POSIX requires at least 3, and requires implementations to support at least 6.

An output file name contains a byte that is not an ASCII letter, "-", "/", or "_"; or it contains a file name component that contains more than 14 bytes or that starts with "-".

FILES

Input files use the format described in this section; output files use *tzfile*(5) format.

Input files should be text files, that is, they should be a series of zero or more lines, each ending in a newline byte and containing at most 2048 bytes counting the newline, and without any NUL bytes. The input text's encoding is typically UTF-8 or ASCII; it should have a unibyte representation for the POSIX Portable Character Set (PPCS) ⟨https://pubs.opengroup.org/onlinepubs/9699919799/basedefs/V1_chap06.html⟩ and the encoding's non-unibyte characters should consist entirely of non-PPCS bytes. Non-PPCS characters typically occur only in comments: although output file names and time zone abbreviations can contain nearly any character, other software will work better if these are limited to the restricted syntax described under the **-v** option.

Input lines are made up of fields. Fields are separated from one another by one or more white space characters. The white space characters are space, form feed, carriage return, newline, tab, and vertical tab. Leading and trailing white space on input lines is ignored. An unquoted sharp character (#) in the

input introduces a comment which extends to the end of the line the sharp character appears on. White space characters and sharp characters may be enclosed in double quotes (") if they're to be used as part of a field. Any line that is blank (after comment stripping) is ignored. Nonblank lines are expected to be of one of three types: rule lines, zone lines, and link lines.

Names must be in English and are case insensitive. They appear in several contexts, and include month and weekday names and keywords such as **maximum**, **only**, **Rolling**, and **Zone**. A name can be abbreviated by omitting all but an initial prefix; any abbreviation must be unambiguous in context.

A rule line has the form

```
Rule  NAME  FROM  TO    -  IN   ON       AT     SAVE  LETTER/S
```

For example:

```
Rule  US    1967  1973  -  Apr  lastSun  2:00w  1:00d  D
```

The fields that make up a rule line are:

NAME Gives the name of the rule set that contains this line. The name must start with a character that is neither an ASCII digit nor "`-`" nor "+". To allow for future extensions, an unquoted name should not contain characters from the set "`!$%&'()*,/:;<=>?@[\]^`{|}~`". "!$%&'()*,/:;<=>?@[\]^`{|}~".

FROM Gives the first year in which the rule applies. Any signed integer year can be supplied; the proleptic Gregorian calendar is assumed, with year 0 preceding year 1. Rules can describe times that are not representable as time values, with the unrepresentable times ignored; this allows rules to be portable among hosts with differing time value types.

TO Gives the final year in which the rule applies. The word **maximum** (or an abbreviation) means the indefinite future, and the word **only** (or an abbreviation) may be used to repeat the value of the **FROM** field.

`-` Is a reserved field and should always contain "`-`" for compatibility with older versions of **zic**. It was previously known as the **TYPE** field, which could contain values to allow a separate script to further restrict in which "types" of years the rule would apply.

IN Names the month in which the rule takes effect. Month names may be abbreviated.

ON Gives the day on which the rule takes effect. Recognized forms include:

5	the fifth of the month
lastSun	the last Sunday in the month
lastMon	the last Monday in the month
Sun>=8	first Sunday on or after the eighth
Sun<=25	last Sunday on or before the 25th

A weekday name (e.g., **Sunday**) or a weekday name preceded by "last" (e.g., **lastSunday**) may be abbreviated or spelled out in full. There must be no white space characters within the **ON** field. The "<=" and ">=" constructs can result in a day in the neighboring month; for example, the IN-ON combination "Oct Sun>=31" stands for the first Sunday on or after October 31, even if that Sunday occurs in November.

AT Gives the time of day at which the rule takes effect, relative to 00:00, the start of a calendar day. Recognized forms include:

2	time in hours
2:00	time in hours and minutes
01:28:14	time in hours, minutes, and seconds
00:19:32.13	time with fractional seconds
12:00	midday, 12 hours after 00:00
15:00	3 PM, 15 hours after 00:00
24:00	end of day, 24 hours after 00:00
260:00	260 hours after 00:00

-2:30	2.5 hours before 00:00
-	equivalent to 0

Although **zic** rounds times to the nearest integer second (breaking ties to the even integer), the fractions may be useful to other applications requiring greater precision. The source format does not specify any maximum precision. Any of these forms may be followed by the letter **w** if the given time is local or "wall clock" time, **s** if the given time is standard time without any adjustment for daylight saving, or **u** (or **g** or **z**) if the given time is universal time; in the absence of an indicator, local (wall clock) time is assumed. These forms ignore leap seconds; for example, if a leap second occurs at 00:59:60 local time, "1:00" stands for 3601 seconds after local midnight instead of the usual 3600 seconds. The intent is that a rule line describes the instants when a clock/calendar set to the type of time specified in the **AT** field would show the specified date and time of day.

SAVE Gives the amount of time to be added to local standard time when the rule is in effect, and whether the resulting time is standard or daylight saving. This field has the same format as the **AT** field except with a different set of suffix letters: **s** for standard time and **d** for daylight saving time. The suffix letter is typically omitted, and defaults to **s** if the offset is zero and to **d** otherwise. Negative offsets are allowed; in Ireland, for example, daylight saving time is observed in winter and has a negative offset relative to Irish Standard Time. The offset is merely added to standard time; for example, **zic** does not distinguish a 10:30 standard time plus an 0:30 **SAVE** from a 10:00 standard time plus a 1:00 **SAVE**.

LETTER/S
Gives the "variable part" (for example, the "S" or "D" in "EST" or "EDT") of time zone abbreviations to be used when this rule is in effect. If this field is "-", the variable part is null.

A zone line has the form

```
Zone  NAME          STDOFF   RULES  FORMAT   [UNTIL]
```

For example:

```
Zone  Asia/Amman    2:00     Jordan EE%sT    2017 Oct 27 01:00
```

The fields that make up a zone line are:

NAME The name of the timezone. This is the name used in creating the time conversion information file for the timezone. It should not contain a file name component "." or ".."; a file name component is a maximal substring that does not contain "/".

STDOFF
The amount of time to add to UT to get standard time, without any adjustment for daylight saving. This field has the same format as the **AT** and **SAVE** fields of rule lines, except without suffix letters; begin the field with a minus sign if time must be subtracted from UT.

RULES
The name of the rules that apply in the timezone or, alternatively, a field in the same format as a rule-line SAVE column, giving the amount of time to be added to local standard time and whether the resulting time is standard or daylight saving. If this field is - then standard time always applies. When an amount of time is given, only the sum of standard time and this amount matters.

FORMAT
The format for time zone abbreviations. The pair of characters **%s** is used to show where the "variable part" of the time zone abbreviation goes. Alternatively, a format can use the pair of characters **%z** to stand for the UT offset in the form ±*hh*, ±*hhmm*, or ±*hhmmss*, using the shortest form that does not lose information, where *hh*, *mm*, and *ss* are the hours, minutes, and seconds east (+) or west (−) of UT. Alternatively, a slash (/) separates standard and daylight abbreviations. To conform to POSIX, a time zone abbreviation should contain only alphanumeric ASCII characters, "+" and "-". By convention, the time zone abbreviation "-00" is a placeholder that means local time is unspecified.

UNTIL

The time at which the UT offset or the rule(s) change for a location. It takes the form of one to four fields YEAR [MONTH [DAY [TIME]]]. If this is specified, the time zone information is generated from the given UT offset and rule change until the time specified, which is interpreted using the rules in effect just before the transition. The month, day, and time of day have the same format as the IN, ON, and AT fields of a rule; trailing fields can be omitted, and default to the earliest possible value for the missing fields.

The next line must be a "continuation" line; this has the same form as a zone line except that the string "Zone" and the name are omitted, as the continuation line will place information starting at the time specified as the "until" information in the previous line in the file used by the previous line. Continuation lines may contain "until" information, just as zone lines do, indicating that the next line is a further continuation.

If a zone changes at the same instant that a rule would otherwise take effect in the earlier zone or continuation line, the rule is ignored. A zone or continuation line *L* with a named rule set starts with standard time by default: that is, any of *L*'s timestamps preceding *L*'s earliest rule use the rule in effect after *L*'s first transition into standard time. In a single zone it is an error if two rules take effect at the same instant, or if two zone changes take effect at the same instant.

If a continuation line subtracts *N* seconds from the UT offset after a transition that would be interpreted to be later if using the continuation line's UT offset and rules, the "until" time of the previous zone or continuation line is interpreted according to the continuation line's UT offset and rules, and any rule that would otherwise take effect in the next *N* seconds is instead assumed to take effect simultaneously. For example:

```
# Rule  NAME    FROM    TO      -   IN   ON       AT    SAVE   LETTER/S
Rule    US      1967    2006    -   Oct  lastSun  2:00  0      S
Rule    US      1967    1973    -   Apr  lastSun  2:00  1:00   D
# Zone  NAME                    STDOFF  RULES   FORMAT  [UNTIL]
Zone    America/Menominee       -5:00   -       EST     1973 Apr 29 2:00
                                -6:00   US      C%sT
```

Here, an incorrect reading would be there were two clock changes on 1973-04-29, the first from 02:00 EST (-05) to 01:00 CST (-06), and the second an hour later from 02:00 CST (-06) to 03:00 CDT (-05). However, **zic** interprets this more sensibly as a single transition from 02:00 CST (-05) to 02:00 CDT (-05).

A link line has the form

```
Link    TARGET          LINK-NAME
```

For example:

```
Link    Europe/Istanbul    Asia/Istanbul
```

The **TARGET** field should appear as the **NAME** field in some zone line or as the **LINK-NAME** field in some link line. The **LINK-NAME** field is used as an alternative name for that zone; it has the same syntax as a zone line's **NAME** field. Links can chain together, although the behavior is unspecified if a chain of one or more links does not terminate in a Zone name. A link line can appear before the line that defines the link target. For example:

```
Link    Greenwich   G_M_T
Link    Etc/GMT     Greenwich
Zone    Etc/GMT     0   -   GMT
```

The two links are chained together, and G_M_T, Greenwich, and Etc/GMT all name the same zone.

Except for continuation lines, lines may appear in any order in the input. However, the behavior is unspecified if multiple zone or link lines define the same name.

The file that describes leap seconds can have leap lines and an expiration line. Leap lines have the

following form:

```
Leap  YEAR  MONTH  DAY  HH:MM:SS  CORR  R/S
```

For example:

```
Leap  2016  Dec  31  23:59:60  +  S
```

The **YEAR**, **MONTH**, **DAY**, and **HH:MM:SS** fields tell when the leap second happened. The **CORR** field should be "+" if a second was added or "-" if a second was skipped. The **R/S** field should be (an abbreviation of) "Stationary" if the leap second time given by the other fields should be interpreted as UTC or (an abbreviation of) "Rolling" if the leap second time given by the other fields should be interpreted as local (wall clock) time.

Rolling leap seconds were implemented back when it was not clear whether common practice was rolling or stationary, with concerns that one would see Times Square ball drops where there'd be a "3... 2... 1... leap... Happy New Year" countdown, placing the leap second at midnight New York time rather than midnight UTC. However, this countdown style does not seem to have caught on, which means rolling leap seconds are not used in practice; also, they are not supported if the **-r** option is used.

The expiration line, if present, has the form:

```
Expires  YEAR  MONTH  DAY  HH:MM:SS
```

For example:

```
Expires  2020  Dec  28  00:00:00
```

The **YEAR**, **MONTH**, **DAY**, and **HH:MM:SS** fields give the expiration timestamp in UTC for the leap second table.

EXTENDED EXAMPLE

Here is an extended example of **zic** input, intended to illustrate many of its features.

```
# Rule  NAME   FROM  TO    -  IN   ON       AT    SAVE  LETTER/S
Rule    Swiss  1941  1942  -  May  Mon>=1   1:00  1:00  S
Rule    Swiss  1941  1942  -  Oct  Mon>=1   2:00  0     -

Rule    EU     1977  1980  -  Apr  Sun>=1   1:00u 1:00  S
Rule    EU     1977  only  -  Sep  lastSun  1:00u 0     -
Rule    EU     1978  only  -  Oct  1        1:00u 0     -
Rule    EU     1979  1995  -  Sep  lastSun  1:00u 0     -
Rule    EU     1981  max   -  Mar  lastSun  1:00u 1:00  S
Rule    EU     1996  max   -  Oct  lastSun  1:00u 0     -

# Zone  NAME          STDOFF     RULES  FORMAT  [UNTIL]
Zone    Europe/Zurich 0:34:08    -      LMT     1853 Jul 16
                      0:29:45.50 -      BMT     1894 Jun
                      1:00       Swiss  CE%sT   1981
                      1:00       EU     CE%sT

Link    Europe/Zurich Europe/Vaduz
```

In this example, the EU rules are for the European Union and for its predecessor organization, the European Communities. The timezone is named Europe/Zurich and it has the alias Europe/Vaduz. This example says that Zurich was 34 minutes and 8 seconds east of UT until 1853-07-16 at 00:00, when the legal offset was changed to 7° 26′ 22.50″, which works out to 0:29:45.50; **zic** treats this by rounding it to 0:29:46. After 1894-06-01 at 00:00 the UT offset became one hour and Swiss daylight saving rules (defined with lines beginning with "Rule Swiss") apply. From 1981 to the present, EU daylight saving rules have applied, and the UTC offset has remained at one hour.

In 1941 and 1942, daylight saving time applied from the first Monday in May at 01:00 to the first

Monday in October at 02:00. The pre-1981 EU daylight-saving rules have no effect here, but are included for completeness. Since 1981, daylight saving has begun on the last Sunday in March at 01:00 UTC. Until 1995 it ended the last Sunday in September at 01:00 UTC, but this changed to the last Sunday in October starting in 1996.

For purposes of display, "LMT" and "BMT" were initially used, respectively. Since Swiss rules and later EU rules were applied, the time zone abbreviation has been CET for standard time and CEST for daylight saving time.

FILES

/etc/localtime
: Default local timezone file.

/usr/share/zoneinfo
: Default timezone information directory.

NOTES

For areas with more than two types of local time, you may need to use local standard time in the **AT** field of the earliest transition time's rule to ensure that the earliest transition time recorded in the compiled file is correct.

If, for a particular timezone, a clock advance caused by the start of daylight saving coincides with and is equal to a clock retreat caused by a change in UT offset, **zic** produces a single transition to daylight saving at the new UT offset without any change in local (wall clock) time. To get separate transitions use multiple zone continuation lines specifying transition instants using universal time.
